Series Preface

This is a new development in surgical publishing; the first two editions of the Oxford Textbook of Surgery are to be replaced by a series of specialty-specific textbooks in surgery. This change was precipitated by the ever-increasing size of a single textbook of surgery which embraced all specialties (the second edition of the Oxford Textbook of Surgery was three volumes), and a decision to adapt the textbooks to meet the needs of the audience; firstly, to suit the requirements of Higher Surgical trainees and, secondly, to make it available online.

Thus, we have produced a key book to deal with the fundamentals of surgery, such as Anatomy, Physiology, Biochemistry, Evaluation of Evidence, and so forth. Then there are to be separate volumes covering individual specialties, each appearing as an independent textbook and available on Oxford Medicine Online.

It is planned that each textbook in each specialty will be independent although there obviously will be an overlap between different specialties and, of course, the core book on Fundamentals of Surgery will underpin the required scientific knowledge and practice in each of the other specialties.

This ambitious programme will be spread over several years, and the use of the online platform will allow for regular updates of the different textbooks.

Each textbook will include the proposed requirements for training and learning as defined by the specialist committees (SACs) of surgery recognized by the four Colleges of Surgery in Great Britain and Ireland, and will continue to be applicable to a global audience.

This ambitious programme will be spread over several years, and the use of the online platform will allow for regular updates of the different textbooks.

When completed, the Oxford Textbooks in Surgery series will set standards for a long time to come.

Professor Sir Peter J. Morris
Nuffield Professor of Surgery Emeritus, and former Chairman of the Department of Surgery and Director of the Oxford Transplant Centre, University of Oxford and Oxford Radcliffe Hospitals, UK

Forewords

The *Oxford Textbook of Neurological Surgery* is a new book complementing the Oxford Textbooks in Surgery series. It is arguably the first British-led comprehensive textbook covering the breadth of neurological surgery since *Northfield's Surgery of the Central Nervous System*.

Although the book was conceived and led from the United Kingdom, it has an extensive international contribution and will be of value to specialists from all countries.

The book bridges the gap between short handbook-type texts and the large encyclopaedic multivolume tomes. It is suited to junior and senior neurosurgical trainees and consultants, and will also be useful to specialists from other disciplines. In addition, it will be of immense benefit to those studying for the UK Intercollegiate Neurosurgical Examination, the European examination, and equivalent examinations in other continents. It is written in such way as to emphasize the clinical implications of the science.

The book is divided into 20 main sections with 99 chapters, 1000 pages in print, and over 1000 figures and tables. The chapters are carefully arranged such that it can be read from cover to cover or used as a reference for specific topics, given the comprehensive index. Each chapter follows a uniform format with abstract and key words, followed by comprehensive coverage of the topic illustrated by clear multicoloured figures.

The hard-copy print edition is complemented by an online version, which provides an alternative format to enabling instant access to specific topics.

The ability to update at the proof stage means the book is up-to-date in covering recent advances; for example, the results of clinical trials.

I congratulate the authors on bringing together experts from all neurosurgical subspecialties and from all across the globe to deliver a book that is clearly laid out, readable, and well-illustrated. I am sure it will find its place as a reference book on the bookshelves of neurosurgeons across the globe.

Franco Servadei

The past four decades have seen advances on a scale and pace that have made the practice of neurosurgery almost unrecognizable in comparison to the specialty in which I trained. The dawning in the 1970s of microsurgery and cross-sectional imaging, along with advances in pre- and perioperative care, sparked technological and technical developments that reinvented concepts of what is possible several times over. Specialization became necessary to take full advantage of the new opportunities to advance patients' outcomes and neurosurgeons were spurred to accumulate the dedicated, detailed knowledge, skills, and experience that drove the specialty forward and made it increasingly complex and diverse.

The editors of the *Oxford Textbook of Neurological Surgery* have taken on a substantial challenge: to provide, in a single, comprehensive volume, the knowledge that spans the practice of modern neurosurgery. Alongside this sheer breadth are integrated two critical perspectives: a rigorous understanding of basic science and the subtlety of neurosurgical operative practice.

It succeeds in filling a gap in the neurosurgical literature: a single volume that provides a thorough review of neurological surgery for trainee and trained surgeons alike. Its approach is forward-looking, highlighting the importance of basic and clinical research and evidence-based medicine. Safe and successful neurosurgery will increasingly require deep anatomical knowledge, clinical judgement, and high levels of technical skill, tied to an ability to synthesize an ever-growing and complex literature into reasoned practice.

UK neurosurgery has a proud history. Modern neurological surgery dawned in Scotland (Glasgow) in 1879 and the Society of British Neurological Surgeons is one of the oldest national societies in the world. But its perspective has been and remains broad, engaging colleagues in the worldwide community of neurosurgeons that transcends shifting national, political boundaries. Reflecting this, although the book is undoubtedly grounded in UK neurosurgery, the editors have successfully drawn in some of the most prolific and experienced surgeons and insightful scientists from around the world. As a result, the *Oxford Textbook of Neurological Surgery* provides an invaluable companion to neurosurgeons, from their earliest years of training into subspecialty experience and consultant practice. It will become the definitive single volume textbook for those who treat surgical disorders of the nervous system in the United Kingdom and around the world.

Sir Graham Teasdale

Contents

Symbols and abbrevations xv
List of contributors xxi

SECTION 1
Principles of neurological surgery

1. **The history of neurosurgery** 3
   Eleni Maratos and Henry Marsh
2. **Clinical assessment** 11
   Peter Bodkin and Elizabeth Visser
3. **Overview of neuroimaging** 31
   Tomasz Matys, Daniel. J. Scoffings, and Tilak Das
4. **The operating theatre environment** 45
   Neil Kitchen and Jonathan Shapey
5. **Perioperative care of the neurosurgical patient** 57
   Karol P. Budohoski, Alessandro Scudellari, Sylvia Karcheva, and Derek Duane

SECTION 2
Tumours and skull base-intrinsic tumour

6. **Low-grade glioma** 75
   Thomas Santarius, Lorenzo Bello, and Hugues Duffau
7. **High-grade gliomas and molecular biology of neurosurgical oncology** 89
   Stephen J. Price, Harry Bulstrode, and Richard Mair
8. **Intracranial metastasis** 107
   Andrew Brodbelt and Rashed Zakaria
9. **Primary central nervous system lymphoma** 117
   Boon Leong Quah, Thangaraj Munusamy, and Colin Watts
10. **Glioneuronal and other epilepsy-associated tumours** 129
    Matthias Simon and Alexander Grote
11. **Radiotherapy and radiosurgery for brain tumours** 141
    Susan Short
12. **Chemotherapy for brain tumours** 149
    Nicholas F. Brown, Daniel Krell, and Paul Mulholland
13. **Surgical techniques in the management of intrinsic tumours** 163
    Shawn Hervey-Jumper and Mitchel Berger

SECTION 3
Tumours and skull base—extra-axial and skull lesions

14. **Meningiomas and haemangiopericytoma (HPC): solitary fibrous tumour (SFT)** 175
    Harjus S. Birk, Seunggu J. Han, Ramez W. Kirollos, Thomas Santarius, and Michael W. McDermott
15. **Chordomas and chondrosarcomas of the skull base** 189
    Rami O. Almefty and Ossama Al-Mefty
16. **Dermoid and epidermoid cysts** 197
    Andrew McEvoy
17. **Esthesioneuroblastoma** 205
    Georgios Klironomos, Lior Gonen, and Fred Gentili
18. **Malignant skull base tumours** 213
    Benedict Panizza and Adel Helmy
19. **Surgical management of tumours of the orbit** 221
    Joseph D. Chabot, S. Tonya Stefko, and Paul Gardner
20. **Skull lesions** 229
    Giorgio Gioffre and Ivan Tmofeev
21. **Surgical management of anterolateral skull base lesions** 241
    Michael D. Cusimano and Michael P. Meier

SECTION 4
Tumours and skull base—CP angle lesions

22. **Schwannomas** 255
Tiit Mathiesen, Petter Förander, and David Pettersson

23. **Glomus tumours** 271
Omar Pathmanaban and Andrew King

24. **Surgical management of cerebellopontine angle and petrous lesions** 281
Nicholas Hall, Yuval Sufaro, and Andrew H. Kaye

SECTION 5
Tumours and skull base—sellar and suprasellar tumours

25. **Pituitary tumours** 299
Kanna Gnanalingham, Zsolt Zador, Tara Kearney, Federico Roncaroli, and H. Rao Gattamaneni

26. **Craniopharyngioma and Rathke's cleft cysts** 321
Rudolf Fahlbusch, V. Gerganov, and H. Metwali

27. **Surgical management of sellar and suprasellar tumours** 339
Jayson A. Neil and William T. Couldwell

SECTION 6
Tumours and skull base—posterior fossa

28. **Medulloblastoma** 353
James Rutka

29. **Ependymoma** 361
Christopher Chandler

30. **Haemangioblastoma** 367
Ammar Natalwala and Donald MacArthur

31. **Surgical approaches to posterior fossa tumours** 375
Jacques J. Morcos, Osaama H. Khan, and Ashish H. Shah

SECTION 7
Tumours and skull base—intraventricular

32. **Intraventricular tumours** 385
Paul Grundy and Vasileios Apostolopoulos

33. **Colloid cyst** 393
Asim Sheikh and Paul Chumas

34. **Choroid plexus tumours** 403
Jonathan Roth, Rina Dvir, and Shlomi Constantini

35. **Surgical management of intraventricular lesions** 411
Eduardo C. Ribas, Guilherme C. Ribas, and Ramez W. Kirollos

SECTION 8
Tumours and skull base—pineal

36. **Pineal tumours** 427
Mueez Waqar, Samantha Mills, Conor L. Mallucci, and Michael D. Jenkinson

37. **Surgical management of pineal region lesions** 439
Christoph M. Woernle, René L. Bernays, and Nicolas de Tribolet

SECTION 9
Tumours and skull base—tumour syndromes

38. **Neurophakomatoses** 449
Fay Greenway, Frances Elmslie, and Timothy Jones

39. **Uncommon brain lesions** 461
Yizhou Wan, Hani J. Marcus, and Thomas Santarius

SECTION 10
Neurotrauma and intensive care

40. **Epidemiology of head injury and outcome after head injury** 475
Nabeel Alshafai and Andrew Maas

41. **Pathophysiology of traumatic brain injury** 483
John K. Yue, Hansen Deng, Ethan A. Winkler, John F. Burke, Catherine G. Suen, and Geoffrey T. Manley

42. **Intensive care management of head injury** 497
Matthew A. Kirkman and Martin Smith

43. **Surgical management of head injury** 509
Hadie Adams, Angelos G. Kolias, Adel Helmy, Peter J.A. Hutchinson, and Randall M. Chesnut

44. **Complications of head injury** 521
Fardad T. Afshari, Antonio Belli, and Peter C. Whitfield

45. **Concussion and sports-related head injury** 531
Mark Wilson

SECTION 11
Vascular neurosurgery

46. **Normal cerebrovascular physiology and vascular anatomy** 539
Diederik O. Bulters and Andrew Durnford

47. **The pathophysiology of aneurysms** 559
Federico Cagnazzo, Giuseppe Lanzino, and Neal F. Kassell

48. **The pathophysiology of subarachnoid haemorrhage** 567
Jason McMillen

49. **Management of subarachnoid haemorrhage** 575
Roberto Rodriguez Rubio, Brian P. Walcott, and Michael T. Lawton

50. **Cerebral arteriovenous malformation and dural arteriovenous fistulae** 591
Michael Morgan

51. **Carotid artery disease and cerebral ischaemia** 615
Kieron Sweeney, A. O'Hare, and Mohsen Javadpour

52. **Extracranial-intracranial bypass for cerebral ischaemia** 627
Mathew R. Guilfoyle and Peter J. Kirkpatrick

53. **Giant aneurysms and bypass surgery** 633
Mario Teo, Omar Choudhri, and Michael Lawton

54. **Spontaneous intracranial haematoma** 643
Berk Orakcioglu and Andreas W. Unterberg

55. **Cavernomata and angiographically occult lesions** 651
Janneke van Beijnum and Hiren Patel

SECTION 12
Spinal surgery—principles

56. **Surgical principles in spinal surgery** 661
Simon Thomson, Chris Derham, and Senthil Selvanathan

57. **Spinal stability** 669
Peter R. Loughenbury and Richard M. Hall

58. **Spinal physiology** 679
Sadaquate Khan, Kevin Tsang, and Lamia Nayeb

59. **Medical pathologies of the spinal cord** 687
Chris McGuigan, Karen O'Connell, Eavan McGovern, and Iain McGurgan

SECTION 13
Spinal surgery

60. **Cervical spinal disease** 697
Navin Furtado, Georgios Tsermoulas, and Adikarige Haritha Dulanka Silva

61. **Thoracic spinal disease** 711
Kieron Sweeney, Catherine Moran, and Ciaran Bolger

62. **Lumbar spinal disease** 719
Christopher G. Kellett and Matthew J. Crocker

63. **Spinal tumours** 733
John Brecknell and Boon Leong Quah

64. **Vascular lesions of the spinal cord** 751
Daniel Walsh

65. **Spinal cerebrospinal fluid dynamics** 761
Graham Flint

66. **Scoliosis and spinal deformity** 769
Nigel Gummerson

SECTION 14
Spinal trauma

67. **Managing spinal cord trauma** 781
Saksith Smithason, Bryan S. Lee, and Edward C. Benzel

68. **Cervical spine injuries** 789
Calan Mathieson, Chris Barrett, and Likhith Alakandy

69. **Thoracic and lumbar spine injuries** 801
Bedansh Roy Chaudhary and Shiong Wen Low

70. **Spinal cord injury rehabilitation** 813
Fahim Anwar, Wail Ahmed, Tamara Tajsic, Damiano G. Barone, and Harry Mee

SECTION 15
Peripheral nerve surgery

71. **Electrodiagnostics** 827
Alan Forster and Robert Morris

72. **Entrapment syndromes** 839
Grainne Bourke and Mobin Syed

73. **Supraclavicular brachial plexus and peripheral nerve injuries** 847
Jonathan Perera and Marco Sinisi

74. **Peripheral nerve tumours** 855
Rikin Trivedi and Vincent Nga

SECTION 16
Functional neurosurgery

75. **Principles of deep brain stimulation** 865
Erlick A. C. Pereira, Alexander L. Green, and Tipu Z. Aziz

76. **Movement disorders** 873
Keyoumars Ashkan and Ismail Ughratdar

77. **Spasticity** 885
John Goodden, Catherine Hernon, and Brian Scott

78. **Pain pathophysiology and surgical management** 895
Richard Mannion and Rokas Tamosauskas

79. **Cranial nerve vascular compression syndromes** 909
Marc Sindou and George Georgoulis

80. **Neurosurgical interventions for psychiatric disorders** 929
Chris Bervoets, Bart Nuttin, and Loes Gabriëls

SECTION 17
Epilepsy

81. **Classification of seizures and epilepsy** 935
Andrew McEvoy, Tim Wehner, and Victoria Wykes

82. **Epilepsy—diagnosis and assessment** 945
Richard Selway

83. **Surgical management of epilepsy** 957
Johannes Schramm

SECTION 18
Paediatrics

84. **Developmental disorders of the brain** 971
Colin Ferrie, Daniel Warren, and Atul Tyagi

85. **Spinal development and spinal dysraphism** 983
Dominic Thompson

86. **Craniofaciosynostosis: Syndromic and non-syndromic craniofacial anomalies** 993
Federico Di Rocco, Pierre-Aurelien Beuriat, and Eric Arnaud

87. **Special considerations in paediatric head and spinal trauma** 999
Andrew Kay, Desiderio Rodrigues, Melanie Sharp, and Guirish Solanki

88. **Paediatric brain tumours** 1009
Jonathan Roth and Shlomi Constantini

89. **Paediatric hydrocephalus** 1023
Matt Bailey, Chris Parks, and Conor L. Malucci

90. **Paediatric neurovascular disorders** 1037
Helen G. McCullagh,Tufail Patankar, Tony Goddard, and Atul Tyagi

91. **Paediatric epilepsy** 1047
Sophia Varadkar and Martin Tisdall

SECTION 19
CSF disorders

92. **Hydrocephalus and normal CSF dynamics** 1057
Alexander Gamble and Harold Rekate

93. **Shunt technology and endoscopic ventricular surgery** 1071
Ian K. Pople and William Singleton

94. **Normal pressure hydrocephalus** 1083
Nicole C. Keong

95. **Pseudotumour cerebri syndrome** 1093
John D. Pickard and Nicholas Higgins

96. **Arachnoid cysts** 1101
Ruichong Ma and Stana Bojanic

SECTION 20
Infection

97. **Microbiology** 1109
Walter A. Hall

98. **Cranial infections** 1117
Thangaraj Munusamy, Boon Hoe Tan, and Eugene Yang

99. **Spinal infection** 1129
Nicholas Haden and Edward White

Symbols and abbreviations

Ω	omega
α	alpha
β	beta
δ	gamma
μg	micrograms
AAA	asleep-awake-asleep
AAICH	anticoagulation-associated intracerebral haemorrhage
AANS	acute and chronic settings
ABC	aneurysmal bone cyst
ABI	auditory brainstem implants
ABR	auditory brainstem responses
AC	anterior and posterior commissure (also arachnoid cyst)
ACA	anterior cerebral artery
ACD	anterior cervical discectomy
ACPP	atypical choroid plexus papilloma
ADC	apparent diffusion coefficient
ADI	atlantodental interval
ADL	activities of daily living
ADNFLE	autosomal-dominant nocturnal frontal lobe epilepsy
ADPKD	autosomal dominant polycystic kidney disease
AED	antiepileptic drug
AF	atrial fibrillation
AGNIR	Advisory Group on Non-ionising Radiation
AICA	anterior inferior cerebellar artery
AIDS	acquired immunodeficiency syndrome
AIP	aryl hydrocarbon receptor-interacting protein
AIS	Abbreviation Injury Score (*also* ASIA Impairment Scale)
ALI	acute lung injury
ALIF	anterior lumbar interbody fusion
ALL	acute lymphatic leukaemia
ALL	anterior longitudinal ligament
AP	anteroposterior
ASA	American Society of Anesthesiologists
ASA	anterior spinal artery
ASIA	American Spinal Injuries Association
ASPECTS	Alberta Stroke Programme Early CT Score
AT	anaplastic transformation
ATA	anterior temporal artery
ATIII	antithrombin III
ATLS	advance trauma life support
ATRT	atypical teratoid rhabdoid tumour
AVF	arteriovenous fistula
AVM	arteriovenous malformation
AZ	Annulus of Zinn
BAEP	brainstem auditory evoked potentials
BBB	blood–brain barrier
BECTS	benign epilepsy with centrotemporal spikes
BIS	bispectral index
BMD	bone mineral density
BMI	body mass index
BOLD	blood oxygen level dependent
BP	blood pressure
BRAT	Barrow Ruptured Aneurysm Trial
BTF	Brain Trauma Foundation
CA	cerebral autoregulation
CAA	cerebral amyloid angiopathy
CAD	coronary artery disease
CAMS	cerebrofacial metameric arteriovenous syndromes
CAPECTH	craniectomy-associated progressive extra-axial collections with treated hydrocephalus
CAR	cerebral autoregulation
CAS	carotid angioplasty and stenting
CBF	cerebral blood flow
CBV	cerebral blood volume
CCA	common carotid artery
CCM	cerebral cavernous malformations
CDC	Centers for Disease Control
CDK	cyclin dependent kinases
CFAM	cerebral function analysing monitor
CHF	congestive heart failure
CHLA	Children's Hospital Los Angeles
CISS	Constructive Interference in Steady State
CM	cavernous malformations
CM	central myelin
CMAP	compound motor action potential
$CMRO_2$	cerebral metabolic rate of oxygen consumption
CN	cranial nerve
CNS	central nervous system (also Congress of Neurological Surgeons)
COPD	chronic obstructive pulmonary disease
COSS	Carotid Occlusion Surgery Study
CPA	cerebellopontine angle
CPC	choroid plexus carcinoma
CPH	choroid plexus hyperplasia
CPP	cerebral perfusion pressure (also choroid plexus papilloma)
CPP	choroid plexus papilloma
CPT	choroid plexus tumour

CRF	corticotrophin factor
CRH	corticotrophin-releasing hormone
CRP	C-reactive protein
CRPS	complex regional pain syndrome
CRW	Cosman-Roberts-Wells
CSF	cerebrospinal fluid
CSW	cerebral salt wasting
CSWS	cerebral salt wasting syndrome
CT	computed tomographic
CTA	computed tomography angiography
CTP	cerebellar tonsillar prolapse
CTS	carpal tunnel syndrome
CTV	clinical target volume
CUSA	cavitron ultrasonic surgical aspirator
DBS	deep brain stimulation
DEBS	direct electrical brain stimulation
DES	drug-eluting stents
DESD	detrusor external sphincter dyssynergia
DEXA	dual-energy X-ray absorptiometry
DI	diabetes insipidus
DIND	delayed ischaemic neurological deficits
DISH	diffuse idiopathic skeletal hyperostosis
DLGG	diffuse low-grade gliomas
DNP	dynamic nuclear polarization
DNT	dysembryoplastic neuroepithelial tumours
DPG	diffuse pontine glioma
DRG	dorsal root ganglion
DRIFT	Drainage, Irrigation and Fibrinolytic Therapy
DSA	digital subtraction angiography
DSB	double-strand break
DTI	diffusion tensor imaging
DVA	deep venous anomaly
DVA	developmental venous anomaly
DVT	deep vein thrombosis
DWI	diffusion-weighted imaging
DWMH	deep white matter hyperintensities
DXA	dual X-ray absorbitometery
ECA	external carotid artery
ECG	electrocardiogram
ECoG	electrocorticography
EDF	elongation derotation flexion
EDL	extensor digitorum longus
EEA	endoscopic endonasal approach
EEG	electroencephalography
EGFR	epidermal growth factor receptor
EIEE	early infantile onset epileptic encephalopathies
ELISA	enzyme-linked immunosorbent assay
EMA	epithelial membrane antigen
EMG	electromyography
ENT	ear, nose, and throat
EOIS	early onset idiopathic scoliosis
EOR	extent of resection
EORTC	European Organization for Research and Treatment of Cancer
EP	evoked potential
EPC	epilepsia partialis continua
ES	ethmoid sinus
ERG	Electroretinogram
ES	Ewing's sarcoma
ESO	European Stroke Organisation
ESR	erythrocyte sedimentation rate
ET	essential tremor
ETT	endotracheal tube
ETV	endoscopic third ventriculostomy
EVD	external ventricular drain
EZ	epileptogenic zone
FA	fractional anisotropy
FCD	focal cortical dysplasias
FCU	flexor carpi ulnaris
FD	fibrous dysplasia
FDA	Food and Drug Administration
FEF	frontal eye field
FES	functional electric stimulation
FFP	fresh frozen plasma
FGN	French Glioma Network
FIESTA	fast imaging in steady state
FIPA	familial isolated pituitary adenoma
FLAIR	fluid attenuated inversion recovery
FLE	frontal lobe epilepsy
FM	Foramen of Monro
FSH	follicle-stimulating hormone
FSU	functional spinal unit
FTT	failure to thrive
FV	flow velocities
FZS	fronto-zygomatic suture
GABA	gamma aminobutyric acid
GAF	Global Assessment of Function
GCS	Glasgow Coma Scale
GCT	germ cell tumours (*also* granular cell tumour)
GFAP	glial fibrillary acid protein
GFR	glomerular filtration rate
GH	growth hormone
GHIH	growth hormone-inhibiting hormone
GHRH	growth hormone release hormone
GI	gastrointestinal
GMFM	Gross Motor Function Measure
GSPN	greater superficial petrosal nerve
GTCS	generalized tonic-clonic seizures
GTR	gross total resection
GTV	gross tumour volume
GW	gliadel wafers
H&E	haematoxylin and eosin
HBO	hyperbaric oxygen
HDDST	high-dose dexamethasone suppression tests
HGG	high-grade glioma
HHT	hereditary haemorrhagic telangiectasia
HIF	hypoxia inducible factor
HIFU	high-intensity focused ultrasound
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HMSN	hereditary motor, and sensory neuropathy
HO	heterotrophic ossification
HPA	hypothalamic-pituitary axis
HPC	haemangiopericytoma
HR	homologous recombination

HRQOL	health-related quality of life
HS	hippocampal sclerosis
HS	hypertonic saline
HSV	herpes simplex virus
HU	Hounsfield units
IA	intra-arterial
IAC	internal auditory canal
IAM	internal auditory meatus
IBE	International Bureau for Epilepsy
ICA	inferior cerebellar artery (also internal carotid artery)
ICA	internal carotid arteries
ICBP	infraclavicular brachial plexus
ICE	ifosfamide, carboplatin, and etoposide
ICH	intracerebral haemorrhage
ICP	intracranial pressure
ICU	intensive care unit
IFOF	inferior fronto-occipital fasciculus
IJV	internal jugular vein
ILAE	International League Against Epilepsy
IO	inferior oblique
IOF	inferior orbital fissure
IOM	Intraoperative monitoring
IPG	implantable pulse generator
IPG	implanted battery-operated pulse generators
IPSS	inferior petrosal vein sampling
IR	inferior rectus
IR	iterative reconstruction
ISAT	International Subarachnoid Aneurysm Trial
ISCoS	International Spinal Cord Society
ISNCSCI	International Standards for Neurological Classification of Spinal Cord Injury
ITB	intrathecal baclofen
IVC	inferior vena cava
IVP	intraventricular pressure
JET	Japanese EC-IC Bypass Trial
KOLT	Kendrick object learning test
kPa	kilopascal
KPS	Karnofsky Performance Status
LCH	Langerhans cell histiocytosis
LDD	L'hermitte-Duclos disease
LDDST	low-dose dexamethasone suppression test
LDL	low-density lipoprotein
LDM	limited dorsal myeloschisis
LFS	Li-Fraumeni syndrome
LG	lacrimal gland
LGG	low-grade glioma
LH	luteinizing hormone
LINAC	linear accelerator
LMN	lower motor neuron
LMWH	low molecular weight heparin
LOC	level of consciousness
LOH	loss of heterozygosity
LOIS	late onset idiopathic scoliosis
LOR	line of response
LOVA	longstanding overt ventriculomegaly in adults
LP	levator palpebrae
LP	lumbar puncture
LR	lateral rectus
LR	Lindegaard ratio
LSO	lumbar sacral orthosis
LSR	lateral spread responses
MAC	minimal alveolar concentration
MAP	mean arterial pressure
MC	Meckel cave
MCA	middle cerebral artery
MCD	malformation of cortical development
MDT	multidisciplinary team
MEG	magnetoencephalography
MEP	minimally endoscopic procedures
MEP	motor evoked potential
MHC	major histocompatibility complex
MI	myocardial infarction
MIP	maximum intensity projection
MIT	minimally invasive techniques
MLF	medial longitudinal fasciculus
MM	multiple myeloma
MMD	moya moya disease
MMS	moya moya syndrome
MMSE	mini-mental state examination
MND	motor neurone disease
MOG	myelin oligodendrocyte glycoprotein
MPBT	malignant paediatric brain tumours
MPNST	malignant peripheral nerve sheath tumours
MR	magnetic resonance
MR	medial rectus
MRA	magnetic resonance angiography
MRA	MR-angio
MRC	Medical Research Council
MRI	magnetic resonance imaging
MRM	magnetic resonance myelography
MRN	magnetic resonance neurography
MRS	magnetic resonance spectroscopy
MRSA	methicillin-resistant Staphylococcus aureus
MRV	magnetic resonance venography
MS	multiple sclerosis
MSH	melanocyte-stimulating hormone
MTG	middle temporal gyrus
MTLE	mesial temporal lobe epilepsy
MTT	mean transit time
MUAP	motor unit action potential
MVA	motor vehicle accidents
MVC	motor vehicle collisions
MVD	microsurgical vascular decompression
Na+	sodium
NAA	N-acetyl aspartate
NASCIS	National Acute Spinal Cord Injury Studies
NCS	nerve conduction studies
NeuN	neuronal nuclei
NFPA	non-functioning pituitary adenomas
NHEJ	non-homologous end-joining
NHL	non-Hodgkin's lymphoma
NICE	National Institute of Clinical Excellence
NIRS	near infrared spectroscopy
NLI	neurological level of injury
NMDA	N-methyl-D-aspartate
NMS	non-motor symptoms

NOAC	new oral anticoagulants
NOS	not otherwise specified
NPH	normal pressure hydrocephalus
NPSA	National Patient Safety Agency
NPUAP	National Pressure Ulcer Advisory Panel
NSAID	non-steroidal anti-inflammatory drug
OC	optic canal
OCR	optico-carotid recesses
OCT	optical coherence tomography
ODI	Oswestry Disability Index
OEF	oxygen extraction fraction
OLE	occipital lobe epilepsy
OLF	ossification of the ligamentum flavum
ON	optic nerve
OPG	optic pathway glioma
OPLL	ossification of the posterior longitudinal ligament
OS	overall survival
OSA	obstructive sleep apnoea
PA	pilocytic astrocytoma
PAR	protease-activated receptors
PBI	penetrating brain injury
PBT	paediatric brain tumour
PCA	posterior cerebral artery
PCC	prothrombin complex concentrate
PCNSL	primary central nervous system lymphoma
PCR	polymerase chain reaction
PCV	procarbazine, CCNU, vincristine
PD	Parkinson's disease (also proton density)
PDGFR	platelet-derived growth factor receptor
PE	preoperative embolization
PE	pulmonary embolism
PEDI	Pediatric Evaluation of Disability Inventory
PEEK	poly-ether-ether-ketone
PEEP	positive end-expiratory pressure
PEG	percutaneous endoscopic gastrostomy
PET	positron emission tomography
PFO	patent foramen ovale
PFS	progression-free survival
PI	pelvic incidence
PICA	posterior inferior cerebellar artery
PIH	prolactin-inhibiting hormone
PIOL	primary intraocular lymphoma
PLL	posterior longitudinal ligament
PML	progressive multifocal leukoencephalopathy
PNET	primitive neuroectodermal tumour
PONV	postoperative nausea and vomiting
PPTID	pineal parenchymal tumours of intermediate differentiation
PRH	prolactin-releasing hormone
PSA	posterior spinal arteries
PSO	pedicle subtraction osteotomy
PT	pelvic tilt (*also* prothrombin time)
PTA	pure-tone audiogram
PTH	post-traumatic hydrocephalus
PTPR	papillary tumour of the pineal region
PTS	post-traumatic seizures
PTSD	post-traumatic stress disorder
PTT	partial thromboplastin time
PTV	planning target volume
PVA	poly-vinyl-alcohol
QoL	quality of life
QOLIBRI	Quality of Life after Brain Injury
RA	rheumatoid arthritis
RANKL	receptor activator of NF-KB ligand
RANO	Response Assessment in Neuro-Oncology
RAPD	relative afferent pupil defect
RCC	renal cell carcinoma
RCN	Rare Cancer Network
RCT	randomized clinical trials
REM	rapid eye movement
REZ	root entry zone
RF	rheumatoid factor
RNFL	retinal nerve fibre layer
RT	radiation therapy
RT	resistance in the tube
RVAD	rib-vertebral-angle difference
SAH	subarachnoid haemorrhage
SARS	sacral anterior nerve root stimulator
SBP	supraclavicular brachial plexus
SCA	superior cerebellar artery
SCA	superior cerebellar artery
SCAVM	spinal cord arteriovenous malformations
SCI	spinal cord injury
SCID	severe-combined immunodeficiency disease
SCM	strap muscles
SCO	spindle cell oncocytoma
SCPP	spinal cord perfusion pressure
SDAVF	spinal dural arteriovenous fistula
SDR	selective dorsal rhizotomy
SDS	speech discrimination score
SEA	spinal epidural abscess
SEEG	stereoencephalography
SEER	Surveillance Epidemiology and End Results
SEGA	subependymal giant cell astrocytomas
SEP	Somatosensory evoked potential
SESH	spontaneous epidural spinal haemorrhage
SFT	solitary fibrous tumour
SGCT	subependymal giant cell tumour
SIADH	syndrome of inappropriate antidiuretic hormone
SIVMS	Scottish Intracranial Vascular Malformation Study
SLE	systemic lupus erythematous
SLF	superior longitudinal fasciculus
SMA	supplementary motor area
SNAP	sensory nerve action potential
SNO	Society for NeuroOncology
SNUC	sinonasal undifferentiated carcinoma
SO	superior oblique
SOF	superior orbital fissure
SOM	spheno-orbital meningiomas
SOV	superior ophthalmic vein
SPECT	single photon emission computed tomography
SPES	single pulse electrical stimulation
SPN	selective peripheral neurotomy
SPV	superior petrosal venous
SR	superior rectus

SSFP	steady state free precession
SSI	surgical site infection
SSMA	supplementary sensorimotor area
SSS	superior sagittal sinus
SST	Short Synacthen Test
STA	superficial temporal artery (*also* superior thyroid artery)
STASCIS	Surgical Treatment of Acute Spinal Cord Injury Study
STG	superior temporal gyrus
STIR	short tau inversion recovery
STR	subtotal resection
SUDEP	sudden unexplained death in epilepsy
SUNCT	short-lived, unilateral neuralgic headache with conjunctival injection and tearing
SVA	sagittal vertical axis
SVM	spinal vascular malformation
SWI	susceptibility weighted imaging
TBI	traumatic brain injury
TCD	transcranial Doppler
TCGA	The Cancer Genome Atlas
TF	tissue factor
TFPI	tissue factor pathway inhibitor
TIVA	total intravenous anaesthesia
TLE	temporal lobe epilepsy
TLSO	thoracolumbar sacral orthosis
TMG	transmural pressure gradient
TMS	tumefactive multiple sclerosis
TN	trigeminal neuralgia
TOF	time of flight
TORCH	Toxoplasmosis, Other (syphilis, varicella-zoster, parvovirus B19), Rubella, Cytomegalovirus (CMV), and Herpes infections
TREZ	trigeminal root entry zone
TRH	thyroid-releasing hormone (*also* thyrotropin-releasing hormone)
TSC	tuberous sclerosis complex
TSH	thyroid-stimulating hormone
TT	thrombin time
TTM	targeted temperature management
TTP	time to peak
TZ	transitional zone
UH	unfractionated heparin
UMN	upper motor neuron
UMNL	upper motor neurone lesions
VA	vertebral artery
VAD	ventricular access device
VAE	venous air embolism
VASO	vascular space occupancy
VBA	vertebrobasilar artery
VDE	velocity of diametric expansion
VEGF	vascular endothelial growth factor
VEP	visual evoked potential
VGAM	vein of Galen malformations
VGPN	vago-glossopharyngeal neuralgia
VHL	Von Hippel-Lindau
VMAT	volumetric modulated arc therapy
VNS	vagus nerve stimulation
VP	vancomycin powder
VP	ventriculoperitoneal
VRE	vancomycin-resistant enterococci
VS	vestibular schwannoma (also ventral striatum)
VTE	venous thromboembolism
vWF	von Willebrand factor
WBC	white blood cell
WBRT	whole-brain radiation therapy
WFNS	World Federation of Neurosurgical Societies
WFSBP	World Federation of Societies of Biological Psychiatry
WHO	World Health Organization
YBOCS	Yale-Brown Obsessive-Compulsive Scale

The history of neurosurgery

Eleni Maratos and Henry Marsh

Introduction

The history of neurosurgery falls naturally into the premodern era, where it is essentially the history of surgery to the skull and of head injuries, and the modern era, where it is the history of surgery to the brain itself, made possible by cerebral localization theory, antisepsis, and anaesthesia, all of which developed in the nineteenth century.

The first known neurosurgical procedures were skull trephines, seemingly carried out on both the living and the dead. It is unclear whether these were performed for therapeutic or ritualistic reasons. There are many trepanned skulls dating back thousands of years to the Neolithic era, and perhaps to even earlier, from sites all over the world.

Ancient Egypt

The earliest neurosurgical writings can be traced to Ancient Egypt and have been preserved in the Edwin Smith Papyrus that dates from *c.*1600 BC. This is the first time that the management of head injuries was based on rational scientific method rather than magic. In a style that is highly reminiscent of modern case reports, the first ten cases focus on head wounds and also contain the earliest known reference to the brain itself (as opposed to the skull), which describes a 'convoluted structure like ripples that happen in copper through smelting'. The cases vividly describe a methodical approach—first ascertaining the depth of the injury and whether there is an underlying skull fracture or exposed brain, and then advocating different management strategies according to the findings. The papyrus has been translated and reproduced by the National Institutes of Health and can be studied online (https://ceb.nlm.nih.gov). As well as the earliest known advice on head injury management, the Edwin Smith Papyrus also contains the first references to spinal immobilization in order to prevent further injury.

Ancient Greece and Byzantium

Hippocrates (460–370 BC) wrote extensively on head injuries in *De capitis vulneribus* (*On Head Wounds*). His management strategy was almost exclusively based on classifying the fracture rather than on the clinical state of the patient. He described five categories of skull fracture, including contre-coup injuries. On head injuries, he wrote *'nullum capitis vulnus contemnendum est'* (no head injury should be considered trivial). His writings were not confined to head injury and he is also credited with the first description of a subarachnoid haemorrhage:

> . . . when persons in good health are suddenly seized with pains in the head and straight away are laid down speechless and breath with stertor they die in seven days unless fever comes on.

He also described contralateral convulsions associated with brain injury; he can therefore perhaps be credited with being the first doctor to describe cerebral localization.

The Alexandrian school introduced formal anatomy dissection in approximately 300 BC. It was at this time that Herophilus began to develop the anatomic nomenclature that we use today (see **Fig. 1.1**). He identified that nerves and tendons were indeed different structures, contrary to what the Egyptians had thought, and he also was the first to describe the anatomy of the ventricles and the venous sinuses. The confluence of the sinuses, of course, still bears his name 'torcula (wine press) Herophili'. He also described the pen nib or 'calamus scriptorius' at the base of the fourth ventricle 'αναγλυφη της χαλαμης' and the choroid plexus (named after its resemblance to the vessels of the placenta).

Celsus, who lived from 25 BC to 50 AD, was the first to describe inflammation (*rubor, dolor, tumor*) and also wrote about extradural haemorrhage, hydrocephalus, trigeminal neuralgia, and spinal fractures. He advocated craniotomy only as a last resort in head injury and described the technique of drilling holes and connecting them up with a hammer and chisel with a protective blade. In another early account of cerebral localization, he advised operating on the side with the greatest pain.

Galen 129–200 AD

With Galen came the encephalocentric model of science and medicine, where the brain was recognized as the seat of intelligence and voluntary movement. He identified the pia (as different from the dura mater), the corpus callosum, the ventricles (alongside Herophilus), and the pineal and pituitary glands. He described the aqueduct of

Fig. 1.1 Herophilus of Chalcedon (*c.* 330–260 BC), a Greek doctor who practised in Alexandria. Here he is seen depicted in discussion with Erasistratus of Ceos.
Wellcome Collection

Sylvius and the foramen of Monro before the anatomists whose names they now possess. He made other significant contributions to neuroscience by identifying that transecting the spinal cord leads to loss of function below the level of the lesion, and he also described what we now call Brown-Séquard syndrome. In addition, he noted that recurrent laryngeal nerve injuries led to hoarse 'voices' in his experimental dogs. He also advocated elevating depressed skull fractures and using irrigation to reduce the heat created by trephining. His teachings were accepted, largely unquestioned, for 1500 years.

During mediaeval times (750–1200 AD) most innovative medical writing came from the Islamic and Arabic worlds, which also kept the Hippocratic and Galenic teachings alive. It was during this time that traditional bedside teaching was established.

The beginning of the scientific era

The sixteenth and seventeenth centuries were remarkable for the advances in all aspects of science and philosophy. Anatomical dissection of cadavers was already practised in mediaeval Europe before Vesalius, but he was more extensive and systematic in his dissections and was the first to challenge the teachings of Galen and Aristotle. William Harvey (1578–1657) published his seminal work on the function of the heart and circulation of blood *de motu Cordis et Sanguinis in Animalibus* (1628). Willis (1621–1675) applied this knowledge to his understanding of cerebral anatomy and showed that occluding parts of his eponymous circle did not compromise flow, thereby confirming their anastomotic nature.

Surgery continued to develop in all areas, although neurosurgery remained confined to trauma. In a challenge to orthodoxy, Yonge (1646–1721) stated that mortality was 'not inevitable' once the dura had been breached. Percival Pott not only worked on tuberculosis (TB) of the spine (which has made a recent resurgence in neurosurgical practice) but also made significant advances in our understanding of head injuries. He asserted that in head injury, trepanning could relieve the pressure from extravasated fluid, thus providing a rationale for the oldest neurosurgical operation. At the same time, Jean Louis Petit (1674–1750) described the classic 'lucid interval' associated with an extradural haematoma as a brief loss of consciousness followed by a gradual deterioration due to accumulation of blood compressing the brain. The importance of brain injury rather than head injury began to be recognized. Bell (Edinburgh 1749–1806) described the loss of pupillary reaction to light and recognized this as an indication to perform a 'rapid and prompt evacuation' of an extradural haematoma. Bell is also credited with identifying that hydrocephalus can be associated with spina bifida.

Although the majority of operations were still for trauma, one key exception was the successful extirpation by Morand (1697–1773) of a temporal abscess following otitis media and mastoiditis. He describes exploring it with his finger and washing out the cavity before placing a silver tube which was slowly withdrawn—a method which resonates today, where silver is once again finding a medical role for its bactericidal properties.

Cotugno (1736–1822) further characterized the cerebrospinal fluid (CSF) pathways and described the 'nervous origins' of sciatica for the first time. He also described hydrocephalus *ex vacuo* as being secondary to cerebral atrophy.

The surgeon/anatomist John Hunter (1728–1793) was a student of Pott's and made major contributions to general surgery and neurosurgery. His extensive anatomy collection houses the Irish giant (Cushing's original acromegalic) and can still be seen at the Hunterian Museum at the Royal College of Surgeons, London.

However, during this time neurosurgical operations were still plagued by infection and the lack of anaesthetic agents meant that operations had to be rapid and not always accurate. The clinical skill of cerebral localization was also yet to be described, so surgery was confined to lesions that had external manifestations.

Early modern to nineteenth century

The modern practice of neurosurgery as we know it today began in the nineteenth century. The parallel advances in anaesthesia and antisepsis allowed mortality rates to fall to acceptable levels and the ability to localize cerebral lesions by clinical examination alone allowed surgeons to tackle occult lesions, thereby dramatically broadening the scope of the specialty. These advances ultimately led to the creation of neurosurgery as a specialty in its own right.

Parallel advances

Anaesthesia

The introduction of ether in the 1840s allowed surgery to be performed in a pain-free manner without the surgeon being rushed or restraints being used. The dentist William Morton persuaded Dr Warren to use ether to excise a submaxillary tumour in 1846 at the Massachusetts General Hospital. Shortly after this, in 1847, Marie Jean Pierre Flourens successfully used chloroform anaesthesia. It was not without risk, but the advantages to both surgeons and patients were clear. As anaesthesia became safer, so the range of pathologies that could be tackled grew and complex surgical approaches could be developed.

Antisepsis

Before antisepsis, neurosurgery was almost inevitably fatal due to 'suppuration'. Louis Pasteur (1822–1895) developed his germ theory and radically changed current opinion as to the origins of

infection. He postulated that meat putrefaction and fermentation were not due to 'spontaneous' degeneration but to living microscopic organisms. Joseph Lister (1827–1912), who was Professor of Surgery at the University of Glasgow, applied Pasteur's germ theory to surgery and in particular to wound infections. He began using carbolic acid and commented that his wounds healed without pus. The mortality from amputations was dramatically cut from 45% to 15%. Meanwhile, in America William Keen (1837–1932) adopted Lister's principles in his operating theatre, applying them to the surgeon, the patient, and to the theatre environment; principles that are still being pursued today. He insisted all surfaces were cleaned with carbolic and carpets and furniture were removed. The surgeon's hands were washed with soap, alcohol, and sublimate, and the patients were also prepped for the first time with a head shave, soap and water, ether, and wet sublimate dressings as well as mercuric chloride washings.

Handwashing was also shown to radically reduce infections in obstetrics and gynaecology by Holmes Semmelweiss. Keen boiled his surgical instruments for 2 hours in a precursor to heat sterilization, which was introduced in 1891 by Ernst von Bergman. In 1883 Neuber began to use sterile gowns and caps, but it was not until William Stewart Halsted (1852–1922) commissioned Goodyear to make some rubber gloves in 1890 to protect his nurse's hands from the mercuric chloride that gloves were routinely used in surgery (see Fig. 1.2). Mikulicz subsequently introduced masks in 1897.

Cushing himself stated in 1915 that 'certainly infections cannot be attributed to the intervention of the devil but must be laid at the surgeon's door'. He published his series of 130 cases with only a single infection—an infection rate of less than 1%, which remains enviable today. A Centre for Disease Control and prevention (CDC) audit on craniotomy infection rates from 1992 to 2003 reported rates between 0.86% for low risk cases and 2.32% for the high risk. Cushing also reported a perfectly respectable 8.4% mortality in the same series (Cushing, 1915). In the 1940s antibiotic prophylaxis was introduced to reduce postoperative infection.

Cerebral localization

In the 1860s the correlation of neurological symptoms and signs with the cerebral location of a lesion began to transform the scope of neurosurgery. The neurological examination is so ingrained in our current practice that it is difficult to imagine a time before cerebral localization. At the beginning of the nineteenth century, localization theory had been associated with the discredited pseudo-science of phrenology. Paul Broca (1824–1880) then showed that speech was localized in the brain's left hemisphere and John Hughlings Jackson (1835–1911) described what came to be known as the 'Jacksonian march' of focal motor activity 'in which parts of the body are affected one after another'. He also correctly identified that a third cranial nerve palsy lateralizes the haematoma to the side of the fixed and dilated pupil. He directed Sir Jonathan Hutchinson (1828–1913) to perform surgeries based on his localizations and ipsilateral pupillary dilatation carries the eponym 'Hutchinson's pupil'.

It was during the same period that David Ferrier (1843–1928) was using Faradic current stimulation in animals including primates to create one of the first cortical maps, including the correct location of the motor cortex. He credited Hughlings Jackson with predicting the outcome of his animal studies. Fritz and Hitzig were using similar cortical stimulation techniques to map the cortex in dogs during the same time period.

Dr Alexander Hughes Bennett (1848–1901) is credited with being the first neurologist to direct the removal of a tumour by cerebral localization alone. In 1885 he directed Sir Rickman Godlee (1849–1925) to remove a motor strip tumour from a patient who had presented with contralateral focal motor seizures and subsequent progressive hemiparesis. The operation was successful, but the patient later died of infection, as was so often the case (Bennett and Godlee, 1965; Kerr et al., 2005).

Fig. 1.2 Photograph of Harvey Cushing and William Halsted in the operating room. Note the rubber gloves, made by Goodyear, that Halsted was the first to use routinely in surgery.

Haemostasis

The development of effective neurosurgery required new methods to deal with the torrential haemorrhage often associated with craniotomy. William Bovie (1882–1958) developed the method of electrocautery for haemostasis and it was first used by Cushing in 1926. The development of blood transfusion in the early years of the twentieth century was also of importance. Until then, craniotomies would sometimes be done as staged procedures, with an interval between the operations to allow the patient's own haematopoeisis to replace the blood lost on opening the scalp and skull.

Early pioneers

These major technical advances in anaesthesia, antisepsis, cerebral localization, and haemostasis set the scene for the early pioneers of neurosurgery to establish neurosurgery as a specialty in its own right.

Victor Horsley 1857–1916

Sir Victor Horsley (1857–1916) was a clinician, researcher, and surgeon, and was therefore ideally qualified to make significant advances in cerebral localization. He published works on the topography of the motor cortex and 'the arrangement of the internal capsule', as well as relating surface anatomy to underlying cortical features in 'topographical relations of the cranium and surface of the cerebrum'. In 1888 he was the first to successfully remove a spinal cord tumour (localized by William Gowers, neurologist, 1845–1915). He was not the first to remove a brain tumour—that was William Macewen (1848–1924)—but he is credited with performing several pioneering operations, including craniosynostosis surgery for raised intracranial pressure and sectioning of the posterior root of the trigeminal nerve for neuralgia; he was also the first to operate on the pituitary. His technical advances included the development of antiseptic beeswax for bone bleeding (still used today) and the Horsley-Clark stereotactic frame. He was a general surgeon himself, but was at the forefront of developing neurosurgery as a specialty and was given the first specifically neurosurgical appointment while at Queen Square. He died in the First World War from desert fever.

William Macewen 1848–1924

William Macewen (1848–1924) was born in Port Bannatyne on the Isle of Bute, Scotland. He was Regius Professor of Surgery at Glasgow University from 1892 to 1924 and was knighted in 1909 when he became Surgeon to the King. His major contributions to surgery were in orthopaedics, establishing bone graft surgery, and setting up the Princess Louise Scottish Hospital for Limbless Soldiers and Sailors where he also designed the Erskine artificial limb. He is credited with performing the first brain tumour operation when he successfully removed a presumed meningioma from a 14-year-old girl in 1879. He did not require the then-novel technique of cerebral localization as there was hyperostosis overlying the meningioma, which directed his surgery. She had indeed presented with cosmetic deformity, and subsequently had refractory seizures contralateral to the lesion, which provided Macewen with the indication to attempt the resection. He was a strong believer in sterile surgical techniques and she survived a further 8 years, and was able to work, before dying of other causes. The low mortality of his operations for cerebral abscess bears comparison with modern series.

William W. Keen 1837–1924

The first American neurosurgeon was William Williams Keen Jr. He studied at Jefferson Medical College and was President of the Philadelphia School of Anatomy. As was commonplace at that time he toured Europe during his education, spending time in Paris and Berlin. He is credited with introducing the Gigli saw to America. He pioneered CSF drainage for hydrocephalus, describing the eponymous parietal burr hole still often used for ventriculoperitoneal shunt insertion 3 cm posterior and superior to the pinna. Although not the first to remove a brain tumour, he was noted for removing some large tumours successfully.

Harvey Williams Cushing 1869–1939

Harvey Williams Cushing is often seen as the father of modern neurosurgery (see **Figs. 1.3** and **1.4**). Arriving on the scene at just the right time when antisepsis, anaesthesia, and cerebral localization

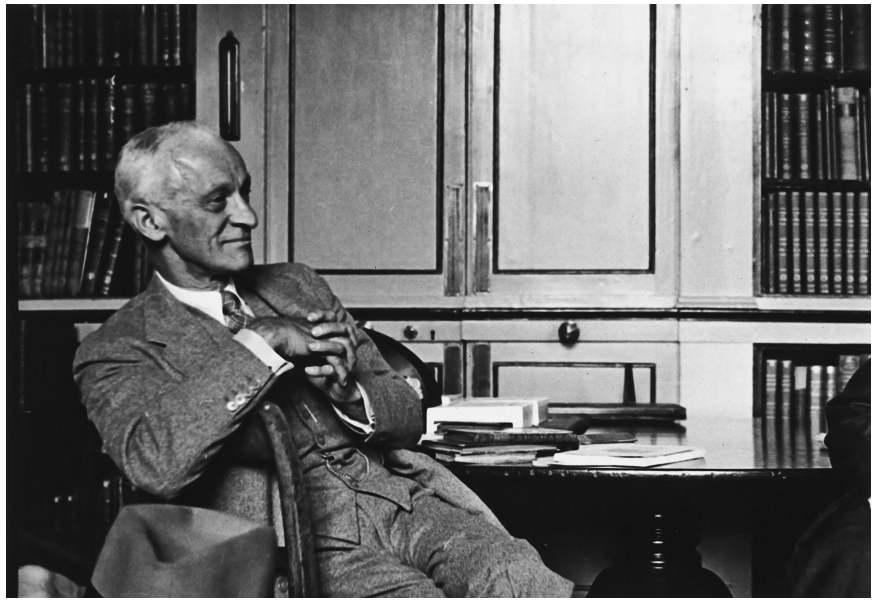

Fig. 1.3 Harvey Cushing, the father of modern neurosurgery.

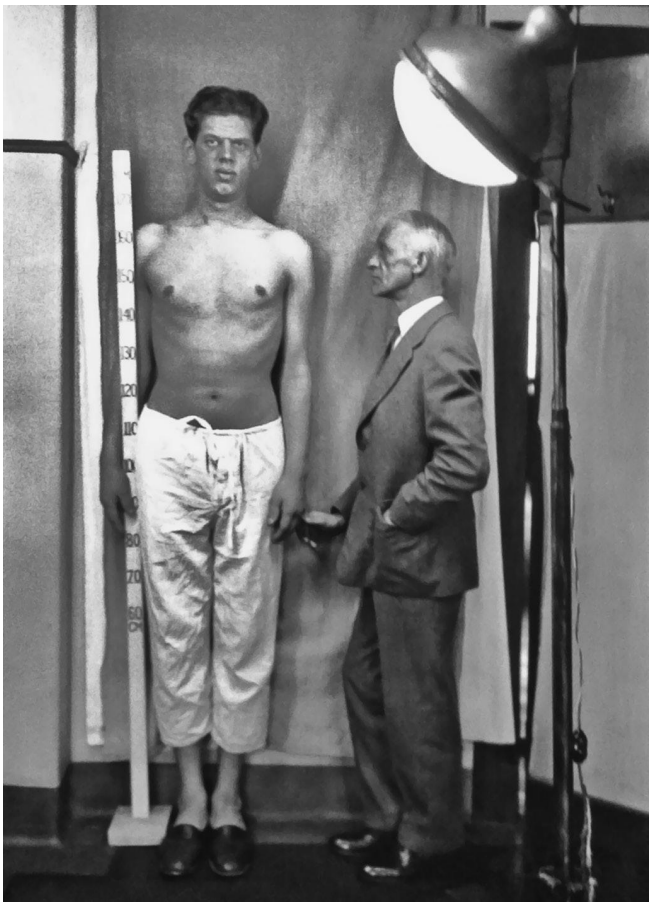

Fig. 1.4 Harvey Cushing stands by a patient with gigantism.
Reproduced from Shin P. Harvey Cushing's Ghosts: Death and Hauntings in Modern Medicine. Yale J Biol Med. 2011;84(2):91–101

were now established, Cushing was well positioned to make his contribution to the specialty.

He was trained in general surgery by Halsted himself, who was Professor of Surgery at the time, and who is credited for teaching Cushing his meticulous surgical technique. Another great influence on Cushing was Sir William Osler (1849–1919), who encouraged him in the more philosophical aspects of medicine including the study of the history of medicine. Cushing was one of Osler's 'latchkeyers', students who lived next door to Osler and were given the 'latchkey' to his extensive library.

In those days it was common for American doctors to spend some time visiting their counterparts in Europe, and Osler encouraged Cushing to do the same. Cushing visited Horsley in London and by his own account was 'a little disappointed' in him. A meticulous surgeon himself, Cushing described Horsley's technique as 'execrable' and commented that he must have many 'septic wounds'. Indeed, at that time Horsley accepted mortality rates of 30–50% from 'brain fungation' (i.e. infection).

Cushing then travelled to France and Switzerland where he worked with Kocher in Bern. In contrast to what he writes about Horsley, he comments that Kocher's technique was 'detailed' and 'tedious' with 'absolute haemostasis'. Cushing's seminal work on intracranial pressure began at this time in the lab of Kronecker. It was here that he made the discovery that 'an increase in intracranial tension occasions a rise of BP which tends to find a level slightly above that exerted against the medulla'—now known as the Cushing reflex. His travels then took him to Italy where he was so impressed with the blood pressure monitor designed by Scipione Riva-Rocci that he brought it back to America with him.

This era from 1901 to 1910 was a key decade for neurosurgery. Cushing recognized the importance of raised intracranial pressure and of meticulous surgical technique. He was responsible for the introduction of intraoperative blood pressure monitoring and following his own experience of a death on the operating table, he also introduced anaesthetic charts to record pulse and respirations during a procedure. With Percival Bailey (1892–1973) and Louise Eisenhardt (1891–1967) he coauthored the standard works on gliomas and meningiomas, and was responsible for pioneering work on the diagnosis and treatment of pituitary disorders.

Walter Dandy 1886–1946

Walter Edward Dandy studied medicine and subsequently spent his whole career at Johns Hopkins Hospital (see **Fig. 1.5**). He was of the same Halsted surgical dynasty as Cushing and was Cushing's research assistant at the Hunterian laboratory that Cushing had established at Johns Hopkins. His work on the production and absorption of CSF acknowledged the importance of the choroid plexus and made advances in our understanding of hydrocephalus of infancy.

His work on 'pneumoventriculography' (1918) radically changed neurosurgery for the next 60 years. In 1913 Luckett had described the radiological appearances of pneumocephalus but Dandy developed the technique by which air ventriculography (or pneumoencephalography as it was known) allowed the interpreter to infer the location of intra-axial masses by the distortion they created in the ventricles. Along with cerebral angiography (discovered by

Fig. 1.5 Walter Dandy, a student of Cushing's and later his rival, made several key contributions to neurosurgery.

Moniz in 1927) this became the mainstay of diagnostic imaging until the advent of the computed tomography (CT) scanner in the 1970s. Previously Cushing and others had used X-rays to identify extra-axial masses such as sellar lesions but until the technique of pneumoencephalography was introduced, intra-axial lesions could only be diagnosed by the clinical skill of cerebral localization. He was the first surgeon to operate for a colloid cyst in 1921.

He advocated total resection of an acoustic neuroma as opposed to Cushing's more conservative subtotal removal, sectioning the fifth cranial nerve for trigeminal neuralgia and developed a transcallosal approach to the pineal. He also identified a ruptured intervertebral disc as a cause of cauda equina syndrome and bilateral sciatica in 1929.

Late twentieth century to today

In recent decades, progress has largely been driven by advances in technology, with the sometimes slightly paradoxical effect of changing management away from neurosurgery, with developments such as interventional radiology for aneurysms and stereotactic radiosurgery for small vestibular schwannomas.

Technological advances

Diagnostic imaging

The development of diagnostic imaging techniques has revolutionized neurological diagnosis (and introduced the modern problem of the incidental finding). Following Dandy's pneumoencephalography the next major advance in imaging techniques was cerebral angiography. This was developed by Antonio Caetano de Egas Moniz (1874–1935) who was subsequently awarded the Nobel Prize in 1949 for the more dubious invention of frontal leucotomy for psychosis (and was also shot and rendered paraplegic by one of his patients). Myelography was introduced by Jean Athanase Sicard (1872–1919) and allowed mass lesions of the spine to be identified.

Parallel advances in X-rays and computing allowed the development of the CT scanner by Godfrey Hounsfield (1919–2004) at EMI. The first CT scan of a patient was in 1971 at the Atkinson Morley Hospital, London, confirming a right frontal lobe tumour. The development of positron emission tomography (PET) and magnetic resonance imaging (MRI) swiftly followed in the 1980s.

Operative microscope

Gunnar Holmgren in Stockholm in 1927 was one of the pioneers of the binocular microscope and its first clinical use was by oto-rhinolaryngologists for the management of otitis media. Several refinements were made to the apparatus, largely led by ears, nose, and throat (ENT) surgeons themselves. Perhaps surprisingly it was not until 1957 that the microscope was first used in neurosurgery. Theodor Kurze, apparently inspired by a film of the ENT surgeon William House using the operative microscope, used it for the removal of a neurilemoma in a 5-year-old.

There are innumerable other advances in the field of neurosurgery. The adoption of the endoscope, for example, has transformed skull base surgery and the introduction of ventriculoperitoneal shunts has radically changed our management of hydrocephalus. These technologies are still, relatively speaking, in their infancy and will continue to develop throughout this century at least.

History of spinal neurosurgery

Although this chapter mainly focuses on the history of cranial neurosurgery, the development of spinal surgery should not be overlooked. Once more, the Edwin Smith Papyrus gives us vivid descriptions of the way spinal trauma was managed in Ancient Egypt. The ability of the Ancient Egyptians, and in particular Imhotep (thought to be the world's first physician) to tie in the clinical picture with the management plan and the prognosis was remarkable. Case 31 clearly describes a complete spinal cord injury secondary to a cervical vertebra dislocation—centuries before Brown-Séquard's treatise on spinal localisation in 1858.

The Hippocratic School in Ancient Greece described the first traction device, advocating correction of an acquired kyphosis following trauma. Hippocrates recognized compression of 'spinal marrow' by displaced vertebrae as the cause of paralysis. As in Ancient Egypt, no treatment was advised if the patient was paralysed. Celsus and Galen did not advocate surgery either, recognizing the poor outcomes associated with spinal cord damage, especially once urinary dysfunction had occurred. Celsus recognized that high cervical lesions were associated with quadriparesis and respiratory compromise while thoracic lesions led to paraparesis. Galen (131–201 AD) coined the terms kyphosis, lordosis, and scoliosis. It is worth noting that he also was the first to describe tuberculous spinal disease (a few hundred years before Percival Pott 1713–1788) and, having conducted experiments where he demonstrated that spinal cord transection led to loss of function below the level of the lesion, he also contributed to the conceptual advance of the brain as the source of voluntary action with signals being passed along the spinal cord. Paulus of Aegina (624–690 AD) was the first to advocate surgery on the spine, removing bony fragments in injured patients with paralysis. Interestingly, in an early reference to 'informed consent' he describes his surgery as being carried out 'after warning of the dangers'.

Very little progress was made in the mediaeval period and the 'dark ages' in Europe. The seat of medicine was transferred to the Arabic world. Previously acquired knowledge from the Alexandrian and Hippocratic schools was preserved by translating the Latin documents into Arabic, but not advanced in any significant way. One notable exception is the Turkish physician Sabunuoglu (*b.*1385) who provides us with the first description of treating sciatica—the first description of degenerative rather than traumatic spinal disease. It was not until 1764 that Cotugno postulated that neural compression was the source of sciatica, a model that was later added to by the French neurologists Lasegue, Dejerine, and Sicard.

During the eighteenth and nineteenth centuries, the Age of Enlightenment in Europe, the foundations for modern spinal surgery were built. Percival Pott (1713–1788) described his now eponymous tuberculous spinal disease and washed out a paravertebral abscess with some success. John Bell (1763–1826) described the flaccid and spastic paralysis and sphincter disturbance associated with spinal cord injury and, with regards to spinal surgery, is quoted as saying 'the cutting into a vertebra is a dream' in 1799. Mr Cline Jr, a surgeon at St Thomas' Hospital, London, is credited with the first 'trepanation' of the spine in 1814 on a paralysed man who was paraplegic after falling from a balcony. He performed a laminectomy and removed the facet joints to reduce the dislocation, but the patient died. There are reports from military history of surgeon Louis operating

on Captain Villedon, who had sustained a spinal cord injury from a thoracic gunshot wound and reportedly regained some distal function postoperatively.

Surgery remained controversial due to its high mortality and morbidity until the advent of antisepsis (Lister 1882–1912 and Semmelweiss 1818–1865) and safe general anaesthesia. Spinal cord localization mirrored cerebral localization with the early work being carried out by Blesius in 1666 (he described the grey-white matter differentiation) and the anterior-posterior spinal nerve roots. The decussation of the pyramids was described by Mistichelli in 1709 and Huber described the denticulate ligaments in 1739. The substantia gelatinosa was described by Rolando in 1809 and Brown-Séquard's description of the decussation of the sensory tracts was published in 1846. Brown-Séquard was a strong advocate of surgery for spinal cord injury. His contribution to spinal cord localization and his description of the spinal cord tracts is immortalized in his eponymous syndrome of hemisection of the cord. Further work on biomechanics of the spine was carried out *in vivo* and *in vitro* by Rauber, Weber, and Messerer in the 1800s.

In the late 1800s, spinal surgery was still mostly confined to trauma and infection (TB). Almost two centuries after Cotugno described the neural compression in sciatica, Oppenheim and Kruse described the first surgery for disc herniation (1909). Mixter and Barr fully described the pathogenesis of disc herniation in 1933 and advocated a 'transdural' approach to the disc. In 1977 Caspar and Yasargil described the microsurgical intralaminar extradural approach that is practised today. Critical to these developments had been Roentgen's discovery of X-rays in 1895, radically improving the diagnosis of spinal fractures. Previously spinal fractures were thought to be almost invariably associated with neurological deficit (90%). Sudeck developed the systematic interpretation of X-rays and established that most fractures in intact patients were missed and that therefore the true rate of paralysis was more like 15–20%. The advent of imaging modalities such as CT (1970s) and MR (1980s) had an equally great impact on the development of surgery for degenerative spinal disease.

Although a few key spinal operative 'firsts' are attributed to nineteenth-century surgeons, it has been the twentieth century where advances in imaging and materials science has allowed the field of spinal surgery to expand into spinal fixation. Anterior, posterior, and lateral approaches to all regions of the spine were developed. The cervical spine has particular challenges due to its poor biomechanical strength and the proximity of important neural and vascular structures. During the last 50–100 years, we have seen the progression from the first anterior cervical surgery of Bailey and Badgley in the 1950s who described the anterior cervical discectomy (ACD) without any graft, to the ACD and fusion (ACDF) advocated by Cloward in 1958 and then by Smith and Robinson. The first anterior cervical plate was designed by Orozco and Lovet and required bicortical screws, which are technically challenging to place. Technological and biomechanical advances allowed the introduction of the unicortical locking screw and then the dynamic load-sharing plates with variable angle screws which was introduced in 2000. Throughout this time, posterior approaches to the subaxial spine have also benefited from advances in materials science with stronger, lower profile screws and posterior cervical fixation has moved forward from the silver wire used in the first posterior c-spine fixation in 1891 via interspinous wires (1942 by Rogers), sublaminar wires (1970), facet wires, and eventually Roy-Camille's lateral mass screws in the 1980s. The history of spinal fixation warrants a chapter in itself. Key advances took forward the principles of open reduction and internal fixation used by orthopaedic surgeons for long bone fractures and applied them to the spine. In 1953 Holdsworth and Hardy described a system of plates and screws. Transpedicular screw fixation was described by King in 1944 but not implemented until 1959 by Boucher. In 1958 Harrington described his system of dorsal instrumentation to correct scoliosis—initially due to polio and then applied to idiopathic. Ventral scoliosis surgery was first described in 1964 by Dwyer. The early focus in disc surgery was to preserve motion and avoid stiffness; this was challenged subsequently when the pathology of disc herniation was found to be secondary to instability and the drive towards fusion became popular. Contrary to this belief, others have focused on developing motion-preserving disc replacements first proposed by Fernstrom in 1966 and patented (although never implanted) by Froning in 1975. The charité intervertebral disc is now the most commonly used artificial disc.

Intradural spinal tumour surgery has progressed along similar lines to cranial surgery, with the first successful removal of an intradural tumour being credited to Horsley in 1887. Elsberg performed the first successful removal of an intramedullary tumour in 1907 and described a two-stage technique for myelotomy and then tumour removal at a second sitting. The technique of pneumoencephalography developed by Dandy was also useful in the spine and, of course, the introduction of the operating microscope greatly improved the success of intradural and intramedullary resections.

Technological advances continue at a rapid pace in spinal surgery. Recent advances in minimal access surgery, image guided screw placement, and endoscopic approaches have all developed in the last 30 years. The thoracoscopic discectomy and fusion of the 1990s has progressed to the treatment of scoliosis and corpectomies using minimal access. Laparoscopic discectomies also developed at a similar time. The father of endoscopy Desormenaux in 1853 could not have foreseen its current myriad applications. Spinal surgery continues to be a rapidly expanding field and the current population demographics mean there will be no shortage of demand for the treatment of spinal trauma, infection or, of course, the degenerative spine.

The future of neurosurgery

The last 100 years have brought dramatic advances in the practice of neurosurgery. The future is likely to see a further move away from open cranial surgery to minimally invasive, endoscopic, and radiologically guided interventional techniques.

Clinical assessment

Peter Bodkin and Elizabeth Visser

Introduction

The practical process of clinical assessment in modern neurosurgery is slightly different to the traditional model. The ground rules of history taking and examination set down by William Osler and the other forefathers of clinical method rightly remain core to our approach, but we must also take into account the realities of the patient journey before the first encounter with a neurosurgeon. Whether by the bedside or in the outpatient setting, it would be rare nowadays for us not to have already been presented with pertinent background information—and indeed, often we will have seen high-quality imaging detailing the patient's pathology with great anatomical detail. The referring physician will most likely have provided a potential list of differential diagnoses. In other words, the patient has usually been neatly packaged well before we ever get to meet them.

Our job, however, is more than simply to supply a surgical fix to a given problem. We are not merely technicians. Although we must take into account the information given to us, we must never take it on face value. All sorts of errors in assessment and incorrect conclusions may have been made along the way. Likewise, imaging is very useful but should never be viewed outside the clinical context. An MRI scan will localize a lesion with more confidence than the best clinician, but technology cannot make us consider a diagnosis of acromegaly from a spongy handshake or common peroneal palsy from the sound of a slapping foot coming to the clinic door.

As we gather and make sense of this information there is an equally, if not more, important process at work. By putting the patient's symptoms into the context of their daily life we begin to develop a relationship with the patient, starting to establish trust and mutual understanding. The rapport built here will be the basis of how a patient measures the success or failure of our interventions.

The traditional neurological clinical assessment described in most textbooks has other subtle differences to those required of the neurosurgeon. This chapter aims to cover that broad spectrum of clinical method for the practising neurosurgeon and those in training.

The neurosurgical history

The main aim of the neurosurgical history is to gain sufficient information to estimate the anatomical location of the problem and to get an impression of the pathological process at work. In particular, the time course and severity of the symptoms will be important guides as to whether surgical intervention is required and how quickly.

As with any important task, being well prepared will provide a good first impression and will save time in the long run. Referral letters, clinical notes, imaging, and other investigations should have been carefully reviewed. Prior discussions with relevant team members may also be useful.

In the clinic, calling the patient from the waiting room yourself can be very valuable. An impression of their social support may be gained by seeing who is with the patient and how attentive they are. Anaesthetic fitness can be crudely assessed by how long it takes to get up and into the clinic room or how out of breath they might be. It is also an opportune moment to make an assessment of gait and a note of walking aids, and so on.

Thought should be given to the physical environment for the meeting. This should be arranged such that the patient and doctor are on as level a playing field as possible. One should be aware that being at a higher eye level or sitting behind a desk may have an intimidating effect and will detract from getting the most out of the encounter. When dealing with digital images, viewing platforms should already be opened with relevant images downloaded.

Introductions should be clear, giving your name and position. Significant others should be welcomed and acknowledged but it should be made clear that the patient is the focus of discussions.

How you open the consultation is important. One should start with open questions, 'So what's been the trouble?', or 'How can I help you?' The referral letter or consultation request has a tendency to emphasize the symptoms that will lure you into seeing the patient in the first place. It is wise, therefore, to avoid saying things like, 'So your doctor has asked me to see you about your facial pain?' Assumptions can be misleading and may encourage patients to tell you what you are expecting to hear.

Once you have encouraged the patient to tell their story, it may be necessary to fill in some gaps. The patient may have painted a picture but there could be large areas missing or fundamental details that are only sketchy. When it comes to the information that is going to influence your decision on treatment keep delving until you feel there is satisfactory detail for a conclusion to be drawn. In the course of this it is important to remember to find out the occupation of the patient and often handedness is pertinent. It is not enough to say a patient

is 'retired'. A retired university professor will have quite different expectations in life compared to a retired ship builder.

The history taking needs to cover time course, anatomical location of symptoms, variability, and character. One must refine questioning with the aim of localizing the lesion or getting clues as to the underlying pathological process. If a patient is not volunteering a symptom, one must consider symptoms that might be associated and ask about them directly. For example, when assessing a patient presenting with spatial disorientation due to a right parietal tumour one needs to remember to ask about problems with their visual fields in case of involvement of the optic radiation, and so on.

The most vital part of the story is often the impact that the condition is having on the patient's way of life. It may seem an unnecessary intrusion to pursue this but most patients are happy to let you know their problems and the knock-on effects on their home, work, and family life. By establishing that you are not solely interested in dealing with their particular pathological entity but rather you want to help them get back to doing the things they enjoy, you turn a medical interview into a more meaningful conversation. The patient will understand that you are treating them and not just their tumour or slipped disc.

Pick up cues. Have an ear for the incongruous. If what you hear doesn't make sense, explore it. Don't let it pass unmentioned. It is also useful to find out what has been done so far to address the problem: pain killers, physio, injections, visits to other physicians, and so on. Is the patient fit for an anaesthetic? Are there drugs that need to be stopped prior to surgery? Could an unhealthy lifestyle be contributing to the problem?

Drawing the history to a conclusion, the patient should feel that their issues have been adequately addressed. 'Is there anything else you'd like to discuss?' is a useful way of allowing any additional information to be voiced. The patient will hopefully be in a more relaxed and open frame of mind by this stage of the interview and might reveal underlying motivations and concerns. Finally, it may be useful to agree on a brief summary and have a final effort to clarify any lingering grey areas or inconsistencies.

The neurosurgical examination

Examination of the unconscious patient

The approach to the patient who has altered conscious level is obviously limited by the inability of the patient to comply with given instructions and to provide verbal feedback. We are therefore restricted to rather crude and basic bedside tests (i.e. examination of pupillary response to light and the Glasgow Coma Score). Often high-stake decisions are made on the basis of these assessments and it is therefore crucial that they are performed with utmost care, being mindful of possible confounding factors (Table 2.1).

Impairments of pupillary response may be due to damage at a number of locations along the afferent and efferent pathways. Direct trauma to the orbit may cause rupture of the pupil sphincter muscles and produce a traumatic mydriasis. Traumatic optic neuropathy may be due to direct disruption due to penetrating injury or indirectly by shearing forces in blunt head trauma. Lesions in the region of the pretectal nuclei or Edinger–Westphal nuclei in the rostral midbrain will also cause mydriasis. There are complex regulatory pathways from various sources including the ipsilateral hypothalamus that drives sympathetic pupillary tone and indeed poorly understood descending control from the cortex that results in ipsilateral or contralateral mydriasis or miosis following a seizure (Plum and Posner, 2007). Therefore, damage in many brain regions may result in pupillary abnormalities (Fig. 2.1). Compression of the parasympathetic fibres along the third cranial nerve by the herniating uncus is a common cause of pupillary abnormality in neurosurgical practice.

Table 2.1 Confounding factors in assessment of GCS

Glasgow Coma Score	Confounding factors
Eye opening (4 = spontaneous, 3 = to speech, 2 = to pain, 1 = do not open)	Orbital injuries Ecchymosis Photophobia
Verbal response (5 = oriented, 4 = confused, 3 = inappropriate words, 2 = incomprehensible sounds, 1 = no sound)	Non-native speakers Maxillofacial injury Endotracheal intubation/tracheostomy Deafness
Motor response (6 = obeys commands, 5 = localizes to pain, 4 = flexion/withdrawal to pain, 3 = abnormal flexion to pain, 2 = extension to pain, 1 = no movement)	Spinal cord injury Upper limb fractures, casts, and fixation

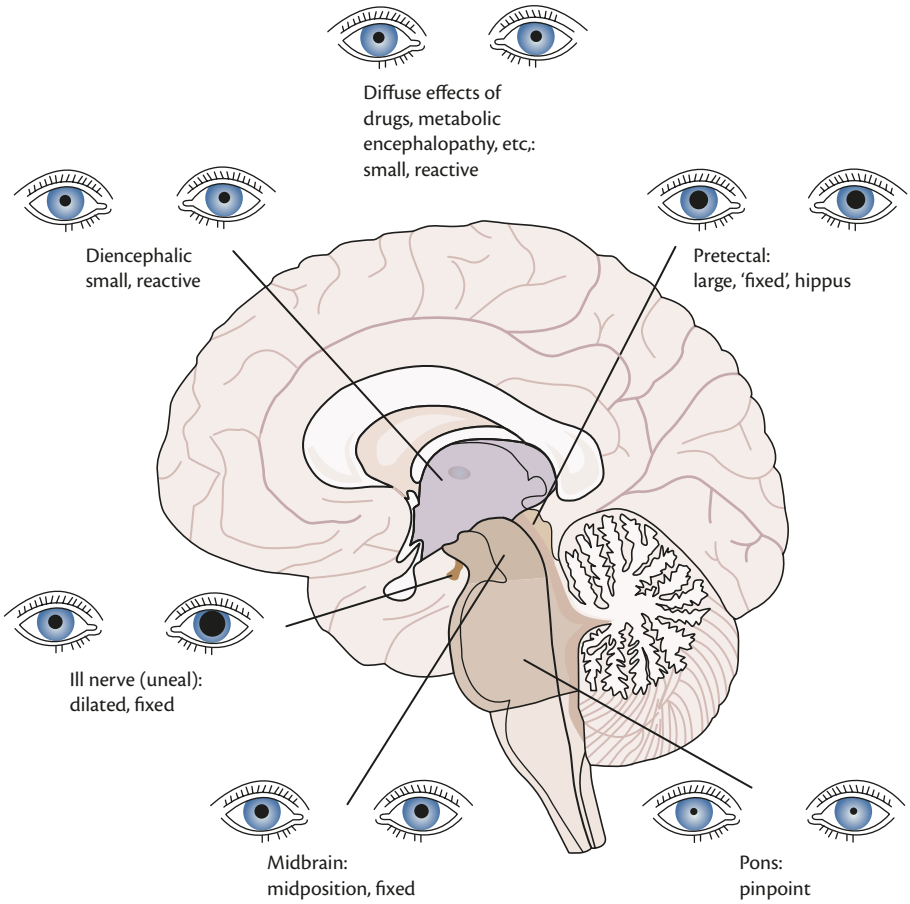
Reprinted from *The Lancet*, Vol 304, Issue 7872, Graham Teasdale, Bryan Jennett, Assessment of Coma and Impaired Consciousness A Practical Scale, pp. 81–4, Copyright (1974), with permission from Elsevier.

The Glasgow Coma Score brings together diverse clinical features to provide a guide to global brain function. Of the three divisions (eye opening, verbal response, and motor response) the motor response is most likely to differentiate the severity of injury. Lesions above the red nucleus produce decorticate posturing (flexion of upper limbs and extension of lower, rubrospinal tract function) and those below produce decerebrate posturing (extension in upper and lower limbs, vestibulospinal tract function). Normal flexion (M4) constitutes flexion with supination; abnormal flexion (M3) constitutes flexion with pronation analogous to decorticate posturing and release of rubrospinal tract function as just described; and extension (M2) is analogous to decerebrate posturing and release of vestibulospinal tract function. It is best to apply painful stimuli to trigeminal territories in case of spinal cord injury causing peripheral numbness. Pressure over the supraorbital notch is sufficient.

Rising blood pressure, falling heart rate, and altered respiratory pattern (Cushing's triad) is a classical response to raised intracranial pressure but is usually a very late, agonal feature.

Examination of language and speech disorders

It is important to appreciate any abnormalities of speech and language as this can impact on the history taking, neurological examination, and assessment of higher function and thus alter the outcome of the consultation in general. The ability to correctly identify disorders of speech can aid in localization of neurological pathology. In order for us to communicate through speech and language, hearing, understanding, voice production, articulation, consciousness, thought, and word finding must be intact. Language is a complex



Diffuse effects of drugs, metabolic encephalopathy, etc,: small, reactive
Diencephalic small, reactive
Pretectal: large, 'fixed', hippus
Ill nerve (uneal): dilated, fixed
Midbrain: midposition, fixed
Pons: pinpoint

interaction of combinations of sounds, writing, and meaning often linked to a cultural background.

To assess understanding start by engaging the patient in normal conversation and asking simple questions: 'What is your name? What is or was your occupation? How did you get here today?' Ensure that the patient can hear you properly and enquire as to what their first language is. Establish if the patient is left- or right-handed. As a rule of thumb, 99% of right-handed individuals have language dominance in their left hemisphere; 60% of left-handed patients will be left hemisphere dominant; 20% bilateral; and 20% right hemisphere dominant.

Now consider the different disorders of language defined here:

1. Aphasia—this is defined as a disorder of spoken language. It is divided into subcategories as follows:
   - **1.1** Non-fluent aphasia (anterior, motor, or Broca's);
   - **1.2** Fluent aphasia (posterior, sensory, or Wernicke's);
   - **1.3** Conduction aphasia;
   - **1.4** Transcortical aphasia (sensory and motor).
2. Alexia or dyslexia is a disorder of acquired reading ability.
3. Agraphia or dysgraphia is defined as disorders of written language.
4. Dysarthria is a disorder of articulation or speech production.
5. Dysphonia is defined as an abnormality of noise production by expired air over vibrating vocal cords.

Further examinations of these disorders include assessment of spontaneous speech, fluency, naming, repetition, articulation, speech volume, reading, and writing, and will help to localize the pathology.

1. Assessment for aphasia

Assess spontaneous speech, fluency, and if the patient uses the wrong words (paraphasia). Ask the patient to name animals or words beginning with 'F' in a minute. This tests word finding ability. Also ask them to name familiar objects: a pen, a watch, a tie, and so on. Now ask the patient to repeat phrases. Table 2.2 summarize the findings on examination and localization.

2. To assess for alexia or dyslexia, ask the patient to read a sentence or obey a written command.
3. Agraphia or dysgraphia can be examined by asking the patient to write a sentence; this can only be assessed if there is no motor disability.
4. Dysarthria is examined by asking the patient to repeat a phrase; for example, 'red lorry, yellow lorry' requires intact lingual function and 'baby hippopotamus' requires intact labial function. Listen for slurring and rhythm of speech. Dysarthria can be described as spastic (caused by pseudobulbar palsy as in motor neuron disease), extrapyramidal (associated with Parkinsonian syndromes, often associated with dysphonia), cerebellar dysarthria (associated

Table 2.2 Assessment of aphasia (Clark, 2009; Fuller, 2013)

	Comprehension	Fluency	Naming	Repetition	Other features	Localization
Non-fluent aphasia	Intact	Non-fluent	Impaired	Impaired	Right hemiplegia, depressed	Left frontal lobe (inferior and temporal insula), Broca's area
Fluent aphasia	Impaired	Fluent	Can be intact	Impaired	Neologisms, meaningless speech, paranoid, could have a visual field defect	Posterior superior temporal lobe, Wernicke's area
Conduction aphasia	Intact	Fluent	Impaired	Impaired	Depressed, cortical sensory loss right arm	Parietal operculum/ arcuate fasciculus
Global aphasia	Impaired	Non-fluent	Impaired	Impaired	Right hemiparesis worst in arm	Peri-Sylvian, both Wernicke's and Broca's areas
Nominal aphasia		Non-fluent	Impaired			Angular gyrus
Transcortical motor aphasia	Intact	Fluent	Impaired	Intact	Halting, effortful speech	Left anterior superior frontal area
Transcortical sensory aphasia	Impaired	Fluent	Can be intact	Intact	Semantic paraphasia	Posterior temporo-occipital-parietal area
Transcortical mixed aphasia	Impaired	Non-fluent	Impaired	Intact		Both Wernicke's and Broca's areas

Data from Clarke, C; Howard, R; Rossor, M; Shorvon, S. (2009) *Neurology: A Queen Square Textbook*. Wiley-Blackwell (p. 252–4), Fuller, G. (2004) Neurological Examination Made Easy, 3e. Churchill Livingstone. (p. 17–25).

with multiple sclerosis, alcohol intoxication, or inherited ataxia), and lower motor neuron dysarthria (this is caused by lesions affecting palatal movement causing nasal speech, tongue movements causing patients to struggle with the letters 'T' and 'S' and facial movement resulting in difficulty with the letters 'B', 'P', 'M', and 'W' and often involves the lower cranial nerves).

5. Finally listen to the volume of speech; if this is reduced it is described a dysphonic speech.

The lobar examination

The examination of the functions of the individual lobes of the brain should be a familiar and fluent part of the neurosurgeon's assessment. One should be aware of the somewhat arbitrary divisions between the lobes, however, and it may well be that one should test more than one lobe if the lesion is on or near a dividing sulcus. Anatomically, Yasargil's seven lobe system is most satisfactory (frontal, central, parietal, occipital, temporal, insular, and limbic; see Ribas, 2010) but here we will use frontal, parietal, temporal, occipital, and cerebellum.

Frontal lobe

As one might expect, as it is the largest lobe, frontal examination has the most components and complexity (Box 2.1). Anatomically, it is useful to consider four distinct regions—the precentral gyrus, the dorsolateral cortex, the orbitofrontal cortex, and medial cortex (Fig. 2.2).

The assessment of the function of the primary motor cortex requires testing for upper motor neurone signs on the opposite side. The patient may adopt postures typical of pyramidal weakness (i.e. flexors stronger than extensors in the upper limbs and vice versa in the lower limbs). Pronator drift is perhaps the archetypal neurosurgical test and is extremely useful in bringing out subtle weakness. Lying anterior to the primary motor cortex lies an area known laterally as the premotor cortex and medially as the supplementary motor area (SMA). The functions of these areas are complex but act in conjunction with the primary motor cortex. The cortical area immediately anterior to the primary motor cortex (Brodmann's Area 6) comprises of the lateral premotor area on the lateral aspect and the SMA on the medial and interhemispheric aspect. The lateral premotor area has reciprocal connections with the cerebellum and is involved with refinement of movements with external sensory cues. The SMA has reciprocal connections with the basal ganglia and is involved with initiation of movements from internal sensory cues. In contrast to the primary motor cortex homunculus (leg medial, upper limb, face, and tongue lateral) the SMA homunculus is arranged horizontally (leg posterior adjacent to the paracentral lobule and primary motor area for leg, upper limb, then face and tongue more anteriorly). The SMA has roles in postural stability in walking, initiating and sequencing movements, and coordination of both sides of the body. Frontal lobe ataxia causes a characteristic magnetic gait as if stuck to the floor (Brun's apraxia). This has similarities to Parkinsonian gait, but does not have the lack of arm swing. It is part of the clinical triad of normal pressure hydrocephalus (disturbance of gait, continence, and cognition). This reflects the anatomical proximity of the micturition inhibitory area (just inferior to

Box 2.1 Scheme for frontal lobe assessment

- Ask about handedness and assess speech
- Observe behaviour—abulia, inappropriate dress, verbal dysdecorum
- Posture/gait—decorticate, 'magnetic'
- Pyramidal weakness
- Saccadic eye movements
- Primitive reflexes
- Look for urinary catheter
- Anosmia and Foster Kennedy syndrome
- Neuropsychological tests—echopraxia, perseveration, conceptualization, working memory

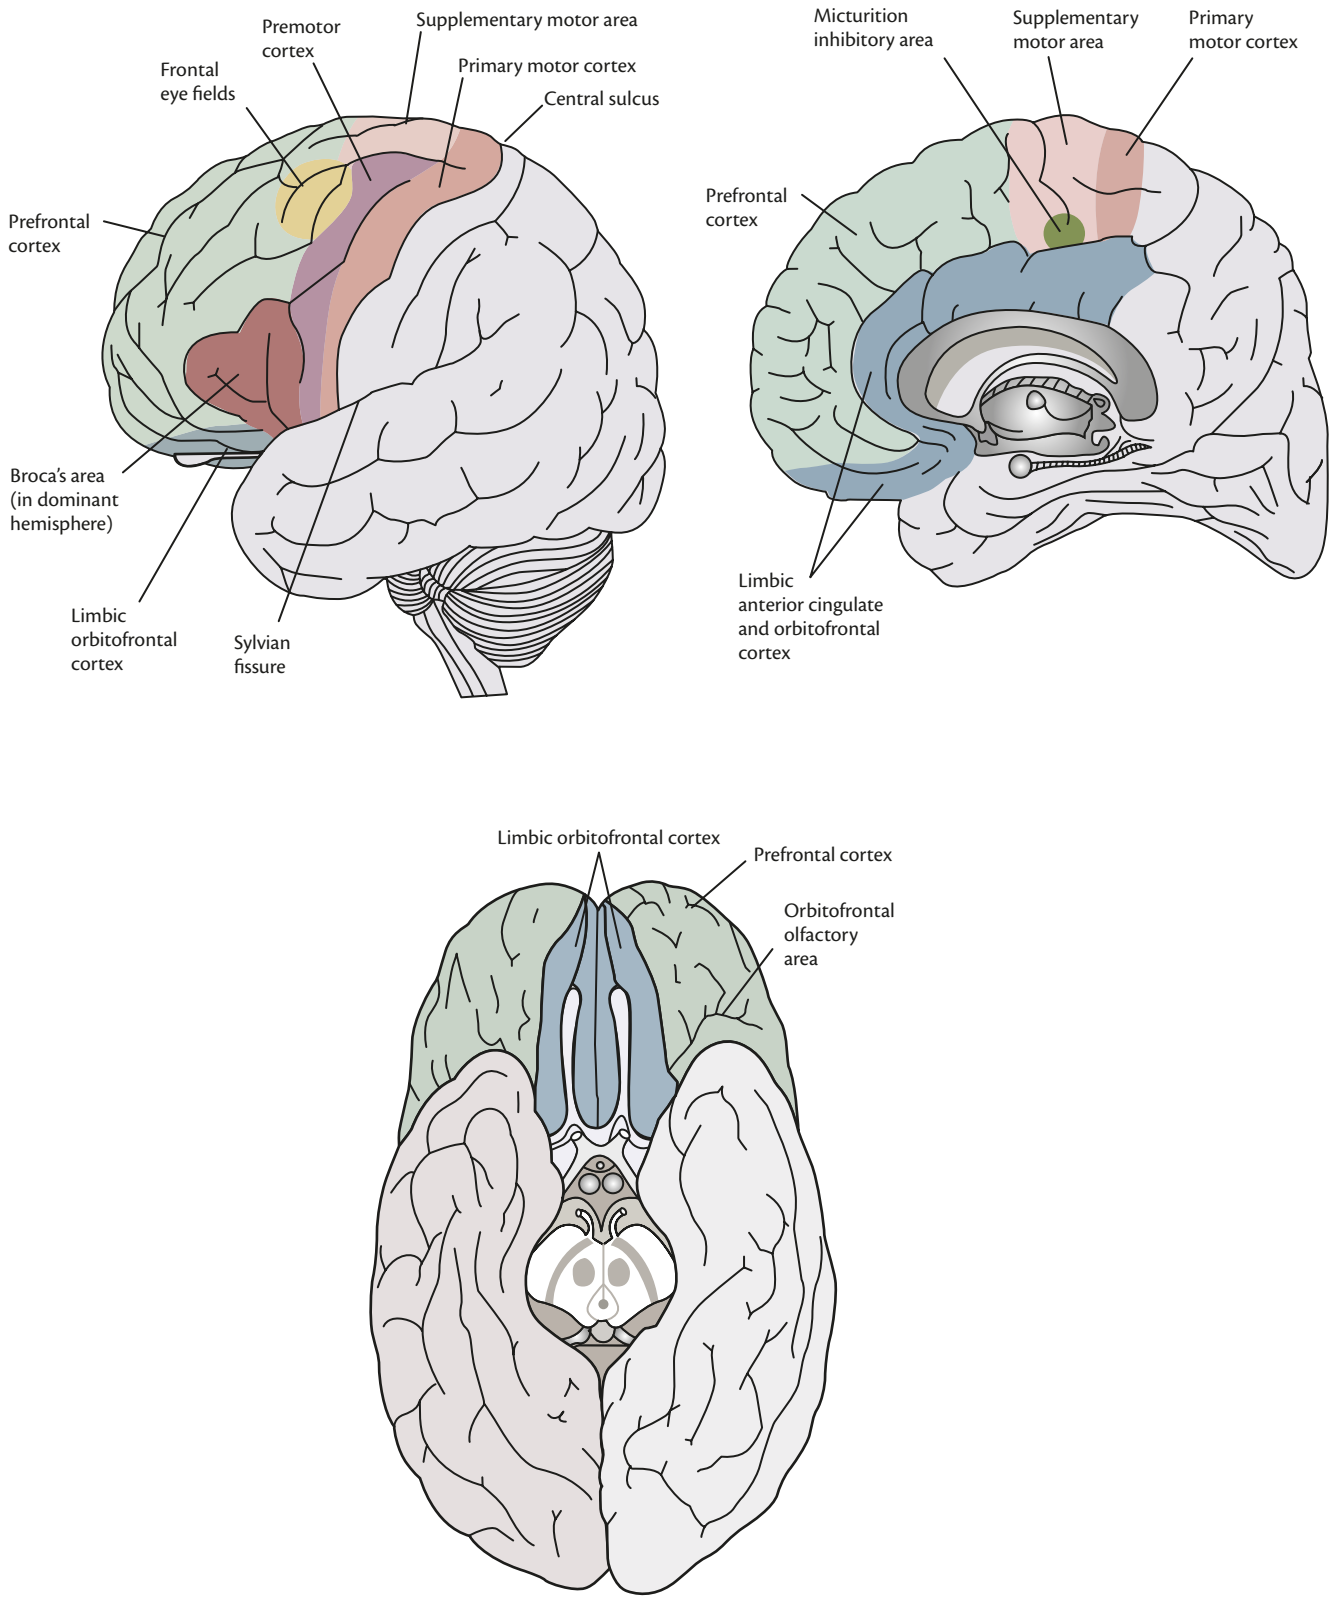

Fig. 2.2 The frontal lobe.
Neuroanatomy through Clinical Cases, 1st Edition by Blumenfeld (2002) Fig.19.11 p. 848. By permission of Oxford University Press, USA.

the SMA) and the more diffuse role of the frontal lobe in cognition. Frontal lobe dysfunction may also cause gegenhalten—the resistance to passive movement.

The frontal eye fields (FEFs, Brodmann's Area 8) lie in the posterior part of the middle frontal gyrus and adjacent precentral sulcus. A mass lesion here may result in horizontal conjugate gaze deviation

towards the side of the lesion (Prévost or Vulpian sign). Seizures will result in looking away from the lesion. Saccadic eye movement should be tested by asking the patient to look between two fixed points (e.g. a fist and a finger) while keeping the head still. Damage to the FEF may result in impaired saccades away from the lesion.

Re-emergence of primitive reflexes or 'frontal release signs' may also be demonstrated. The grasp reflex is assessed by gently passing a finger across the palm. It is most reliably done by distracting the patient by asking them to count backwards from ten. The palmomental reflex is a brief contraction of the ipsilateral mentalis muscle in response to stroking the palm. The snouting reflex is seen when the lips purse in response to tapping the upper lip or the sucking reflex when pressing an object to the lips. Glabellar tap may also cause persistent blinking, whereas in the normal individual it attenuates. It should be remembered that these reflexes may well be seen in normal individuals, particularly in older people (25% of normal adults have the palmomental reflex; see Brazis et al., 2011).

The prefrontal area contains a large volume of brain that has complex roles in control of behaviour. One may divide these into restraint (the restriction of behaviour to that which is socially and culturally acceptable), initiative (motivation to put thoughts into action), and order (to sequence tasks appropriately; see Blumenfeld, 2002). Simply observing and talking with the patient will give insights into this. Apparently quite contradictory behaviours may be encountered, some patients lacking any kind of 'get up and go' compared to others for whom it is difficult to stop talking, or who are overfamiliar or tactless. In general, abulia is more frequently seen in lesions of the dorsolateral convexity whereas disinhibition is often an orbitofrontal feature. There are many neuropsychological tests that are pertinent to examining the frontal lobes (**Box 2.2**).

Parietal lobe

The parietal lobe (**Fig. 2.3**) may be divided into the postcentral gyrus, posteriorly is the superior parietal lobule and inferior parietal lobule (angular and supramarginal gyrus). Processing of somatic sensations and perceptions occurs in the postcentral gyrus (monomodal); the posterior parts are polymodal assimilating inputs from somatic, visual, and other sensory modalities mostly for the control of movement especially the hand and upper limb (Kolb and Whishaw, 2009). The left inferior parietal lobule has a role in language and is considered under that heading. Disorders of the parietal lobe will impair sensation. However, as much of somatic sensation is processed in the thalamus there will not be complete numbness but rather more subtle impairments. These may be tested looking for sensory extinction, astereoagnosia, dysgraphasthesia, and two-point discrimination (**Box 2.3**).

Lesions of the dominant parietal lobe have been associated with a collection of signs known as Gerstmann's syndrome. Although rare in combination, it is still useful to have these four signs in mind for completeness of examination (**Box 2.4**). For the non-dominant parietal lobe (**Box 2.5**) there is a preponderance for there to be contralateral neglect. This may be noted from the patient's appearance with lack of grooming on one side. Other features may become apparent such as loss of geographical orientation (getting lost in familiar places), dressing apraxia, and anosognosia (lack of awareness of illness).

Box 2.2 Neuropsychological tests of frontal lobe function

Luria's three-step test
This tests motor sequencing. Tell the patient you are going to show him a series of hand movements. Without verbal prompting show a sequence of fist, edge, palm, and repeat five times. Ask the patient to do the same. The patient may demonstrate perseveration with repetition of the same movement or be quite unable to do the sequence in order.

Go/no-go test
This tests ability to shift set. Hold two fingers out palm down—'put out one finger when I do this', hold down one finger—'put out two fingers when I do this'. Do this several times. Then change the instructions. Place two fingers—'put out one finger when I do this'. Place one finger—'do nothing when I do this'. The inability to follow the second set of instructions implies a deficit.

Verbal fluency
Produce as many words beginning with a particular letter in one minute, proper nouns not allowed. Normally 12 or more.

Tower of Hanoi
A game moving discs between stacks aiming to achieve goal in as few moves as possible

Wisconsin card sorting test
This is a card matching test testing executive function.

Stroop test
Read out a list of coloured words (i.e. the word green spelt out in yellow text). Test of restraint.

Temporal lobe

The temporal lobes have roles in processing auditory information (Heschl's gyrus), visual information (inferotemporal cortex), emotion (amygdala), and memory and spatial navigation (hippocampus). Its role in language is important especially in the vocalization (dominant) and perception of (non-dominant) emotion in language (emotional prosody). It should be recalled that Meyer's loop passes over the roof of the temporal horn and lesions may, therefore, cause a 'pie in the sky' quadrantanopia. Apart from simple tests of memory, speech, and visual fields there are limited bedside tests for the temporal lobe. Neuropsychologists may perform dichotic listening tests where different recordings are presented to either ear of a pair of headphones to assess selective auditory attention or may carry out advanced tests of verbal and non-verbal memory.

Occipital lobe

Vision and its interpretation is the primary function of the occipital lobe and is dealt with in that section.

Cerebellum

The cerebellum coordinates smooth, planned motor actions by analysing extensive sensory inputs from the brain and spinal cord. The midline structures (the vermis and flocculonodular lobes) control coordination of trunk and eye movement. The cerebellar hemispheres maintain control of limb movement and aid motor planning. Because cerebellar outputs remain ipsilateral or cross twice, lesions of a cerebellar hemisphere will cause an ipsilateral deficit. Ataxia is a characteristic sign of cerebellar dysfunction. Movements are clumsy due to poor coordination between agonist and antagonist muscle groups. There is imprecision of trajectory though space (dysmetria) and also in timing of movements. Truncal ataxia may make even sitting up in bed very difficult. Gait may be wide-based and staggering. Appendicular ataxia may be tested by asking the patient to repeat rapid alternating movements of the limbs (e.g. supinating/pronating one hand on the other). When abnormal this is known as dysdiadochokinesia. One can also ask the patient to outstretch their arm, then touch their nose, or to touch the examiner's finger and back to their nose. An intention tremor may be also elicited. Holmes

This article was published in Gross Anatomy and General Organization of the Central Nervous System in Nolte's *The Human Brain*, John Nolte, Copyright Elsevier (2009).

rebound test demonstrates overshooting. For example, with arms outstretched and eyes closed, the examiner pushes one arm downward. On release the patient's arm shoots up higher than originally placed. There is ipsilateral hypotonia and a pendular knee jerk may be found. The cerebellum has a role in articulation and when damaged will cause dysarthria with laboured, slurred speech. Mutism is a well-recognized problem following surgical resections in the midline, well documented in children following medulloblastoma resection. The anatomical basis is from disruption of a dentato-rubro-thalamo-cortical pathway such that bilateral dentate nucleus injury causes mutism. This explains why dominant hemisphere SMA injury, bilateral thalamotomies and mesencephalic strokes (red nucleus) can result in the same syndrome. Cerebellar mutism was originally, mistakenly, attributed to approaches that split the vermis given the close proximity of the dentate nuclei to the midline.

Nystagmus may also be present with the fast phase towards the abnormal side. Vertical nystagmus (e.g. downbeat nystagmus may be seen in Chiari malformation). Head tilt may occur in children with posterior fossa lesions. Cognitive-affective symptoms are increasingly being recognized in cerebellar disorders.

Box 2.3 Examination of parietal lobe function (either hemisphere)

Sensory extinction
Ask patient to hold out arms with eyes shut. Touch either one or both sides of the corresponding part of the body and ask where he has been touched. Extinction occurs when the patient says that only one side is being touched when in fact it is both.

Stereognosis
With the patient's eyes closed, place a familiar object in their hand and ask them to identify it. Coins of different denominations may be used.

Graphesthesia
Ask the patient to identify the number or letter that you trace on their palm. It should be agreed which way is up before starting.

Two-point discrimination
Using callipers or a bent paper clip, ask the patient if they can feel one or two points. On the fingertips one should be able to recognize two separate points to about 2–4 mm apart, on the palm 8–15 mm.

Visual fields
Examine for homonymous inferior quadrantanopia.

Constructional apraxia
Ask patient to copy a 3D drawing.

Box 2.4 Parietal lobe examination—dominant hemisphere (Gerstmann's syndrome)

Dyscalculia
Ask the patient to subtract 7 from 100 and continue subtracting 7 sequentially.

Agraphia
Ask the patient to write a simple sentence.

Finger anomia and left-right disorientation
These two can be examined together by crossing your hands and asking, 'Which finger am I wiggling?' (Fig. 2.4) or alternatively asking the patient to touch their right ear with their left ring finger. Remember to also assess speech (see earlier).

Fig. 2.4 Testing finger anomia and left-right disorientation: 'Which finger am I wiggling?' Correct answer: 'Your left ring finger.'

Box 2.5 Parietal lobe examination—non-dominant hemisphere

Unilateral spatial neglect

Ask the patient to mark the middle of a horizontal line. Displacement of the centre towards the side of the brain lesion (generally right hemisphere) indicates neglect. Target cancellation tests can also be used. This is where a patient is asked to circle every 'a' on a page or something similar. Only one side of the page will be attended to.

Crossed response test

Ask patient to move the limb opposite the one that is touched (motor neglect).

Dressing apraxia

Ask the patient to take off a jumper or other item of clothing. Turn it inside out and ask the patient to put it back on the right way.

Paper cutting

Ask patient to use a pair of scissors to cut out a shape from a piece of paper.

The visual system examination

This section will detail the examination of the eye and cranial nerves II, III, IV, and VI. A thorough history is necessary to understand the patient's range of visual symptoms. These may include drooping eyelids, blurred vision, double vision, 'seeing things', visual loss (transient or persistent, partial, or complete), abnormal movements of the visualized world, eye pain, headache, or orbital pain. In this section we will provide an examination example that avoids missing the most important eye signs.

The neuro-ophthalmological examination should include:

1. *Visual acuity*

   Optic nerve, chiasmal, optic tract lesions, and ocular pathology can all influence visual acuity. This is assessed with corrected vision or refractive vision, like the patient's own glasses or a pin hole. The standard is the Snellen chart that measures vision at a distance of 6 metres. This is expressed as a fraction (distance in metres from chart/distance in metres at which letters should be seen). If the acuity is reduced but is correctable with refraction; this is due to an ocular defect. If the acuity is not correctable, then it signifies a problem in the visual pathway. If the patient is unable to see the largest print, the chart can be brought closer or assessed by finger counting, perception of hand movements, or perception of light.

2. *Colour vision*

   This is most useful for assessing the optic nerve function. It is assessed by using Ishihara plates and scored in each eye individually by the number of plates correctly identified. The speed of identifying the plate should also be considered when comparing the eyes. Remember that 8% of males and 0.5% of females may have X-linked recessive congenital colour deficiency or dyschromatopsia. In these patients the loss of colour vision will be bilateral with normal visual acuity and fields. A cruder method of assessing colour vision is to ask the patient to look at a coloured target like a red cap and in the affected eye it may seem faded or 'washed out'.

3. *Visual field testing*

   Visual fields are tested to direct confrontation and each eye is assessed individually. The patient should fixate on the examiner's nose and cover each eye in turn. This test can detect hemianopia, quadrantanopia, altitudinal, and central field defects. With the eye covered ask the patient if all the parts of the examiner's face are clear, or if there are parts that are blurred or missing. Ask the patient to count fingers in each quadrant.

   Peripheral fields are best assessed with a white hat pin, whereas central fields and blind spots should be tested with a red hat pin. The latter is assessed against the examiner's blind spot by moving the pin. Visual field defects are mapped out according to the patient's description. Abnormalities are illustrated as follows (see Fig. 2.5) and can localize the defect in the visual pathway All patients with a suspected visual field

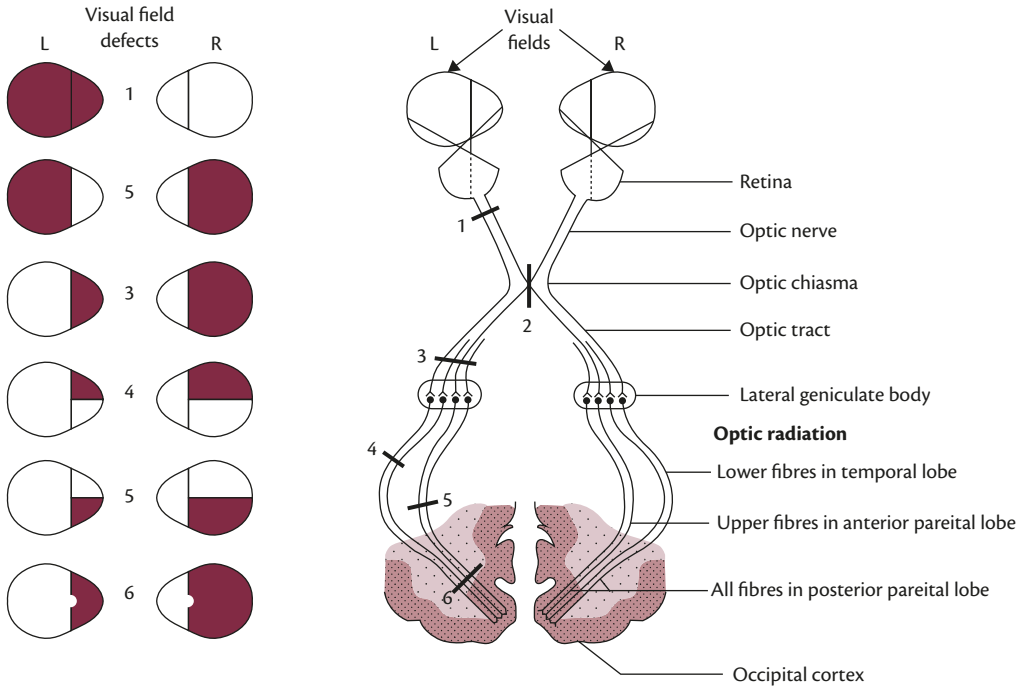

Fig. 2.5 Assessment of visual fields and localization of defects.
From: *Macleod's Clinical Examination*, Ninth edition figure 7.8 page 211, J. Munro and C.R.W. Edwards.

Box 2.6 Parinaud's syndrome

- Impairment of upgaze
- Large irregular pupils that do not react to light but can accommodate (light-near dissociation)
- Eyelid abnormalities—lid retraction or ptosis
- Impaired convergence
- Nystagmus retractorius

defect should have formal perimetry for accurate localization and monitoring. Macular sparing with ischaemic occipital lobe lesions relates to the dual blood supply to the occipital pole from both the middle cerebral artery as well as the posterior cerebral artery.

4. *Pupils*

The pupillary light reaction pathways include the optic nerve (afferent) and the parasympathetic component of the third cranial nerve (efferent). Accommodation arises from the frontal lobes (afferent) and the parasympathetic component of cranial nerve III (efferent).

Inspect first for anisocoria, and then ask the patient to fixate on a distant target and then test the direct and indirect light reflexes, the pupillary reactions to accommodation and finally perform the swinging light test.

4.1 *Size*

The examination of the pupils should first be conducted in room light, if the anisocoria is greater in light than in dark, the parasympathetic system is abnormal, and the larger pupil is abnormal. A cranial nerve III paresis, Adie's pupil, or damaged iris sphincter are examples of the parasympathetic pathway. Then examine for anisocoria in dim light, if this is greater in dim light, a sympathetic dysfunction is present and the smaller pupil is abnormal. Horner's syndrome is a manifestation of a sympathetic disorder. If the anisocoria is the same under both conditions, it is not indicative of a neurological problem.

Conditions that impair light response but do not affect accommodation (light-near dissociation) include Parinaud's syndrome (Box 2.6), neuro-syphilis, diabetes mellitus, Adie's pupil, bilateral optic neuropathy, and aberrant regeneration of cranial nerve III.

4.2 *Light response (direct and indirect)*

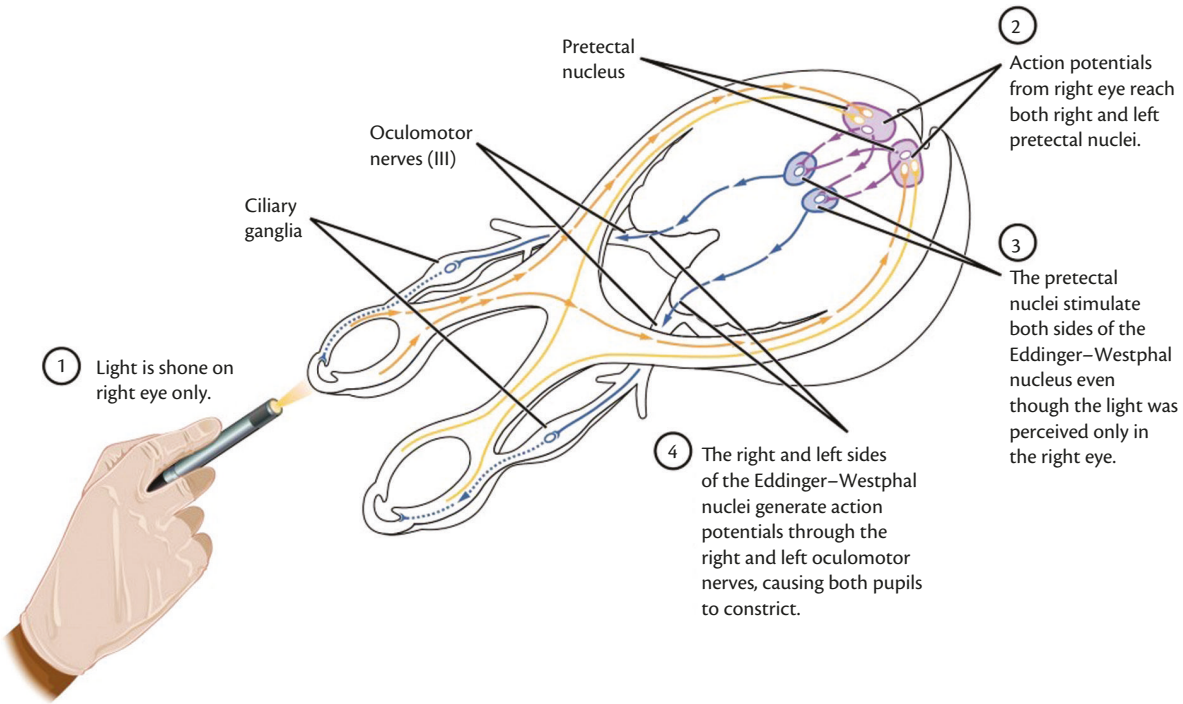
Shine a bright light in each eye, and observe the pupils for speed and magnitude of constriction (see Fig. 2.6). If the pupil does not react normally to light, examine the response by viewing a near target. Again, check for speed and magnitude of constriction to a near target and the speed of dilatation when looking at a distant target.

4.3 *Swinging light test*

To perform this test the lights should be dimmed while the patient should fixate on a target in the distance. Swing the light from eye to eye for about a second at a time. Look for the initial movement in each pupil (normally constriction). To diagnose a relative afferent pupil defect (RAPD), one pupil should consistently dilate rather than constrict. The presence of a RAPD is indicative of optic neuropathy (Table 2.3).

5. *Ophthalmoscopy*

For the purposes of this chapter we advise that ophthalmoscopy should be performed on all patients to examine for papilloedema that can suggest raised intracranial pressure and optic pallor suggestive of optic atrophy. Systematically examine the optic disc, the bloods vessels, and then the retinal background.



Pretectal nucleus
2
Action potentials from right eye reach both right and left pretectal nuclei.
Oculomotor nerves (III)
Ciliary ganglia
3
The pretectal nuclei stimulate both sides of the Eddinger–Westphal nucleus even though the light was perceived only in the right eye.
1
Light is shone on right eye only.
4
The right and left sides of the Eddinger–Westphal nuclei generate action potentials through the right and left oculomotor nerves, causing both pupils to constrict.

Fig. 2.6 The light reflex.

Table 2.4 summarizes some findings that can aid in the localization of lesions that present with visual symptoms using the techniques described so far.

6. *Eye movements*

6.1 *Fixation, nystagmus, and saccades*

Disorders of fixation include nystagmus and saccadic intrusions. The examination will stem from a history of involuntary eye movements or oscillopsia. Congenital fixation disorders are usually asymptomatic and incidentally noticed.

Nystagmus is the rhythmic oscillation of the eyes. Start the examination with eyes in the primary position, then different positions of gaze. Note the fast phase of the nystagmus and the direction or if it is pendular. Also note if the nystagmus is similar in both eyes and if there is a latent component or increased nystagmus with one eye covered. Different types of nystagmus can aid in localization of pathology as summarized in Table 2.5.

Assessing how rapidly and accurately patients can fixate on an eccentric target by testing saccades can expose a subtle internuclear ophthalmoplegia or sixth cranial nerve palsy. It is tested by asking the patient to look at two different objects on either side of the patient's head. The patient is asked to alternate gaze between the objects. Note saccadic initiation, velocity, and accuracy. This can be either too small (hypometric) or too large (hypermetric).

6.2 *Eye movements and cranial nerves III, IV, and VI*

Eye movements include saccades controlled by the frontal lobe, pursuit (the slow movement that facilitate fixation on a moving object) that is controlled by the occipital lobe, the vestibulo-ocular reflex (that allows compensation of eye position for movement of the body or head) controlled by the cerebellar vestibular nuclei and convergence (fixating on an object close to the face) that is controlled by the midbrain. Input from the different control centres have to be integrated to allow synchronous eye movement. The medial longitudinal fasciculus (MLF) in the midbrain runs between the nuclei of cranial nerves III and IV in the midbrain and VI in the pons. The eye muscles are the lateral rectus controlled by cranial nerve VI, the superior oblique controlled by cranial nerve IV, and all the rest are controlled by cranial nerve III.

6.2.1 *Cranial nerve III palsy (oculomotor nerve)*

A complete palsy is a triad of ptosis, a large and unreactive pupil, and the eye position of 'down and out' (Fig. 2.7). Pupil sparing implies that the deeper nerve fibres have been affected most likely from ischaemia. The parasympathetic fibres lie circumferentially on the outside of the nerve and are more commonly affected by compressive causes, classically a posterior communicating artery aneurysm.

Internuclear ophthalmoplegia is the result of a lesion of the MLF. The patient has dysconjugate eye movements; there is incomplete adduction of one eye and jerky nystagmus of the other eye on abduction when testing lateral gaze. It is described as left-sided when there is failure of left adduction when looking to the right (Fig. 2.8). The horizontal conjugate gaze centre resides in the paramedian pontine reticular formation at the level of the fifth cranial nerve nucleus. On an attempt to move the eyes in a horizontal direction, the abducting eye is able to move (VI) but the signal to the third nerve is unable to pass through the MLF to the third nerve is nucleus and there is a failure of adduction. The resulting diplopia may underlie the nystagmus in the abducting eye as there is an attempt to overcome this. The vertical gaze centre resides in the rostral interstitial nucleus of the MLF (riMLF) at the level of the third nerve/superior colliculus.

Table 2.4 Localization of lesions in the visual system (see Beck and Smith, 1988)

	Optic nerve	Optic chiasm	Optic tract	Temporal lobe	Parietal lobe	Occipital lobe
Visual acuity	Normal or reduced	Normal or reduced	Normal or reduced	Normal	Normal	Normal
Colour vision	Normal or reduced	Normal or reduced	Normal or reduced	Normal	Normal	Normal
Visual field	Central scotoma	Bitemporal	Homonymous incongruous	Homonymous superior	Homonymous inferior or complete	Homonymous exquisitely congruous
Relative afferent pupil defect	Present	Present or absent	Present or absent	Absent	Absent	Absent
Disc pallor	Present or absent	Present or absent	Present or absent	Absent	Absent	Absent

6.2.2 *Cranial nerve IV palsy (Trochlear nerve)*

This presents with diplopia on looking down and head tilt away from the side of the palsy with no clear squint (Fig. 2.9). The pupil of the affected eye may lie slightly higher than the normal eye, but this is not obvious.

On suspecting a fourth nerve palsy, it is useful to ask the patient to look at a horizontal object (e.g. the top of the door frame alternately with each eye). A trochlear palsy will produce two images angled towards the abnormal side (Fig. 2.10).

6.2.3 *Cranial nerve VI palsy (Abducens nerve)*

This presents with diplopia with two images with horizontal separation (Fig. 2.11). There is a squint, diplopia away from the weak muscle. The pupil is normal.

7. *Lid position*

Inspect for the eyelid position, contour, and measure the palpebral fissures keeping the eyes in the primary position. The upper lid usually covers 1 mm of the cornea, more than that indicates ptosis. Also examine for variable ptosis in different directions of gaze as seen in congenital ptosis and Duane's syndrome. Fatigable ptosis (>2 mm after 2 minutes) on up gaze is suggestive of neuromuscular weakness such as myasthenia gravis.

8. *Orbits*

Finally, during inspection of the orbits one should look for proptosis, enophthalmos, or ocular injection. One should stand behind the patient to assess proptosis looking down over the forehead. A Hertel exophthalmometer provides a more accurate measurement. It may be useful to auscultate over the closed eyelid for a bruit that could signify a carotid-cavernous fistula.

Examination of the cranial nerves

This section will include the examination of the cranial nerves not discussed in the section on eye examination.

1. Cranial nerve I (olfaction). Ask if the patient has noticed any change in smell. Examine with two different smells (e.g. coffee or orange). Olfactory test kits are available.
2. Cranial nerve II (typically acuity, fields, and pupillary function). A complete examination would also include fundoscopy, assessment of blind spot, and colour vision.
3. Cranial nerves III, IV, and VI (eye movements).
4. Cranial nerve V (sensation to the face and muscles of mastication). The trigeminal nerve has both motor and sensory components: the maxillary division is the nerve of the first branchial arch derivatives. The motor examination is performed by palpating the muscles of mastication when the patient clenches the jaw and look for jaw movement when asked to open the mouth against resistance. Also tap the jaw jerk. The sensory examination is performed by testing all three divisions of the trigeminal nerve (ophthalmic, maxillary, and mandibular divisions) with light touch. Lastly, perform the corneal reflex (afferent limb Va, efferent limb VII) by gently touching the cornea with a small piece of cotton wool. The approach to the cornea should be lateral to the field of vision. An alternative method is to gently blow in the eye and assess response. Also note the normal conjunctival reaction of lacrimation and injection.
5. Cranial nerve VII (facial expression and taste to anterior two-thirds of the tongue). The facial nerve innervates the muscles of facial expression, stylohyoid, stapedius, and the posterior belly of the digastric muscle, and is the nerve of the second branchial arch (Fig. 2.12). When facial weakness occurs it is important to decide if the weakness is upper (UMN) or lower motor neuron

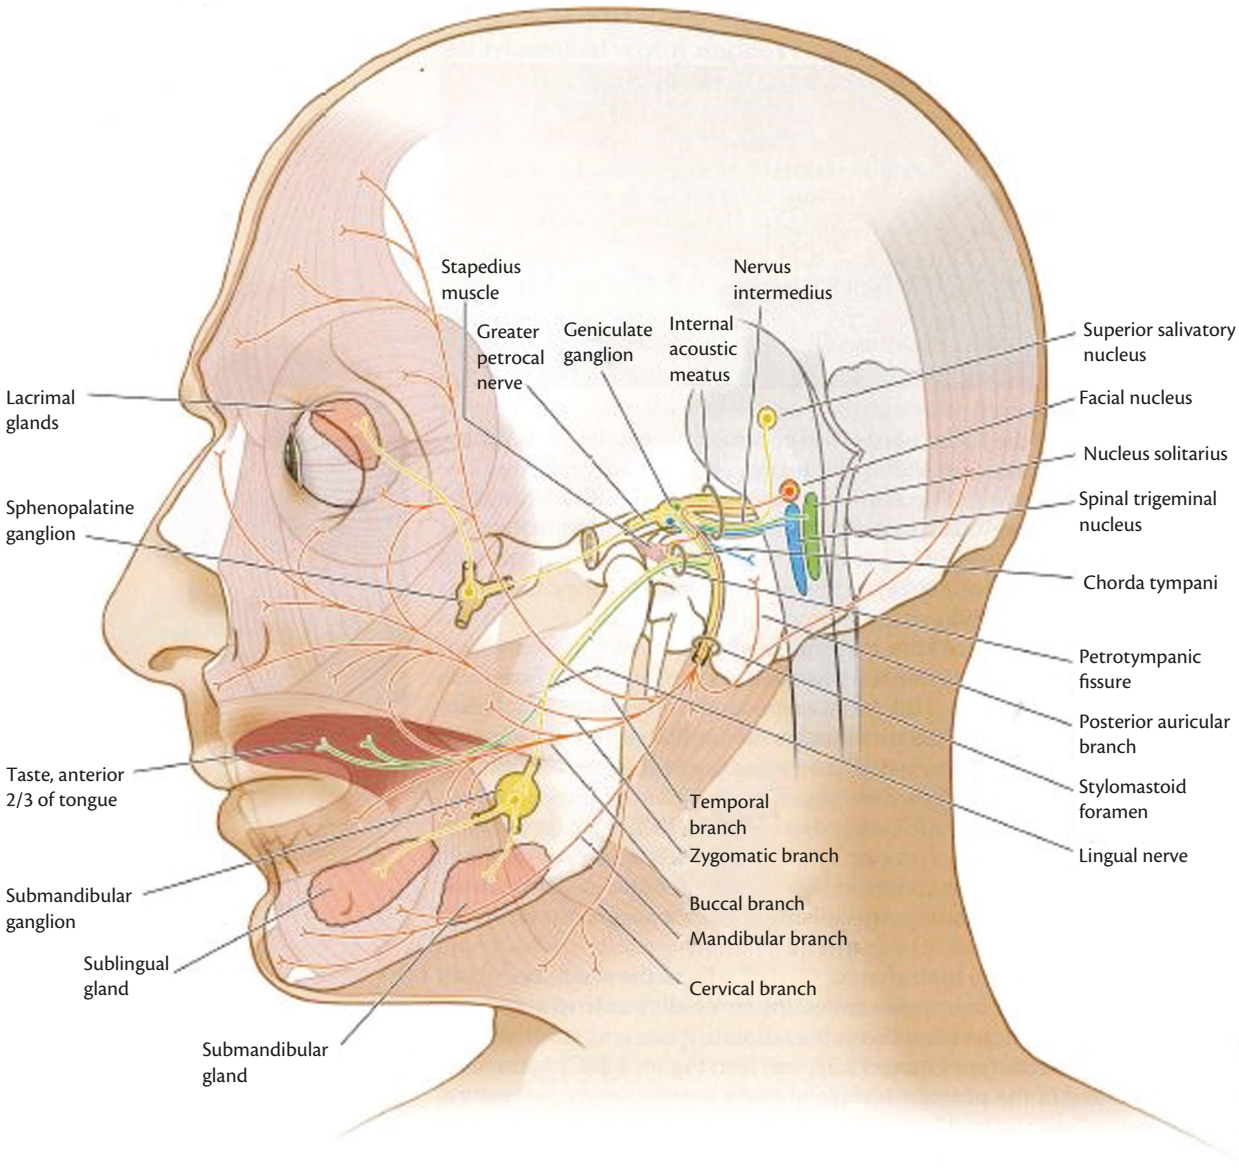

Fig. 2.12 Facial nerve—motor, parasympathetic, and special sense innervation.
Blumenfeld, Hal. (2002) *Neuroanatomy through Clinical Cases*. Sunderland, Massachusetts: Sinauer. Fig 12.10, chapter 12 p. 480.

(LMN). The different clinical features are explained by the bilateral innervation from the nuclei of the facial nerve supplying the superior facial muscles. Firstly, look for asymmetry in facial movement, which can be very subtle: just a hint of incomplete eye closure, slow blinking, or delay in a grin. Then ask the patient to raise the eyebrows (frontalis, temporal branch), close the eyes tightly (orbicularis oculi, zygomatic branch), blow out the cheeks (buccinators) or whistle (orbicularis oris, both buccal branch), show your teeth (zygomaticus major, buccal or marginal mandibular branch), wrinkle the chin (mentalis, marginal mandibular branch), and wrinkle the neck (platysma, cervical branch). The severity of facial palsy is classified using the House–Brackmann scale (see Chapter 24 on the surgical management of cerebellopontine angle lesions).

In UMN weakness the forehead is seen to be stronger than the lower face, also called sparing of the forehead. Unilateral weakness can be due to vascular lesions, demyelination, tumours, or brain stem lesions. Bilateral weakness can be due to pseudobulbar palsy or motor neuron disease.

In LMN weakness, the lower face is seen to be as weak as the forehead. Bell's palsy is a common cause of this and is usually worst within 12 hours from the onset and can be associated with pain around the mastoid, loss of taste, and hyperacusis. Other causes of LMN facial weakness are pontine lesions, cerebellopontine angle lesions, and parotid tumours. Causes of bilateral LMN facial weakness are disorders of the neuromuscular junction like myasthenia gravis, motor neuron disease, myopathies, neurosarcoidosis, or Guillain–Barré syndrome.

6. Cranial nerve VIII (auditory and vestibular nerves). The auditory examination is conducted by testing each ear individually. Cover the ear on the opposite side of the ear being tested. Test the hearing by rubbing your fingers together or whispering. If there is reduced hearing, perform Rinne's and Weber's tests. For these tests you will need a 512 Hz tuning fork. Rinne's test compares bone versus air conduction. The tuning fork is struck and the base is placed on the mastoid process (bone conduction). When the tone disappears, the tuning fork prongs are placed over the external auditory meatus (air conduction). The normal response is for the tone to reappear when the tuning fork is moved in front of the external auditory meatus (i.e. air conduction is better than bone conduction, AC>BC). This reflects the amplification provided by the tympanum and middle ear ossicles. Weber's test involves striking the tuning fork and placing the base over the midline over the forehead. The tone should be heard equally in both ears. If it localizes to one side this can reflect a sensorineural hearing deficit on the contralateral side, or a conductive hearing loss on the ipsilateral side with an increased sensitivity in that ear. These tests can be difficult to interpret and the formal investigation is pure tone audiometry, and with sensorineural hearing loss imaging of the internal auditory canal.

   To examine vestibular function, examine the gait and look for nystagmus. Other tests of value are the Hallpike's test used in patients with positional vertigo. This is performed with the patient sitting up, then turning the head to one side, lie the patient back quickly with their head extended, the examiner should support the patient's head. Observe for nystagmus, associated delay, and also if it fatigues. Ask if the patient experiences vertigo. Repeat this on both sides. If the nystagmus is fatigable and delayed, this is in keeping with peripheral vestibular disturbance such as benign paroxysmal positional vertigo. If not fatigable, this is caused by a central abnormality. Unterberger's test is performed by asking the patient to stand facing the examiner with their arms stretched out in front of him. Ask the patient to close their eyes and march on the spot. Watch for any rotation. Patients turn to the side of vestibular pathology. Only perform this if the patient is able to stand safely. Romberg's test is to assess proprioceptive loss, not specifically balance or vestibular function.

7. Cranial nerve IX and X (palatal movement, swallow, and gag reflex). The glossopharyngeal and vagus nerves are examined together. Firstly, listen to the voice quality for evidence of bulbar weakness, then ask the patient to cough. Inspect the position of the uvula and then ask the patient to say 'Aah'. If there is weakness, the uvula will deviate away from the side of the lesion. The gag reflex is rarely performed and should not be performed if there is any doubt about their safety to swallow as there is potential for aspiration. Video fluoroscopy is safer in such patients.
8. Cranial nerve XI (power to sternocleidomastoid and trapezius). The accessory nerve is examined by testing the power of the trapezius muscles by asking the patient to shrug their shoulders, noting any asymmetry in the initial movement and on inspection. Winging of the scapula may be seen with weakness of trapezius (although serratus anterior palsy from damage to the long thoracic nerve is more common). Test the power and bulk of the sternocleidomastoid muscles by asking the patient to rotate the head to the opposite side against resistance.
9. Cranial nerve XII (tongue power and movements). Examination of the hypoglossal nerve should start with inspection of the tongue lying in the floor of the mouth. Note any wasting or fasciculations. When the patient is asked to protrude the tongue, it will deviate towards the weak side or the side of the unilateral lesion. The speed and fluidity of the movement will be affected in bilateral pyramidal lesions. Power is assessed by asking the patient to press against resistance from the examiner's finger on the outside of the cheek by pressing the tongue firmly on the inside of the same cheek.

Examination of autonomic function and dysfunction

An understanding of how the autonomic system is organized is required to interpret clinical signs that may be encountered during head and neck examination.

Sympathetic fibres arise from the preganglionic cell bodies of the lateral horns of T1–4, form the sympathetic chain and distribute postganglionic fibres via the inferior (to vertebral artery, C7–8), middle (to inferior thyroid artery and C5–6), and superior cervical ganglia (to carotid artery and C1–4). This chain lies posteromedial to the carotid sheath and anterior to the longus muscles. The postganglionic fibres then ride along the external carotid to supply the ciliary ganglion and hence the dilator of the pupil, and the external carotid to supply the submandibular ganglion (submandibular and sublingual glands) and the otic ganglion (parotid gland). A lesion to first, second, or third-order sympathetics will result in Horner's syndrome where there is pupil constriction, partial ptosis, and loss of hemifacial sweating (**Fig. 2.13** and **Box 2.7**). The remainder of the sympathetic

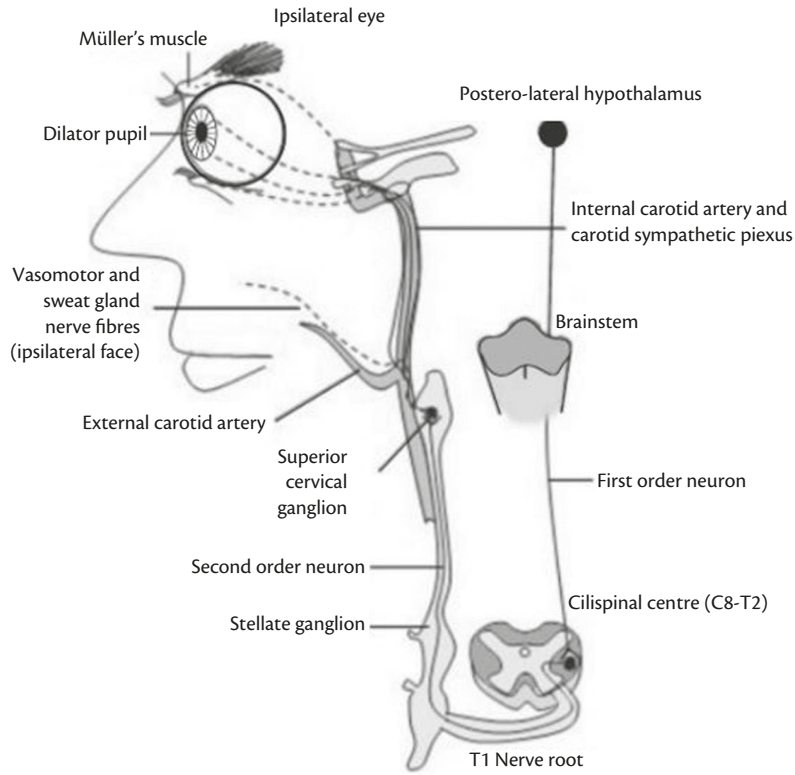

Fig. 2.13 The sympathetic supply of the pupil and causes of Horner's syndrome (Kong, 2007).

Reproduced with permission from Kong, YX, Wright, G, Pesudovs, K, O'Day J, Wainer Z, Weisinger H, Horner syndrome, *Clinical and Experimental Optometry*, volume 90 issue 5, pp. 336–44. Copyright ©2007 Optometrists Association of Australia and John Wiley & Sons.

supply to the head and neck travels with the internal carotid artery: the deep cervical nerve forms over the petrous segment of the carotid, continues into the middle fossa through the foramen lacerum, and joins the parasympathetic greater superficial petrosal nerve (GSPN) to form the Vidian nerve. The Vidian nerve passes through its own canal to supply autonomic fibres to the pterygopalatine ganglion and distribute parasympathetics with branches of the maxillary division of the trigeminal nerve.

Parasympathetic fibres are carried by four cranial nerves: III, VII, IX, and X. There are four equivalent brainstem parasympathetic nuclei: Edinger Westphal nucleus (III); superior salivatory nucleus (VII); inferior salivatory nucleus (IX); and the dorsal vagal nucleus (X). The vagus provides no cranial parasympathetic supply but provides supply to all the viscera of the thorax and abdomen as far as the midgut (two-thirds of the transverse colon). The preganglionic parasympathetic fibres of the remaining three cranial nerves synapse in four ganglia: ciliary ganglion (III via nerve to inferior oblique); pterygopalatine ganglion (VII via the GSPN); submandibular ganglion (VII via the chorda tympani); and otic ganglion (IX via lesser superficial petrosal nerve). Thus, the facial nerve has two parasympathetic branches that originate at the brainstem level within the nervus intermedius (Fig. 2.12). Crocodile tears syndrome is an uncommon consequence of damage to the facial nerve where there is misdirection of regenerating gustatory fibres to the lacrimal gland resulting in tearing when presented with food.

The postganglionic parasympathetic fibres are then delivered to the target glands by a branch of the trigeminal nerve. Fibres from the ciliary ganglion pass along the short ciliary nerves (branch of nasociliary nerve, Va) to control pupillary constriction and accommodation. Fibres from the pterygopalatine ganglion pass to the lacrimal gland via the zygomaticotemporal (Vb) and lacrimal (Va) nerves. The remainder of the fibres from the pterygopalatine ganglion supply the nose, palate, and nasopharynx sinuses via branches of the maxillary division of the trigeminal nerve. The fibres from the submandibular ganglion supply submandibular and sublingual glands via the lingual nerve (Vc).

Finally, the fibres from the otic ganglion supply the parotid gland via the auriculotemporal nerve (Vc).

Examination of the peripheral nervous system: Upper and lower limbs

The neurological examination of the extremities is based on inspection, assessment of tone, power, reflexes, coordination, and sensation. Having been directed by the history further localization will rely on key examination findings (e.g. confirmation of long tract signs in the patient with suspected myelopathy, correlating deficits in corresponding myotomes and dermatomes in radiculopathy, testing spinothalamic versus dorsal column function in possible syringomyelia, differentiating signs of peripheral neuropathy versus radiculopathy in brachialgia or sciatica, and so on). Understanding the differences between upper and lower motor neurone signs is of course crucial. With this in mind there should be a logical process of elimination, the order of which is open to personal choice and circumstances.

Box 2.7 Differential diagnoses for Horner syndrome

First-order neuron lesions

Arnold–Chairi malformation
Basal meningitis (e.g. syphilis)
Basal skull tumours
Cerebrovascular accident/lateral medullary syndrome
Demyelinating disease (e.g. multiple sclerosis)
Intrapontine haemorrhage
Neck trauma
Pituitary tumour
Syringomyelia

Second-order neuron lesions

Pancoast tumour
Birth trauma with injury to lower brachial plexus
Cervical rib
Aneurysm/dissection of aorta, subclavian, or common carotid artery
Central venous catheterization
Trauma/surgical injury (radical neck dissection, thyroidectomy, carotid angiography, coronary artery bypass graft, upper spine chiropractic manipulation)
Chest tube insertion
Lymphadenopathy (e.g. Hodgkin's disease, leukaemia, tuberculosis, mediastinal tumours)
Mandibular tooth abscess
Lesions of the middle ear (e.g. acute otitis media)
Neuroblastoma
Lumbar epidural anaesthesia

Third-order neuron lesions

Internal carotid artery dissection
Cluster/migraine headaches
Carotid artery thrombosis
Carotid-cavernous fistula
Herpes zoster
Orbital apex tumour
Idiopathic

Box 2.8 Gait abnormalities

- Hemiplegic—spastic leg traces a semicircle due to fixed plantarflexion and extension at the knee
- Diplegic—narrow-based, scissoring gait often due to cerebral palsy
- Myelopathic—broad-based clumsy gait
- Equine—high stepping gait seen in patients with foot drop due to L5 radiculopathy or common peroneal palsy
- Myopathic—waddling gait with pelvis dropping on alternating sides
- Parkinsonian—slow little steps *marche à petits pas*
- Cerebellar—veering uncontrolled gait
- Magnetic—feet seem to be stuck to the floor, seen in normal pressure hydrocephalus

Inspection

There should be an initial general inspection noting features such as abnormal posturing, or preferential use of one limb over another. Stigmata of related systemic disease such as rheumatoid arthritis may be apparent. Assessment of gait may be done at this point. Characteristic pathological gaits point to particular neuroanatomical disorders (Box 2.8). Heel-toe (tandem) walking and Romberg's test are useful adjuncts. Classically, Romberg's test is positive only with disorders of proprioception. Notably, this is not a test of cerebellar function as ataxia would be present with or without closing the eyes with cerebellar disorders. Inspection should continue with examination for atrophy of muscle groups, fasciculations, tremors, and scars such as previous carpal tunnel decompression.

Tone and reflexes

The resistance of muscle groups across a joint is a result of a complex system involving feedback from muscle spindles and Golgi tendon organs, monosynaptic reflexes with agonist and antagonist alpha motor fibres, inhibitory supraspinal control, and processing via the cerebellum. Tone can be decreased (hypotonia) or increased (spasticity or rigidity). Spasticity is a velocity dependent increase in muscle tone in response to a passive stretch, with exaggerated tendon jerks, in association with other features of the upper motor neurone syndrome (Lance, 1980). At the end of range of movement there is often a characteristic 'give' (clasp knife). Rigidity is not velocity or force dependent and lacks any 'give'. Spasticity is more often associated with corticospinal damage whereas rigidity is generally extrapyramidal in origin. Assessment may be by gentle internal and external rolling of the leg, brisk raising of the knee, or pronation/supination at the wrist.

The deep tendon reflexes are tests of a monosynaptic arc. The afferent neurone is stimulated by activity of a Golgi tendon organ; the efferent neurone is an alpha motor neurone. The most frequently tested reflexes are the biceps (C5), supinator (C6), triceps (C7), knee (L3/4), and ankle (S1) jerks. The patient should be in a relaxed posture. A tendon hammer should be used to briskly strike the tendon. If absent, reinforcement can be used by asking the patient to clench the teeth or by interlocking the fingers against resistance.

Specific tests of upper neurone dysfunction include Hoffmann's sign, the plantar response, and clonus. A positive Hoffmann's sign is when quickly flicking the distal phalanx of the middle finger downwards causes flexion of the thumb. Clonus should be tested with the knee flexed, and anything more than five beats of the ankle is pathological.

Power

Muscle groups may be tested in several ways. One can ask the patient to maximally contract the muscle and then attempt to counteract it (isometric). Alternatively, one can attempt to counteract the muscle group through a range of motion (isotonic). The Medical Research Council (MRC) scale provides a reproducible grading system (see Table 2.6). The emphasis placed on examining different muscle groups will depend if one is looking for pyramidal weakness, long tract disease, radiculopathy, or a peripheral nerve problem. When

Table 2.6 MRC grading of power

Grade 5	Normal power
Grade 4	Submaximal movement against resistance
Grade 3	Movement against gravity but not against resistance
Grade 2	Movement with gravity eliminated
Grade 1	Flicker of movement
Grade 0	No movement

testing the nerve roots or level of cord dysfunction, the American Spinal Injuries Association workbook (ASIA, 2015) provides an excellent, logical schema (Fig. 2.14). For each level, a particular action is specified to test individual nerve roots.

Sensation

As for the motor examination, sensation should be tested either in a radicular manner or according to peripheral nerve distribution (Fig. 2.15). In addition to peripheral localization, there are different modalities to be considered. Importantly, one should remember that discriminative light touch, proprioception, vibration, and two-point discrimination are conducted through large fast-conducting fibres in the dorsal columns. Pinprick (superficial pain), and temperature are conducted through smaller, slower fibres in the spinothalamic tracts. Again, the ASIA chart is an invaluable guide as to the optimal points for testing sensation. An exact point on the skin is indicated where light touch and pin prick should be tested. It is vital to compare one side against the other as one proceeds. Areas of hypoaesthesia or hyperaesthesia should be carefully mapped out. Asking the patient to close their eyes may provide additional objectivity.

On testing joint position sense, it is important to remember that the patient may be able to tell the direction of motion by how pressure is exerted on a digit. One should, therefore, ensure that the thumb or the great toe are held side to side rather than above and below. Should proprioception be lost, one should test the next proximal joint.

Examination techniques for some common peripheral neuropathies are detailed in Boxes 2.9, 2.10 and Table 2.7.

Putting it all together

As one progresses with the history and examination the information should constantly be distilled, therefore refining the line of questioning and narrowing the focus of examination. Eventually, one has to draw these disparate pieces of information together, make sense of them, and attempt to identify the most likely anatomical source of the patient's complaint and potential pathological processes that may have caused it. Once this point has been reached, it is necessary to decide on whether further investigations are required and what they might consist of.

In the course of this decision-making process, one needs to be rigorous in ensuring strictest objectivity.

> Doctors … are more interested in patients they can help, and diseases they can cure, than the ones they can't. There is, therefore, a tendency for them to make the diagnosis fit their skills or even . . . to have a vested interest in inventing illnesses which they can cure. (Handy, 1990)

Fig. 2.15 Cutaneous distribution of peripheral nerves (Harrison and Kasper, 2015).

Box 2.9 Examining for carpal tunnel syndrome

- Atrophy of thenar eminence
- Test opposition of thumb by making an O sign
- Test abduction of thumb, lay back of hand down and point thumb upwards
- Splitting of sensation of the ring finger—more sensation on ulnar side
- No loss of sensation in central palm as the palmar cutaneous branch runs above flexor retinaculum
- Phalen's sign (good predictive value)
- Tinel's sign (poor predictive value)
- Absence of benediction sign (attempts to make fist, but thumb and index finger remain extended)—this is due to more proximal compression of median nerve

Box 2.10 Examining for ulnar neuropathy at the elbow

- Wasting of first dorsal interosseous muscle and hypothenar eminence
- Wartenberg's sign—little finger remains abducted, has a tendency to catch on pockets
- Test finger abduction
- Ulnar paradox—ulnar claw hand seen with ulnar nerve damage at the wrist, not present with more proximal lesion at the elbow
- Froment's test—test of adductor pollicis, the only muscle supplied by the ulnar nerve in the thenar eminence. With hands supine ask patient to hold onto piece of paper. Flexion of the thumb on withdrawing the paper indicates positive test
- Tender and enlarged ulnar nerve in the ulnar groove, positive Tinel's test
- Splitting of sensation of the ring finger—more sensation on radial side
- Remember to rule out C8 radiculopathy, Pancoast's tumour, and thoracic outlet syndromes (look for Horner's syndrome to help differentiate)

Table 2.7 Clinical features differentiating L5 radiculopathy and common peroneal palsy[a,b]

	L5 radiculopathy	Common peroneal palsy
Pattern of weakness	Foot inversion (tibialis posterior, the foot invertor, supplied by L4 and L5 via tibial nerve, *not* the peroneal nerve) Hip abduction (gluteus medius and minimus supplied by L4/L5/S1 via superior gluteal nerve)	Foot eversion
Nerve root tension signs	On hip flexion	On ankle inversion
Tinel's test at fibular neck	Negative	Positive

[a] Always remember central causes for foot drop, especially a parafalcine meningioma pressing on the motor cortex.

[b] For peripheral causes the frequencies are as follows: peroneal neuropathy (46%); lumbar radiculopathy (15%); sciatic nerve disorder (5%) (Jeon, 2013).

In considering a patient for an operation there is always a balance to be struck. What are the risks of surgery versus the risk of doing nothing? A clear understanding of natural history is required just as much as the potential complications of a particular operation.

The history and examination provide the foundation stones of patient management. What one does with this information must be guided by our knowledge of neurosurgical conditions. This is described in subsequent chapters.

Overview of neuroimaging

Tomasz Matys, Daniel. J. Scoffings, and Tilak Das

Introduction

The development of computed tomography (CT) (Hounsfield, 1995) and magnetic resonance imaging (MRI) (Mansfield and Maudsley, 1977; Lauterbur, 1989) in the last 40 years has revolutionized neuroimaging, overcoming the limitations of previously used methods that relied on the demonstration of displacement of intracranial vessels or ventricles, and instead allowing the direct visualization of intracranial pathology (Hoeffner et al., 2012). The first clinical CT examination was performed on a patient with a brain tumour and it could be argued that no other field of medicine has benefited more from the further development of cross-sectional imaging techniques than neuroscience. Refinement of MRI and nuclear medicine methods, with the introduction of positron emission tomography (PET) in particular, has allowed for imaging of selected aspects of central nervous system function, such as blood flow, tissue microenvironment, and metabolism. Future progress will no doubt include continuing improvement in the spatial and soft tissue resolution of anatomical imaging and extending the application of functional methods, but also hopefully clinical translation of the full scope of molecular imaging, allowing visualization of specific cellular and molecular events underlying the disease process in addition to its pathological and functional sequelae (Hoffman and Gambhir, 2007; Massoud and Gambhir, 2007).

In this chapter we discuss current neuroradiology imaging modalities that are useful in neurosurgical practice. Due to space constraints, information regarding the underlying physical principles is limited to the basics, while more comprehensive descriptions can be found elsewhere (Allisy-Roberts and Williams, 2007). We focus here on the general usefulness and limitations of neuroradiological methods rather than the imaging manifestations of individual disease processes, which are discussed elsewhere in the relevant chapters of this book. The interested reader can find further information in dedicated neuroradiology monographs (see Nadgir and Yousem, 2016).

Principles of imaging

Radiographs and fluoroscopy

Radiographs ('plain X-rays') are produced by passing a collimated beam of X-rays through a patient onto an image receptor, traditionally a cassette containing combination of a fluoroscopic screen and radiographic film, but in modern practice a digital detector is typically used. The tissues in the patient's body attenuate the X-ray beam to differing degrees so that the intensity of the X-rays reaching the detector varies across its surface. In this way radiographs can distinguish between air (black), fat (dark grey), soft tissue and water (light grey), and bone (white). The radiographic image is also a two-dimensional representation of a three-dimensional structure and it is typically necessary to obtain images in different (often orthogonal) projections to infer the position of a given abnormality within the patient.

With the increasing availability of CT and MRI, the role of conventional radiographs in the assessment of patients with neurosurgical disease has reduced, but they retain a role in certain circumstances. The advantages of radiographs include their ease of acquisition, low cost, widespread availability, the ability to obtain images at the bedside, and also to obtain a degree of dynamic information by acquiring radiographs with the patient in different positions (e.g. standing, in flexion, and extension of the spine). Although they have high spatial resolution, a major disadvantage of radiographs is their limited soft tissue resolution. Indications for radiographs include assessment of the continuity of the extracranial components of ventricular shunts, the position and integrity of spinal implants and prostheses, and the follow-up of patients with spinal fractures in whom loss of normal alignment or progression of vertebral body compression is suspected. Radiographs are less sensitive than CT in the detection of spinal fractures and have a very limited role in the primary assessment of suspected spinal injury. Flexion-extension radiographs are often used in evaluation of potential instability in patients with degenerative or spondylolytic spondylolisthesis.

Fluoroscopy provides real-time images of the area of anatomical interest by passing a continuous or pulsed X-ray beam through the patient onto an image-intensifier, most commonly using a C-arm apparatus which can be rotated and positioned around the patient to provide the desired view. Uses of fluoroscopy include the identification of the correct level for spine surgery, monitoring the placement of spinal fixation devices or prostheses, and the performance of lumbar puncture in patients in whom bedside lumbar puncture (LP) has been unsuccessful due to obesity or degenerative changes.

Computed tomography

CT basics and techniques

Introduced into clinical practice in 1973, CT was the first diagnostic imaging modality to enable direct visualization of the brain (Wolpert, 2000). Similar to plain film radiography, CT is based on a differential attenuation of X-rays by tissues, but uses a differently collimated beam sweeping around the patient in a circular fashion and reaching a large number of individual detectors; the image is then created using mathematical reconstruction algorithms. In brief, when an X-ray photon travels along a particular line through the patient's body, it experiences energy loss that depends on attenuation coefficients of tissues it encounters on its path. By measuring photon energy from multiple directions around the object, it is possible to calculate the attenuation coefficients for each voxel (volume element) within the examined volume. Attenuation coefficient values are then converted into more convenient-to-use radiodensity values ('CT numbers') calculated in relation to water and air, and expressed in Hounsfield units (HU). The scale of CT numbers ranges from –1000 HU (air) to over 3000 HU (cortical bone), with 0 HU being the attenuation of distilled water. Typical values for different central nervous system (CNS) tissues are given in **Table 3.1**.

The way in which the multidirectional information is obtained and the speed of acquisition have dramatically changed with technological advances, from a pencil-like X-ray beam translating along a slice in the original machine to a fan-shaped beam and increasing number of detectors along the circumference of the gantry and across multiple rows (Ginat and Gupta, 2014). An important development in CT scanning technology was the advent of helical or spiral CT, where the data is obtained in continuous fashion while the patient moves smoothly through the gantry and the X-ray tube rotates, continuously tracing a spiral trajectory around the body. While this mode of acquisition allowed significant improvements in body CT scanning, it introduces unwanted 'windmill artefacts' (Barrett and Keat, 2004), and sequential CT may still be preferable for head imaging. In neuroradiological applications, helical CT does allow excellent quality CT angiography for the evaluation of neck and intracranial vessels, as well as isotropic resolution volumetric reconstructions that can be visualized in any arbitrary plane.

To convert raw CT data into a useful image, the matrix of radiodensities is displayed as shades of grey. From the range of the Hounsfield scale, possible CT numbers span up to 4000 levels of radiodensity, yet the human observer can theoretically perceive approximately 720 shades of grey in optimal conditions (Kimpe and Tuytschaever, 2007) and this is much lower in practice. It is therefore not possible to map the entire dynamic range of CT numbers to greyscale at the same time, necessitating the use of a 'window' centred at a certain level and of particular width to display a suitable fragment of this range. Values of radiodensities within the window are displayed as shades of grey, while values below and above the window boundaries are displayed as black and white, respectively. Because most tissues of interest in the brain lie in the range of 0 to 100 HU, these are optimally depicted using a window centred at a level of around 40 HU and width of 80 HU (Fig. 3.1A). As the radiodensity of acute haemorrhage lies close to the upper limit of the standard window, haemorrhage appears bright and is readily apparent; it is however difficult to appreciate blood immediately adjacent to bone. Using 'subdural windows' with at a slightly higher level and a larger width (e.g. L/W 70/200) makes acute blood better distinguishable from the adjacent bone (**Fig. 3.1B**). Setting the window level to negative values allows differentiation of fat from air. To interrogate bone detail, the window needs to be set to a higher level and width (e.g. L/W 500/3000, **Fig. 3.2**).

One of the most important parameters that affect image quality is the kind of mathematical reconstruction algorithm, also referred to as a reconstruction kernel or filter. Use of different kernels changes the balance between spatial resolution and image noise. A smooth kernel generates images with lower noise and better low-contrast detectability more suited to brain examinations, at a cost of reduced spatial resolution. A sharp kernel generates images with high spatial

Table 3.1 Attenuation values of the main tissues/materials in neuroimaging

Material	Hounsfield units
Acute blood	56 to 76
Air	–1000
Bone	1000 to 3000
Calcification	140 to 200
Cerebrospinal fluid	0
Fat	–30 to –100
Grey matter	32 to 41
White matter (centrum semiovale)	23 to 34

This table was adapted from *Neuroradiology: The Requisites*, David Yousem, Robert Zimmerman, Robert Grossman, Copyright Elsevier (2010).

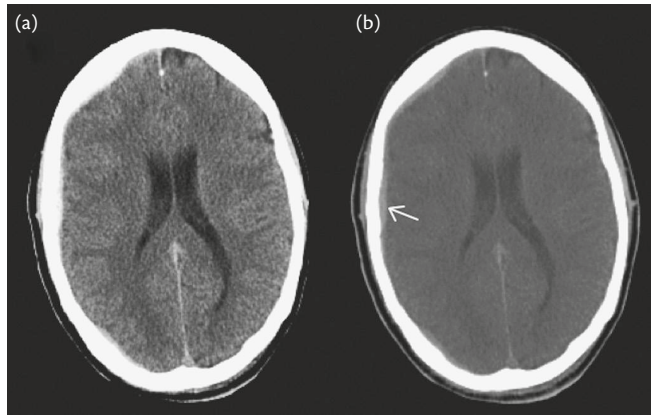

Fig. 3.1 Standard window (A, level/width 40:80) provides good differentiation of the grey and white matter but high-density haemorrhage adjacent to the skull is difficult to appreciate. Widening the window (B, 'subdural window' 70:200) makes the thin right sided subdural haemorrhage (arrow) more conspicuous.

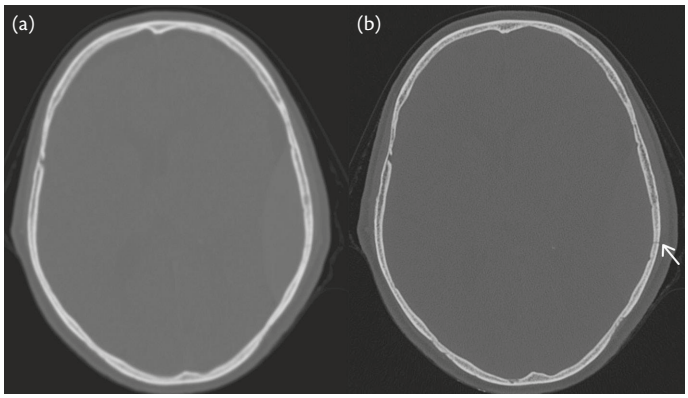

Fig. 3.2 Image of the skull seen on bone window (L/W 500:3000) reconstructed using standard (A) and bone (B) kernel. Hairline fracture of the left squamous temporal bone is much more conspicuous using bone kernel reconstruction (arrow).

resolution better suited to the assessment of bony structures. Use of bone kernel is essential for detection of fractures (Fig. 3.2) and should be a part of any CT performed in the context of trauma, as well as sinonasal and temporal bone examinations.

CT contrast media and risks

Iodinated contrast media have historically been the contrast agent of choice for X-ray and CT applications due to high attenuation of iodine compounds thanks to its high atomic number (Lusic and Grinstaff, 2013). In CT brain imaging, contrast media are used to detect areas of blood-brain barrier breakdown, where contrast medium leaks into parenchyma, or to opacify blood vessels in CT angiography, including venography.

The risks of iodinated contrast media include allergic reactions and contrast-induced acute kidney injury. To minimize this, it is important to identify susceptible individuals (Box 3.1) and take appropriate preventative steps (Iodinated Contrast Media Guideline, Royal Australian and New Zealand College of Radiologists).

The current standard is to use non-ionic, low osmolarity compounds. The incidence of severe reactions with this type of media is 0.04% and for very serious reactions is 0.004% (Hunt et al., 2009). A typical adult dose of intravenous contrast medium for head CT is 50 ml of a compound containing 300 mg/ml iodine. Larger amounts are used in angiographic applications. Contrast medium can also be administered intrathecally through a lumbar, cervical, cisternal, or ventricular approach (Nadgir and Yousem, 2016); this may require lower concentration compound approved for intrathecal use, especially in children.

Box 3.1 Risk factors for contrast-induced acute kidney injury (CI-AKI) and allergic reaction to contrast media

Risk factors for CI-AKI

Known kidney disease (including kidney transplant)
Presence of diabetes
Metformin (risk of lactic acidosis)

Risk factors for allergic reaction to contrast media

Previous allergic reaction to iodinated contrast media
Previous significant allergic reactions to other substances or history of eczema
History of asthma
Use of beta blockers

The Royal Australian and New Zealand College of Radiologists. Iodinated Contrast Media Guideline. Sydney: RANZCR; 2018.

Advantages and disadvantages of CT

CT plays an extremely important role in neuroimaging, particularly in the emergency and neurosurgical settings (Nadgir and Yousem, 2016). It is a rapid, easily accessible, and efficient modality for screening patients with major traumatic injury. It has high sensitivity to haemorrhage, particularly in the first 24 hours compared to MRI, and can demonstrate features of raised intracranial pressure and brain herniation, allowing for rapid decision-making in early stages of traumatic injury. For the detection of subarachnoid haemorrhage (SAH), it remains the initial imaging study of choice in suspected cases and can be rapidly followed by CT angiography when SAH is identified. Similarly, it remains a useful technique for assessment of cerebral infarction and, in conjunction with CT angiography and CT perfusion, for guiding thrombolytic therapy in patients with suspected ischaemic stroke (Kidwell and Wintermark, 2010).

For postoperative examinations in both brain and spine, CT is useful in evaluating for complications (such as haemorrhage, infarct, or hydrocephalus), and the position of ventricular drains or other adjuncts. Portable head CT scanners are now available allowing examination at a neurocritical care bed without the need for transporting an unstable patient.

CT venography can often be used as an alternative to MR venography or help with troubleshooting in the case of confounding artefacts on MRI.

CT is the best modality for assessing bone lesions and is essential for the evaluation of skull, skull base, facial, and spine fractures. It is also the technique of choice for primary evaluation of the temporal bones and paranasal sinuses.

CT sensitivity for calcification is helpful with the diagnosis of calcium-containing CNS tumours (e.g. meningioma, oligodendroglioma, craniopharyngioma), metabolic disorders (e.g. hyperparathyroidism), and congenital lesions (e.g. TORCH infections, tuberous sclerosis). Finally, CT myelography is a viable alternative to MR in spine imaging in patients with absolute contraindications to MR imaging.

The use of radiation remains a drawback for CT technology. For a head CT, the average effective dose is approximately 2 millisievert (mSv), compared to an annual background radiation of 2–5 mSv. Other neuroradiological examinations incur higher doses (Table 3.2). Possible effects of radiation can be divided into deterministic (predictable and depending on cumulative radiation dose, for example, cataract due to lens irradiation), and stochastic (chance-like, for example, induction of malignancy) (Allisy-Roberts and Williams, 2007). The risk of cataract should be taken into account, especially in children (Michel et al., 2012).

In pregnancy, the dose to the fetus from head and neck CT is low and the risk of inducing childhood cancer is thought to be < 1 in 1 000 000. Examinations with direct exposure of the fetus (e.g. spinal CT) result in higher risk (1 in 1000–10 000) and should be avoided (The Royal College of Radiologists, 2009). The administration of iodinated contrast agents carries a theoretical risk of fetal thyroid suppression and thyroid function should be checked in the first week after birth.

Table 3.2 Typical radiation dose in neuroradiological CT-based examinations (Cohnen et al., 2006; Mettler et al., 2008)

Examination	Average dose (range)
CT head	1.7 mSv
CT angiogram head	1.9 mSv
CT angiogram neck	2.8 mSv
CT perfusion cerebral	1.1–5.0 mSv
Comprehensive stroke protocol	Up to 9.5 mSV
CT spine	6 mSV

Data from Cohnen, M et al., Radiation exposure of patients in comprehensive computed tomography of the head in acute stroke, *AJNR. American Journal of Neuroradiology*, volume 27, issue 8, pp. 1741–5. 2006, and Mettler, F.A et al., Effective doses in radiology and diagnostic nuclear medicine: a catalog, *Radiology*, volume 248, issue 1, pp. 254–63. 2008.

Advances in CT technology include attempts to reduce the necessary radiation dose while maintaining acceptable image quality, particularly important for paediatric imaging. The main way of reducing radiation exposure is adapting the dose by changing the tube voltage and current (and therefore X-ray photon energy and beam intensity) according to the patient's size, weight, and specific imaging application. A different method that allows scanning with a lower dose while maintaining image quality is replacement of the conventional reconstruction technique, known as filtered back projection, with iterative reconstruction (IR) which requires additional computation time but generates images with lower noise and higher spatial resolution, as well as reduced beam hardening and metal artefacts. Although the effects are more pronounced in body imaging, dose reductions have also been demonstrated for head imaging (Kilic et al., 2011; Mirro et al., 2016). The images appear subjectively different between the two reconstruction techniques and IR is therefore still under clinical evaluation.

Magnetic resonance imaging (MRI)

MRI basics and techniques

MRI takes advantage of the phenomenon of nuclear magnetic resonance, inherent to nuclei that have a magnetic moment due to an uneven number of protons or neutrons; in practice this mainly involves imaging of hydrogen nuclei (^{1}H) containing a single proton. MRI is based on a radiofrequency signal that is emitted when protons aligned with a strong magnetic field are tipped out of alignment by an externally applied radiofrequency pulse and then return to equilibrium (**Fig. 3.3**). The emitted signals are read out in a spatially ordered fashion and reconstructed into an image reflecting the magnitude of signal in a given voxel. The type of excitation pulse, time at which the signal is read out, and interval between excitations can be varied resulting in a different contrast in the final image (Allisy-Roberts and Williams, 2007). Two principal MRI sequences provide image weighting that depends on T_1 or T_2 relaxation times of the tissue (**Table 3.3**); appearances of the brain on the most commonly used sequences are shown in **Figure 3.4**. Images weighted according to proton density (PD) can be obtained together with T_2-weighted images with no additional scanning time required; they provide good contrast between the grey and white matter, and are of value in certain situations, but are not universally used in neuroradiology. Water has high signal on T_2-weighted sequences, and because most pathological processes are associated with increased water content (oedema), they appear hyperintense on T_2 weighted images. Fat is hyperintense on T_2-weighted images but unlike water it shows high T_1 signal. Besides fat, T_1 hyperintensity can also be due to melanin, protein-rich fluid, calcification, and gadolinium-chelate contrast agents (see later). Haemorrhage has complex appearances on MRI with combination of signal intensities dependent on the degradation phase of blood products (**Table 3.4**).

Signal in MRI can be produced using spin echo or gradient recalled echo sequences (Bitar et al., 2006; Allisy-Roberts and Williams, 2007). Spin echo provides better signal-to-noise ratio and is generally preferable, but slower than gradient echo. Acquisition of large volumetric datasets, required for example by neurosurgical navigation systems, is therefore performed using a variant of the gradient echo sequence. An important feature of gradient echo sequences is the lack of compensation of magnetic field inhomogeneities, resulting in its sensitivity to local susceptibility effects. This is used in practice for detection of haemorrhage, as the local susceptibility effect caused by iron in haemosiderin results in a very low signal with 'blooming' on gradient echo sequences. Even better depiction of haemosiderin, for example, microhaemorrhages in the setting of traumatic brain injury, is achieved with susceptibility weighted imaging (SWI), a high-resolution 3D velocity-compensated long echo time gradient echo sequence (Di Ieva et al., 2015). Gradient echo sequences are also used in other situations in which image contrast depends on susceptibility effects such as dynamic susceptibility contrast perfusion imaging and blood-oxygenation level dependent methods.

Image contrast in MRI can be varied using suppression techniques designed to null signal from a specific tissue. In the brain, this is used in fluid-attenuated inversion recovery (FLAIR), which nulls the cerebrospinal fluid signal; it is routinely used with T_2-weighting to make parenchymal T_2 hyperintensity more conspicuous (T_2-FLAIR, usually referred to simply as FLAIR). This should not be confused with a less common T_1-FLAIR sequence, which is used for example to improve grey-white matter contrast that is otherwise reduced at higher magnetic field strengths.

Fat suppression techniques increase conspicuity of fluid signal on T_2-weighted images or contrast enhancement on T_1-weighted images in situations where they could be masked by the presence of fat (such as detection of oedema in the vertebral column or paraspinal soft tissues, or contrast enhancement at the skull base, respectively). Fat suppression can be achieved by short tau inversion recovery (STIR) or spectral saturation. STIR is useful near bone-containing structures (orbit, skull base, sinuses), metallic foreign bodies, and across large fields of view, for example, in spine imaging. STIR is however problematic when combined with contrast medium, when spectral fat saturation is used instead.

Balanced steady state free precession (SSFP) sequences provide high resolution and excellent signal-to-noise ratio with a mixed T_2/T_1-weighting. In neuroimaging, these sequences are usually performed with a heavy T_2-weighting delivering high contrast resolution between cerebrospinal fluid and contained structures, such as the cisternal segments of the cranial nerves and adjacent blood vessels. Balanced SSFP techniques such as fast imaging in steady state (FIESTA) or constructive interference in steady state are therefore useful in investigation of vascular loops as the cause underlying trigeminal neuralgia or hemifacial spasm, as well as in screening for cerebellopontine angle tumours. Other uses include the evaluation of inner ear structures, and identification of cerebrospinal fluid leaks (Saindane, 2015).

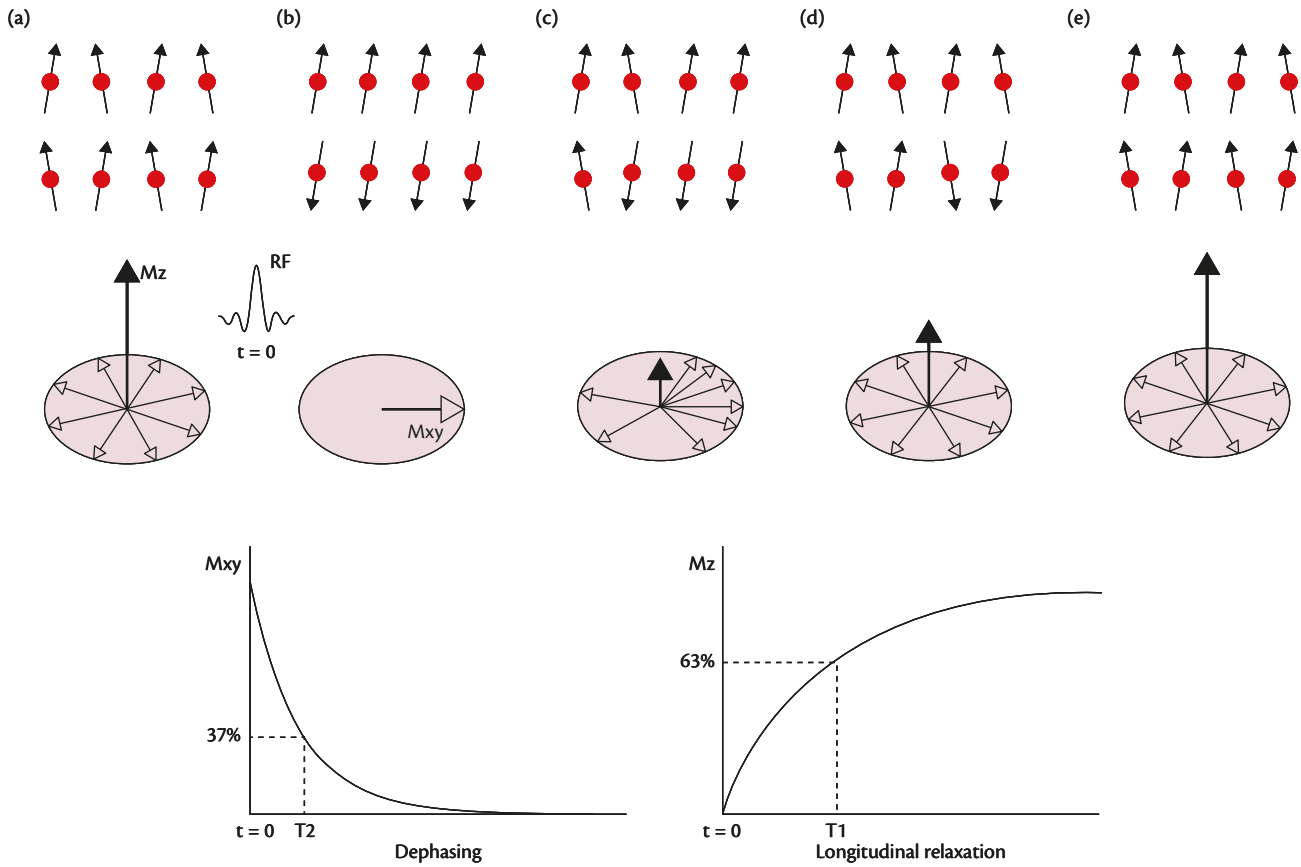

Fig. 3.3 Due to having a charge and spin, protons display magnetic properties and behave like magnetic dipoles. Outside of a magnetic field, the dipoles are randomly distributed and the net magnetization is zero in any direction in space. When placed in a magnetic field, the magnetic dipoles align with the field, either parallel ('spin up') or antiparallel ('spin down') to it, and start to precess (wobble around their axes) with a frequency dependent on the strength of the magnetic field (Larmor frequency). (A) Because a small excess of dipoles (approximately three per million) point 'spin up' their longitudinal magnetization vectors add up creating net longitudinal magnetization Mz. Due to precession, each dipole also creates a transverse magnetization vector rotating in the transverse plane. However, because the dipoles precess in different phases, their transverse magnetization vectors cancel each other and the net transverse magnetization remains zero. (B) Application of an external radiofrequency (RF) pulse turns some dipoles spin down; a so-called 90°RF pulse turns exactly half of the excess dipoles spin down, so now equal numbers of dipoles point in either direction and the net Mz vector is null. The RF pulse also causes synchronization of the phase of precession, so all the dipoles precess together (they achieve phase coherence) and their transverse magnetization adds up to produce a net transverse magnetization vector Mxy, rotating in the transverse plane. (C–E) After the RF pulse ends, within a short time the protons return to their initial state by losing phase coherence (dephasing, resulting in a loss of transverse magnetization Mxy) and by returning to the spin up orientation (longitudinal relaxation, resulting in 'regrowth' of the longitudinal magnetization vector Mz). These processes happen exponentially with time constants T2 and T1, respectively—T2 indicates the time after which dephasing is complete in 63% (so 37% phase coherence remains), and T1 corresponds to the time at which 63% of the longitudinal magnetization has recovered (bottom panels). T2 is always shorter and dephasing is complete (D) before longitudinal relaxation (E). T1 and T2 times depend on the type of the tissue and determine tissue contrast on T1- and T2-weighted sequences. Tissues with short T1 appear bright on T1-weighted sequence, while long T2 results in low signal on T2-weighted sequence (e.g. fat has high signal on T1- and T2-weighted sequences due to short T1 and relatively long T2).

Table 3.3 Signal intensity of different substances and tissues on T1- and T2-weighted MRI sequences

Substance	T1-weighted sequence	T2-weighted sequence
Water/Cerebrospinal fluid	↓	↑
Fat	↑	↑
Air	↓	↓
Cortical bone	↓	↓
Red bone marrow	=/↑	↑
Yellow bone marrow	↑	↑

Diffusion-weighted imaging (DWI) is sensitive to the movement of water molecules. DWI weighting is usually achieved by applying special diffusion-encoding gradients along the three principal spatial directions, and combining the signal into a trace image. Because the DWI trace image has both diffusion weighting and T_2-weighting, apparent hyperintensity can be due to restricted diffusion, or 'shine-through' phenomenon if the underlying area is T_2-hyperintense. It is therefore essential to review the apparent diffusion coefficient map (ADC), which eliminates the effect of T_2 weighting and demonstrates restricted diffusion as low signal intensity. Restricted diffusion may reflect a reduction in the size of the extracellular space that can be a result of cell swelling (e.g. in ischaemic stroke) or high cellularity (e.g. in lymphoma or

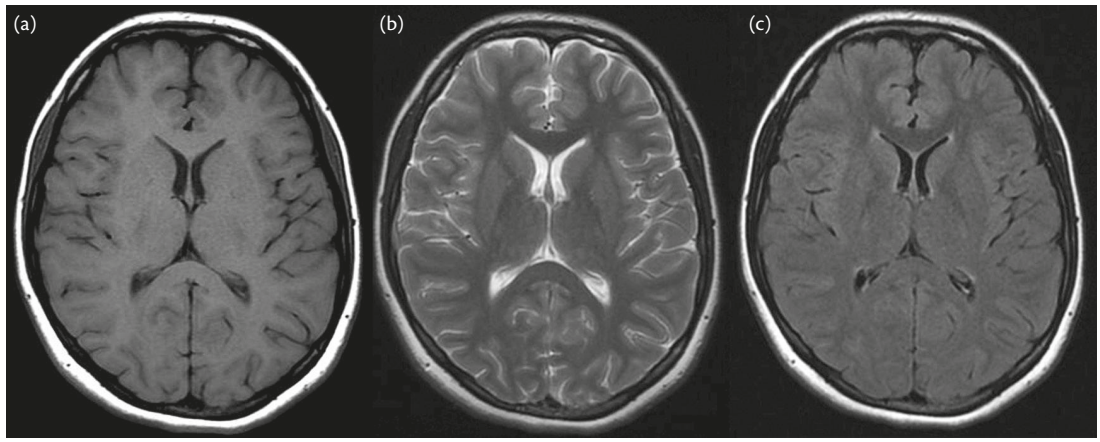

Fig. 3.4 Appearances of the brain on routine MRI sequences. (A) On T_1-weighted image grey matter is darker ('greyer') than white matter. (B) On T_2-weighted image the white matter is darker than grey matter and fluid is hyperintense. (C) T_2-FLAIR show similar contrast between the grey and white matter as T_2-weighted images but the signal from CSF is nulled.

medulloblastoma), as well as in lesions such as cholesteatoma or epidermoid cyst. In neurosurgical practice, the most important application of DWI is differentiation of pyogenic abscess from other ring-enhancing lesions, with the contents of the abscess demonstrating markedly restricted diffusion.

Applying diffusion gradients in at least six different directions underlies diffusion tensor imaging (DTI) which enables calculation of the predominant direction of diffusion in a given voxel. Because the movement of water is relatively unrestricted along the white matter tracts, DTI allows calculation of nerve fibres' direction and reconstruction of white matter tracts (DTI tractography), useful in neurosurgical planning (Waldman et al., 2009; Saindane, 2015). DTI also enables estimation of several measures of diffusion anisotropy with promising results in imaging and prognostication in traumatic brain injury (Hulkower et al., 2013) and high-grade gliomas (Price et al., 2007; Yan et al., 2016).

Functional MRI (fMRI) is based on blood oxygen level dependent (BOLD) effect resulting from different magnetic properties of oxyhaemoglobin (diamagnetic) and deoxyhaemoglobin (paramagnetic). Areas of the cortex with increased neuronal activity demonstrate higher oxygen consumption, but also increased perfusion due to neurovascular coupling; the effect of increased perfusion predominates, and the net result is a relative increase in MRI signal. Different activation paradigms allow the individual mapping of important cortical functions such as sensorimotor cortex and language localization (Stippich and Blatow, 2007).

Table 3.4 Signal intensity of haemorrhage of different stages on T1- and T2-weighted MRI sequences

Haemorrhage stage	Haemoglobin product	T1-weighted sequence	T2-weighted sequence
Hyperacute (<24 hrs)	Oxyhaemoglobin	=	↑
Acute (1–3 days)	Deoxyhaemoglobin	=	↓
Early subacute (3–7 days)	Intracellular methaemoglobin	↑	↓
Late subacute (1–4 weeks)	Extracellular methaemoglobin	↑	↑
Chronic (>1 month)	Haemosiderin	↓	↓↓

Contrast media in MRI

The majority of the contrast media used in MRI are paramagnetic agents based on gadolinium compounds. The pharmacokinetics of these agents are similar to those of iodinated contrast media with rapid passage from the vascular compartment to the interstitial compartment; an exception is gadofosveset, a blood pool agent that binds to albumin and remains in the vascular compartment. Gadolinium compounds do not pass through an intact blood-brain barrier so contrast enhancement is considered reflective of blood-brain barrier breakdown, apart from circumventricular organs, which have an incomplete blood-brain barrier and demonstrate physiological contrast enhancement that should not be mistaken for abnormality (Horsburgh and Massoud, 2013). Contrast enhancement is more conspicuous on MRI than on CT, and is invaluable in characterization of tumours, vascular disease, inflammation, and infection, both in the brain and in the spine.

Gadolinium compounds are generally safe but there are potential side effects associated with the release of unbound gadolinium from its chelates and accumulation in tissues. Nephrogenic systemic fibrosis is a rare but disabling dermopathy resembling scleroderma and eosinophilic fasciitis, first observed in patients on dialysis undergoing gadolinium contrast-enhanced MRI. Most cases were associated with the use of less stable linear agents that are now classified as high risk (Table 3.5). These compounds require renal function monitoring and are contraindicated in patients with glomerular filtration rate (GFR) below 30 ml/min/1.73 m^2, in neonates, and in the perioperative liver transplantation period; breastfeeding should

Table 3.5 Classification of gadolinium-based MRI contrast agents according to the risk of nephrogenic systemic fibrosis

High risk	Medium risk	Low risk
Gadodiamide (Omniscan)	Gadoxetic acid (Primovist)	Gadoteric acid (Dotarem)
Gadoversatamide (OptiMARK)	Gadobenic acid (MultiHance)	Gadoteridol (ProHance)
Gadopentetic acid (Magnevist)	Gadofosveset (Vasovist)	Gadobutrol (Gadovist)

Data from Drug Safety Update Jan 2010, vol 3 issue 6: 3. https://www.gov.uk

be discontinued for at least 24 hours after high-risk agent administration. Similar precautions are recommended but not mandatory for medium- and low-risk agents.

Recently it has been recognized that repeated administration of gadolinium-based contrast agents leads to accumulation of gadolinium in the brain, with the highest concentrations detected in the dentate nucleus and globus pallidus (Kanda et al., 2015b; McDonald et al., 2015). Accumulation of gadolinium is seen in patients receiving the less stable linear, but not macrocyclic compounds (Kanda et al., 2015b), and occurs even in the presence of normal renal function (Kanda et al., 2015a; McDonald et al., 2015). The clinical significance of these findings is however currently unknown.

General application of MRI in neurosurgery

Structural MRI has several advantages over CT and is the investigation of choice in the assessment of intracranial and spinal pathology with the exception of a few specific situations. In structural imaging, MRI provides superior tissue contrast, greater sensitivity to parenchymal abnormalities and contrast enhancement, better demonstration of anatomy, and allows imaging in any plane without using ionizing radiation; further information can be gained by addition of functional sequences. Disadvantages of MRI include long scanning time making it problematic in medically unstable patients and more prone to motion artefacts; therefore CT, with its established value in demonstration of intracranial haemorrhage and fractures, remains the investigation of choice in emergency situations, especially in trauma. CT is also better in demonstrating cortical bone and calcification, and remains more easily available and less costly. Use of MRI can be limited by several safety issues related to the static magnetic field, radiofrequency pulses, and gradient fields. MRI cannot generally be performed in patients with pacemakers, ferromagnetic aneurysm clips, implants, or foreign bodies. Care must be taken when imaging patients with shunt valves, cochlear implants, and heart valves, as well as in pregnancy; departmental practices vary. Finally, claustrophobia may preclude many patients from undergoing the MRI investigation or limit the scan time.

Positron emission tomography (PET)

PET is a nuclear medicine technique that uses tracers labelled with positron-emitting isotopes. The most commonly used radionuclide is fluorine-18 (^{18}F) due to its relatively long half-life that approaches two hours and is sufficiently long to allow transportation from an external cyclotron facility to the imaging centre. Short-lived isotopes require an on-site cyclotron (^{11}C, ^{13}N, ^{15}O) or are produced in a generator (^{68}Ga, ^{82}Rb). In the target organ, positrons emitted by the radionuclides travel a very short distance before interacting with electrons in neighbouring atoms and undergoing annihilation with the emission of two high energy photons that travel in opposite directions, which are detected by a ring array of solid-state scintillator detectors. The image is reconstructed based on the coregistration of pulses between opposite pairs of detectors, allowing placement of the annihilation event along a specific line of response (Fig. 3.5). Time of flight PET (TOF-PET) also measures tiny differences in time of arrival of the two photons to the opposite detectors, allowing more precise placement of the annihilation event to a segment along the line of response. Data needs to be corrected for the attenuation of photons inside the patient; this is achieved by using a rotating radiation source in standalone PET or direct information on attenuation

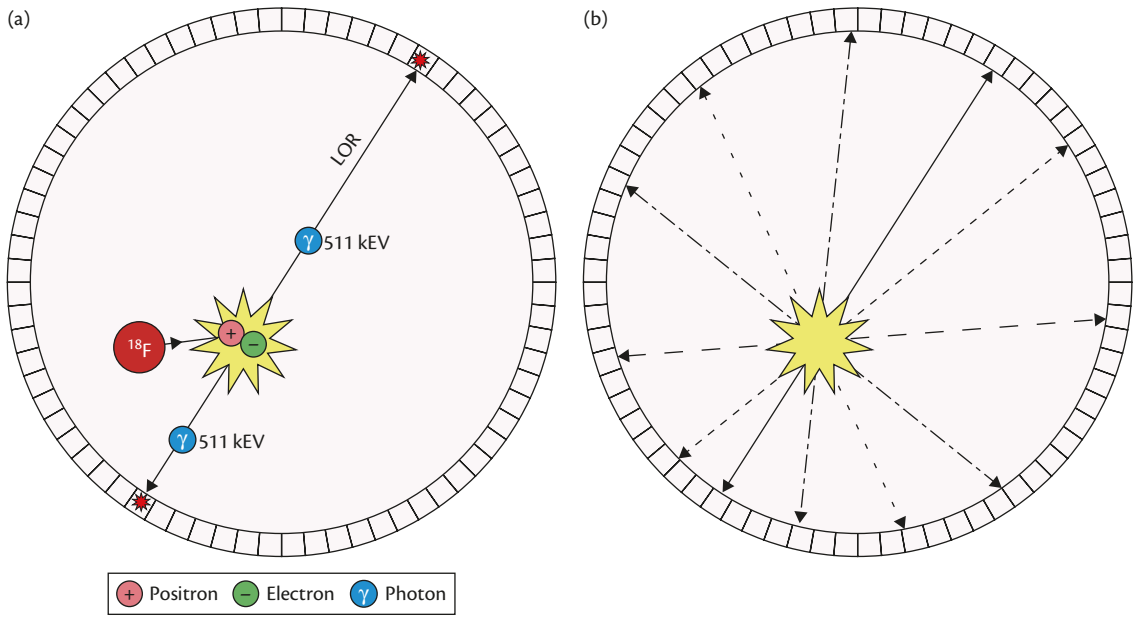

Fig. 3.5 (A) A positron-emitting isotope (most commonly 18F) releases positrons which collide with electrons in the target organ resulting in a series of annihilation events. Each annihilation event results in the emission of two high energy (511 keV) photons travelling in a straight line in opposite directions (at 180° to each other) at the speed of light. The two photons reach a ring of detectors placed around the gantry at the same time (if the annihilation happens in the centre of the gantry) or within a very short time window (if annihilation happens off-centre). The detection of such a coincidence event allows localization of the source of photons somewhere along the line of response (LOR) joining the pair of detectors which registered the photons. In time of flight (TOF) PET the tiny difference in time it takes for each photon to reach the detector for off-centre events is also taken into account, allowing the localization of the annihilation event more precisely along the LOR. (B) As photons produced by a series of annihilation events travel along different lines of response, combining information from multiple detected coincidence events allows localization of the radiation source.

obtained from a CT scan in PET-CT hybrid scanners. Data correction in MRI-PET is more challenging and requires calculation of attenuation values from anatomical MRI images.

PET is extremely sensitive, being able to detect picomolar quantities of tracer labelled with a positron emitter. In theory, any physiologically occurring substance, drug, or receptor ligand can be labelled, making PET the most promising technique for functional and molecular imaging. The most widely used tracer is ^{18}F-fluorodeoxyglucose (^{18}F-FDG), the uptake of which reflects the rate of glucose metabolism. Use of ^{18}F-FDG in the brain is problematic due to high rate of physiologic glucose metabolism; its potential applications include imaging of high-grade brain tumours, anaplastic transformation of low-grade gliomas, differentiation of radiation necrosis from tumour progression, differentiation of lymphoma from toxoplasmosis in immunocompromised patients, as well as detection of focal cortical dysplasia in epilepsy investigation. The armamentarium of PET tracers and range of potential applications in brain imaging is expanding; these are summarized in Table 3.6.

Most PET scanners in clinical use currently are either standalone machines, or PET-CT hybrids. Increasingly, PET-MRI hybrid scanners are becoming available. In view of the superior tissue contrast and resolution of MRI in the brain, integrated PET-MRI has potential advantages in neuroimaging. So far, it has been possible to combine sequential PET and MRI images acquired sequentially on separate scanners but hybrid PET-MRI imaging greatly facilitates such fusion eliminating the need for subsequent coregistration. More importantly, simultaneous acquisition of PET and MRI images could be of value when measuring parameters that undergo temporal changes, such as cerebral perfusion or hypoxia (Catana et al., 2012). These methods are currently largely limited to neuroimaging research, and their clinical usefulness remains to be established.

Other nuclear medicine techniques

Most nuclear medicine techniques use tracers labelled with radioligands emitting gamma radiation. The most commonly used radionuclide is ^{99m}Tc (technetium) due to a combination of optimal half-life, ease of production, and ease of incorporation into radiopharmaceuticals. Other isotopes used in neuroimaging include ^{111}In (indium) and ^{133}Xe (xenon). Emitted gamma rays can be detected using a planar gamma camera or rotating gamma camera in single-photon emission computed tomography (SPECT). Applications of SPECT in neuroradiology include cerebral perfusion measurements with ^{99m}Tc-HMPAO, ^{99m}Tc-ECD, and ^{133}Xe, diagnosis of dementia, identifying seizure focus in epilepsy, dopamine transporter imaging in diagnosis of parkinsonian syndromes, and brain tumour evaluation (McArthur et al., 2011). Planar gamma camera images are obtained in radionuclide cisternography, usually with ^{111}In-DTPA, performed for investigation of hydrocephalus or CSF leaks.

Myelography

Although MRI is the preferred method for examination of most spinal abnormalities, myelography remains indicated in patients who cannot undergo MRI (e.g. because of a pacemaker) and it also has a role in the detection of CSF leak sites in patients with spontaneous intracranial hypotension (Kranz et al., 2016). Iodinated contrast medium is injected into the spinal subarachnoid space, most commonly after lumbar puncture but sometimes after a lateral puncture at C1–2 if lumbar puncture cannot be performed. The puncture is typically done using fluoroscopic guidance and the injection of contrast is monitored by intermitted fluoroscopy to ensure that inadvertent epidural or subdural injection has not occurred. The contrast is then moved along the spinal canal to the appropriate location(s)

Table 3.6 Examples of PET tracers used in neuroimaging

PET tracer	Mechanism of action and applications
^{11}C-methionine, ^{18}F-FET	Transport into the cell via amino acid transporter increased in malignant tumours—characterization of tumour extent, biopsy guidance, treatment planning, response assessment (radiation necrosis, recurrence, pseudoresponse), prognostication; assessment of striatal dopamine pathway (^{18}F-DOPA)
^{18}F-FLT	Uptake correlated with activity of thymidine kinase-1 in proliferating cells—assessment of tumour grade, treatment response, prognostication
^{18}F-FMISO, ^{18}F-FAZA	Accumulation in hypoxic cells—assessment of hypoxia in brain tumours with potential relevance to tumour progression and resistance to treatment
^{11}C-PK11195, ^{18}F-GE180	Binding to translocator protein (TSPO) expressed in activated microglia and cancer cell lines—assessment of microglial activation/inflammation, assessment of tumour grade
^{68}Ga-DOTA-TOC ^{68}Ga-DOTA-TATE	Somatostatin analogues with high uptake in certain intracranial tumours—diagnosis of meningioma, pituitary adenoma, hemangioblastoma, medulloblastoma, PNET
^{11}C-PiB (Pittsburgh compound) ^{18}F-florbetaben, ^{18}F-florbetapir ^{18}F-flutemetamol	Binding to beta-amyloid plaques—diagnosis of Alzheimer disease
^{11}C-PBB3 ^{18}F-FDDNP	Binding to tau protein/neurofibrillary tangles—diagnosis of Alzheimer disease and tauopathies
^{11}C-flumaeznil ^{11}C-diprenorphine ^{11}C-SCH23390 ^{11}C-raclopride	Benzodiazepine receptor ligand—receptor binding studies Opioid receptor ligand—receptor binding studies Dopamine D_1 receptor ligand—receptor binding studies Dopamine D_2 receptor ligand—receptor binding studies
$^{15}O_2$ and [^{15}O] H_2O ^{11}C-leucine, ^{11}C-tyrosine ^{11}C-albumin $^{11}CO_2$, ^{11}C-DMO	Cerebral blood flow, oxygen metabolism Protein synthesis rate Plasma volume pH

by tilting the examination table and radiographs are obtained with the patient supine, prone, and in oblique positions. Myelography is typically then followed by a CT examination of the spine, which provides greater anatomical information than can be obtained from radiographs alone and allows excellent depiction of bony anatomy and spinal nerve roots on the same image.

Contraindications to myelography include allergy to iodinated contrast media, seizure disorders, bleeding disorders, or patients taking anticoagulants or antiplatelet agents, patients with suspected raised intracranial pressure, and uncooperative patients. Complications are uncommon with modern water-soluble iodinated contrast agents but include postdural puncture headache, seizures, bleeding at the puncture site, nerve root injury, and arachnoiditis (Sandow and Donnal, 2005).

Ultrasound

Ultrasound (US) is sound that has a frequency greater than the upper threshold of human hearing, approximately 20 kHz. Ultrasound used for medical imaging typically has a frequency between 2 MHz and 18 MHz. When transmitted from an ultrasound probe into the body, an US beam undergoes reflection and refraction when it passes through changes in tissue density and compressibility. The US probe can detect the returned echoes and determine their depth of origin within the patient based on the time since transmission and the speed of sound in tissue. The intensity of the returned echoes is affected by the reflectivity of the tissue and the degree to which it attenuates the US beam. It is thus possible to construct a two-dimensional greyscale image in which the position and brightness of each pixel corresponds to the site of origin and strength of an echo arising within the patient, so-called B-mode imaging (Allisy-Roberts and Williams, 2007).

Bone and calcified tissues are both highly reflective and attenuating, preventing through transmission of sound, so appear as a bright white interface beyond which there is an 'acoustic shadow' in which no information is obtained. Conversely fluid is of low reflectivity and attenuates the beam weakly, thus appearing as an anechoic area beyond which there is increased through transmission of sound relative to adjacent tissues and resulting in posterior acoustic enhancement.

The attenuation of the US beam by bone limits the utility of B-mode imaging for assessing the brain in adults and children. Transfontanellar US scanning of neonates and infants can be used to assess the size of the ventricles, detect intraventricular and parenchymal haemorrhage in preterm neonates, and evaluate the brain parenchyma in cases of hypoxic ischaemic encephalopathy. Ultrasound of the spine can also be performed in neonates for assessment of suspected cases of dysraphism to assess the position of the conus, presence of diastematomyelia, or associated intraspinal masses.

When US waves are reflected by a moving interface their frequency is changed by the Doppler effect, resulting in an increase in frequency if the interface is moving towards the transducer and a reduction in frequency for a reflector that is moving away. The velocity of reflector motion affects the amount of change in frequency. This effect is exploited by pulsed-wave Doppler US to obtain waveforms from blood vessels that show the velocity and direction of blood flow with respect to the transducer. In colour Doppler imaging the information regarding direction and velocity of blood flow is overlaid on a greyscale B-mode image as a colour-coded map.

Doppler US can be used to detect the presence of carotid artery stenosis in patients with carotid bruits, transient ischaemic attacks, or ischaemic strokes. The degree of carotid stenosis is generally assigned to a percentage range based on the increase in blood flow velocity through area of stenosis. It is also possible to assess the blood flow of major intracranial arteries by transcranial Doppler (TCD). This requires the use of low frequency (2–3 MHz) transducers that can penetrate through the relatively thin bone of the pterion or by scanning through the foramen magnum. TCD can be used to perform bedside monitoring of patients with aneurysmal subarachnoid haemorrhage to look for increases in blood flow velocity that can indicate vasospasm (Marshall et al., 2010). Some institutions also use intraoperative colour Doppler US for the assessment of CSF flow at the foramen magnum in cases of foramen magnum decompression for Chiari I malformation.

Vascular imaging

Digital subtraction angiography

Digital subtraction angiography (DSA) (Wolpert, 1999) remains the reference standard for imaging of vascular disorders of the brain and spine, although with improvements in CT angiography and MR angiography, the indications for DSA as the first-line investigation have decreased. DSA is usually performed under local anaesthesia, although sedation or general anaesthesia may be necessary in uncooperative patients, for interventional neuroradiology procedures and, depending on operator preference, in diagnostic spinal angiography. The usual route of access to the arterial system is through the common femoral artery; where this is not possible then transradial or transbrachial arterial approaches may be used. After puncture with a needle, a soft-tipped guidewire is threaded through the needle into the artery and the needle is then removed and exchanged for a polyethylene catheter. A variety of catheter shapes are available, the selection partly depending on operator preference but also on the degree of arterial tortuosity. Under fluoroscopic guidance the catheter can be positioned in the internal and external carotid arteries and the vertebral arteries as necessitated by the indication for the DSA. Neuroangiography is typically performed using biplane angiography units that have two X-ray tubes and image intensifiers or, increasingly often, flat panel digital detectors. This allows acquisition of images simultaneously from two different projections, reducing the length of the examination and the volume of contrast material that needs to be injected. Images are acquired using pulsed X-rays immediately before (so-called mask images) and then during the injection of contrast material into the artery. By subtracting mask images from those obtained during the injection of contrast, images are produced that eliminate bone and soft tissue detail and show only the contrast within the blood vessels. If the patient moves during image acquisition the mask images will not be correctly registered with the postcontrast images and they may need to be aligned manually. It is also possible to obtain three-dimensional images by rotating the C-arm around the patient's head during the injection of contrast (rotational 3D DSA).

Possible complications of cerebral DSA include those common to all invasive angiographic procedures such as puncture site haematoma (approximately 5%), arterial dissection, and contrast reactions. Manipulation of catheters in the aortic arch and neck arteries

also carries a small risk of neurologic deficits, which are most often transient (approximately 2.5%) but can rarely be permanent (approximately 0.2%). The risk of neurological complications depends on the operator's experience and is increased in older patients and longer procedures.

CT angiography and CT venography

CT angiography (CTA) involves the rapid acquisition of a thin section data set of the area of clinical interest during the first pass of an injected bolus of iodinated contrast material. Acquisition of images during the arterial phase can be achieved by bolus tracking or test bolus methods. Bolus tracking involves triggering the scan acquisition when the attenuation within a chosen vessel, most often the internal carotid artery, reaches a predetermined level after the start of contrast injection. The test bolus method determines the optimum time to start scan acquisition by using a separate injection of a small volume of contrast medium. Although image interpretation always requires review of the axially acquired source images, reconstruction of the 3D data using multiplanar reformats, maximum intensity projection (MIP), and volume-rendered images can facilitate the identification of abnormalities and enhance the appreciation of their relationship to surrounding vessels.

Advantages of CTA over DSA include its non-invasive nature, more widespread availability, and the ease and speed of acquisition. Disadvantages of conventional CTA include its poor temporal resolution—images are essentially a 'snapshot' that do not provide dynamic information, reduced spatial resolution relative to DSA, and potential obscuration of small vascular abnormalities adjacent to bone. Bone-subtracted CTA images can be obtained by acquiring a mask of CT data before injecting contrast and subtracting it from the postcontrast images in a manner analogous to DSA, or by using dual energy X-ray acquisition (although this requires a dedicated dual energy CT scanner).

CT venography is similar in principle to CTA except that the images are acquired when the majority of the injected contrast is in the venous phase. The timing of image acquisition is less critical and can generally be achieved with a fixed scan delay of 40 seconds after the start of contrast injection.

MR angiography (MRA) and venography (MRV)

There are several different methods by which angiographic images can be obtained with MRI. Non-contrast methods rely on signal differences between flowing blood and surrounding stationary tissues (Lim and Koktzoglou, 2015). Time-of-flight magnetic resonance angiography (TOF-MRA) depends on flow-related enhancement, where stationary tissues saturated by repeated radiofrequency pulses display low signal, while non-saturated blood flowing into the imaged slice is hyperintense. Phase-contrast angiography (PC-MRA) uses two bipolar gradients inducing a phase shift in blood flowing along the gradient direction, which is proportional to the flow velocity. By changing the gradient strength, velocity encoding sensitivity (Venc) can be tailored to optimally demonstrate arterial or venous flow. Both TOF-MRA and PC-MRA can be performed using two (2D) or three-dimensional (3D) acquisition. Contrast-enhanced MRA (CE-MRA) is similar in principle to CTA, whereby the vessel visualization depends on intravenously injected contrast agent. In practice, 3D TOF-MRA is the main technique used to image intracranial vasculature, with sensitivity and specificity in aneurysm detection similar to CTA when performed on a three-tesla system (Lim and Koktzoglou, 2015). Large aneurysms or aneurysm with slow flow are better demonstrated with CE-MRA, which can also be performed as time-resolved examination (Saindane, 2015) for evaluation of arteriovenous malformations or dural fistulas. In detection of carotid artery stenosis, TOF-MRA is less sensitive and specific than CE-MRA (Gough, 2011) and tends to overestimate the degree of stenosis. MRV is most often performed using a phase-contrast method, as time of flight can be confounded by hyperintense appearances of a subacute thrombus that can mimic normal flow-related enhancement (Nadgir and Yousem, 2016). MRV can also be performed as contrast-enhanced examination (Sadigh et al., 2016).

Other vascular techniques

As mentioned earlier, high sensitivity of SWI to even small quantities of blood products renders it highly useful for detection of intracranial haemorrhage, for example, microhaemorrhages in cerebral amyloid angiopathy or traumatic brain injury. In addition, due to its sensitivity to paramagnetic properties of deoxyhaemoglobin, SWI allows excellent demonstration of venous structures (Di Ieva et al., 2015). SWI has been shown to be useful in demonstrating venous drainage of arteriovenous malformations (AVMs) and evaluation of the extent of their neurosurgical resection, as well as depiction of micro-AVMs (Mossa-Basha et al., 2012; Saindane, 2015).

In addition to evaluation of the vessel lumen, there has been increasing emphasis on the assessment of the vessel wall. In carotid artery imaging, the main focus is on the evaluation of atherosclerotic plaque, in particular its stability and propensity to rupture (Young et al., 2011). Intracranial vessel wall imaging can be useful in evaluation of intracranial atherosclerosis, moyamoya disease, vasculitis, reversible cerebral vasoconstriction syndrome, and intracranial arterial dissection (Mandell et al., 2017).

Imaging methods to measure cerebral blood flow and metabolism

Imaging of cerebral perfusion and metabolism has a wide variety of research and clinical applications including assessment of acute stroke, hypoxic brain injury, vasospasm, characterization of cerebrovascular reserve, and evaluation of traumatic brain injury (Coles, 2006; Dani and Warach, 2014). Major applications are found in neuro-oncology where different methods are combined to derive information on tumour type and grading, differentiation from non-neoplastic lesions, biopsy guidance, response assessment, and differentiation of chemotherapy and radiotherapy effects from tumour progression (Herholz et al., 2007; Waldman et al., 2009; Kim et al., 2016). Regional differences in blood flow and metabolism also provide additional diagnostic information in dementia and neurodegenerative disease (Schuff, 2013; Ishii, 2014). Space constraints dictate only a brief description of the available modalities; more comprehensive analysis can be found in the references provided, as well as dedicated volumes (Gillard et al., 2010; Barker et al., 2013).

Measuring cerebral blood flow

The imaging methods used to measure cerebral perfusion can be based on inert diffusible tracers or non-diffusible intravascular tracers (Coles, 2006). The former rely on the Fick principle stating that

uptake of any substance by the target organ depends on its arteriovenous concentration gradient and the organ perfusion. Techniques that use diffusible traces include xenon-enhanced CT with non-radioactive ^{131}Xe, and nuclear medicine methods such as SPECT with ^{99m}Tc-HMPAO, ^{99m}Tc-ECD or radioactive ^{133}Xe isotope, and PET with $^{15}O_2$. Quantitative $^{15}O_2$ PET and xenon CT are considered the gold standard for measuring cerebral perfusion, but are not routinely used in clinical imaging (Thompson et al., 2010). Magnetically tagged water molecules in MR perfusion using arterial spin labelling also behave like a diffusible tracer, and this approach is likely to be increasingly applied in a clinical setting (Grade et al., 2015).

Techniques that require intravascular injection of a non-diffusible tracer are more widely available and are increasingly becoming part of routine imaging, especially in stroke and neuro-oncological imaging. The basic principles underlying measurement of perfusion parameters with these methods by CT or MRI are similar and rely on rapid serial imaging during the first pass of an injected bolus of contrast material (Konstas et al., 2009a). In simple terms, the resulting changes in attenuation (CT) and signal intensity (MRI) in the brain depend on the combination of the inherent perfusion characteristics of the tissue and the inflow of contrast from the arteries supplying the voxels of interest (arterial input function), assuming that the contrast agent remains within the vascular space. The area under the contrast concentration curve and the width of the contrast bolus provide estimates of cerebral blood volume (CBV) and mean transit time (MTT), respectively, and the cerebral blood flow (CBF) can be calculated from the central volume theorem (CBF = CBV/MTT). CT perfusion (CTP) is now widely used in the evaluation of the extent of core infarction and ischaemic penumbra in acute stroke (Konstas et al., 2009a; Konstas et al., 2009b) and in diagnosis and management of vasospasm following subarachnoid haemorrhage (Mir et al., 2014). The greatest advantage of CTP is the linear relationship between the concentration of iodine and tissue attenuation, and direct measurement of arterial input and venous output functions, allowing for direct calculation of vascular parameters. A disadvantage of perfusion CT compared with MRI has been the use of ionizing radiation, and its limited craniocaudal coverage, now largely overcome with larger detector array CT scanners and shuttling table techniques.

Perfusion MRI techniques are based either on measuring susceptibility effects of gadolinium contrast agent causing a reduction of T_2* signal (dynamic susceptibility contrast, DSC), or its relaxivity effects reflected by an increase in T_1 signal (dynamic contrast enhancement, DCE). Quantitative assessment of absolute perfusion parameters is more difficult than for CTP and requires mathematical and pharmacokinetic modelling with several assumptions about the behaviour of the injected tracer, and correction accounting for contrast leakage into extravascular space (Jackson, 2004). To simplify comparisons, perfusion parameters derived from DSC can be expressed as relative values, usually normalized against contralateral white matter. DCE allows calculation of several parameters that characterize the microvascular environment, including permeability. The most commonly used indices include estimates of blood flow (F), permeability surface area product per unit mass of tissue (PS), the volume transfer constant (K_{trans}), volumes of the extravascular extracellular space (V_e) and blood plasma (V_b), as well as semiquantitative indices derived from the shape of the enhancement curve (Thompson et al., 2010; Griffith and Jain, 2015).

An emerging technique of cerebral blood volume quantification is vascular space occupancy imaging (VASO), which uses T_1 difference between the blood and tissue to separate the two compartments. VASO MRI can detect changes in CBV with high temporal resolution without the use of injected contrast medium, and provides absolute CBV measurements when also performed with intravenous contrast agent (Lu and Uh, 2013).

Recently there has been renewed interest in measuring brain perfusion using intravoxel incoherent motion imaging (IVIM) which is based on the observation that signal in diffusion weighted MRI depends not only on diffusion itself, but also on blood flow within the capillary bed (pseudo diffusion). By using a range of diffusion gradient strengths and bi-exponential fitting or kurtosis models, the effects of capillary flow and true diffusion can be separated, providing an estimation of perfusion (Federau et al., 2014).

It is also worth mentioning here the methods used to evaluate brain oxygenation, which depends on perfusion and oxygen metabolism. The gold standard technique is $^{15}O_2$ PET which may be supplemented with $[^{15}O]H_2O$ and $[^{15}O]CO$ administration (triple oxygen PET), providing absolute values of cerebral metabolic rate of oxygen ($CRMO_2$) and oxygen extraction fraction, in addition to cerebral perfusion indices. Emerging MRI-based methods include quantitative BOLD, phase- and susceptibility-based imaging, and intravascular T_2-based approaches (Christen et al., 2013).

Measuring cerebral metabolism

The two major imaging modalities currently used for assessment of cerebral metabolism are PET and magnetic resonance spectroscopy (MRS). As described earlier, depending on the tracer PET allows estimation of local or regional glucose metabolism (^{18}FDG-PET) and oxygen metabolism ($^{15}O_2$, triple oxygen). In brain tumours, PET allows estimation of amino acid transport (^{11}C-methionine, ^{18}F-FET), protein synthesis (^{11}C-methionine and ^{11}C-leucine) and DNA synthesis (^{18}F-FLT), as well as tissue-level hypoxia (^{18}F-FMISO and ^{18}F-FAZA).

MRS is based on chemical shift, a specific change in resonance frequency that arises as a result of electron shielding when an atom of interest is chemically bound within a compound. MRS allows probing of the biochemical milieu in a defined voxel of interest (single voxel spectroscopy) or as 2D or 3D magnetic spectroscopic imaging (CSI), mapping the concentration of a given compound across the brain. MRS is generally a challenging technique due to low sensitivity and low signal-to-noise ratio, and requires higher strength and precise shimming of the magnetic field. The most commonly used form of MRS due to relative abundance of the target nucleus is proton spectroscopy (^{1}H-MRS). In the brain, ^{1}H-MRS detects a spectrum of several metabolites considered markers of specific metabolic aspects, in particular N-acetyl aspartate (NAA, a marker of neuronal integrity), choline (Cho, a marker of membrane turnover), creatine, and myoinositol (markers of cellular energy status). Pathologic conditions cause changes in the spectral pattern, or appearance of abnormal metabolite peaks such as lactate (Lac, marker of metabolic acidosis and cell death), or lipids (marker of tissue breakdown); for example, high-grade gliomas demonstrate a reduction in NAA and elevated Cho, accompanied by lipid and lactate peaks (Herholz et al., 2007). More technically challenging ^{31}P-MRS allows estimation of energy metabolism by detecting spectra from phosphorus-containing molecules of ATP, phosphocreatine, and inorganic phosphate, as well as of the neuronal membrane

metabolism by detecting phosphomonoesters and phosphodiesters (Herholz et al., 2007).

Recently there has been intense interest in dynamic nuclear polarization (DNP or hyperpolarization), a technique aiming to address the inherent problem of low sensitivity in spectroscopy by increasing the proportion of nuclei contributing to magnetic resonance signal. Normally, magnetic moments of nuclei polarized in a magnetic field align either parallel (spin up) or antiparallel to the field (spin down); net magnetic resonance signal is attributed to the tiny difference between the number of nuclei pointing each way (with just a few more nuclei per million pointing spin up). DNP is performed by extreme cooling of a sample containing nuclei of interest and free radicals as a source of unpaired electrons in a solid state, and subjecting it to a strong magnetic field. In these conditions, electron spins become highly polarized, and this polarization is partly transferred to nuclear spins by microwave irradiation, resulting in a more than 10 000-fold increase in signal-to-noise ratio (Ardenkjaer-Larsen et al., 2003). Such a treatment cannot of course be performed *in vivo*, but can be used to hyperpolarize a sample containing MRS-detectable nuclei, which can be quickly warmed up, injected into a patient, and imaged with increased signal-to-noise ratio. Systems capable of DNP in humans are now available, and there is intense research effort in this area. The most common metabolite currently used in DNP is [1-^{13}C]pyruvate, which after injection is converted into [1-^{13}C]lactate by lactate dehydrogenase (LDH), [1-^{13}C]alanine by alanine transaminase, and $^{13}CO_2$ by pyruvate dehydrogenase (PDH), the latter further converted into [^{13}C]bicarbonate. Conversion of pyruvate into lactate is increased in malignant tumours, even in the presence of sufficient oxygen (Warburg effect), which is leveraged in cancer diagnosis and assessment of treatment response (Kim et al., 2016). Other promising markers which proved potentially useful in animal models include [1,4-^{13}C]fumarate for detection of cellular necrosis, [^{13}C]bicarbonate for *in vivo* measurement of pH, and [5-^{13}C]glutamine for assessment of tumour metabolism, while [1-^{13}C]urea can be used as a perfusion marker. It is also possible to inject and detect several hyperpolarized substrates simultaneously, provided that their chemical shift is sufficiently different to distinguish them spectroscopically (Brindle et al., 2011).

Future directions

Current conventional radiological methods allow demonstration of anatomical and macroscopic pathological features of disease with excellent sensitivity and resolution. Functional imaging methods that have enabled insight into variety of physiological and pathological phenomena as described earlier, are an important first step beyond anatomical imaging towards more precise characterization of the disease process. These methods however remain generally non-specific, demonstrating changes that are common endpoints of many possible pathological pathways. One avenue towards more specific information is radiomics—conversion of images into higher dimensional data and subsequent feature extraction and data mining in a manner analogous to genomic, proteomic, or metabolomic approaches, with the aim to obtain imaging signatures corresponding to particular features of disease (Gillies et al., 2016). Radiomic features include both semantic measures (e.g. shape, size, or vascularity), and mathematically derived agnostic descriptors (such as histogram skewness or kurtosis, fractal, and texture analysis). Radiomics provides useful additional information for diagnosis, treatment selection, and prognostication, but its inherent limitation is the same as of the original imaging method used to obtain the source data. The ultimate goal would be to obtain information on the cellular and molecular events that precede and underlie the observed anatomical and functional sequelae by using probes specific to a particular molecular target or biochemical pathway. This would lead to better understanding of abnormal biology, enable earlier detection, and provide precise diagnosis and disease staging. Molecular imaging could also provide better endpoint biomarkers in the drug discovery process, allowing rapid assessment of treatment effect on molecular level even before phenotypical response occurs (Massoud and Gambhir, 2007). Arguably, the most important application of such methods will be in neuro-oncology, where there are already several examples of clinical applications of detecting specific receptors, or protein products specific to certain enzyme isoforms (Kim et al., 2016). It is likely that PET and MRI will be used for detection of imaging probes due to limitations of optical, photoacoustic, or ultrasound techniques for intracranial imaging, although these could be used intraoperatively or during endoscopy. Nanoparticles are emerging as an ideal imaging agent (Thakor and Gambhir, 2013) that can be targeted to a specific tissue and labelled for detection by a chosen assay, or even multiple methods, for example, for preoperative imaging by MRI, and intraoperative localization using photoacoustic and optical imaging (Kircher et al., 2012). Concurrent loading of nanoparticles with a therapeutic agent enables combination of diagnostics and therapy—theranostics (Kelkar and Reineke, 2011; Thakor and Gambhir, 2013), in which imaging is paired to the targeted delivery of a chemotherapeutic, gene-silencing agent; or radioactive isotope; or to radiosensitization, photodynamic, or photothermal interventions. In the future, imaging will undoubtedly be the key element of precision medicine, enabling precise diagnosis and individualized therapy tailored for the individual patient and targeted to a particular pathological entity (Kim et al., 2016).

The operating theatre environment

Neil Kitchen and Jonathan Shapey

The neurosurgical operating theatre

Over the last century the neurosurgical operating theatre has evolved with significant improvements in lighting, equipment, air flow, and sterility. Further developments with intraoperative imaging and integrated navigation systems are now beginning to emerge. (**Fig. 4.1**).

Modern standard theatre complexes are divided into zones in order to minimize bacterial contamination. The operating room is an aseptic zone, the anaesthetic room is a clean zone and other areas are dirty zones. Standard theatres have a unidirectional air flow system to reduce the risk of airborne contamination with a minimum of 20 air changes per hour. Air is filtered before it enters the operating theatre and travels from the cleanest areas to the more contaminated ones, but the air flow is disrupted if theatre doors are left open. Smoke tests may be used to assess how air flows through operating theatres. Ultraclean theatres with laminar flow hoods have been developed for use during orthopaedic implant surgery but their use in neurosurgery is problematic because of the difficulties of positioning equipment, especially the operating microscope.

The temperature and humidity of operating theatres are also regulated. An average temperature of 20–22°C is comfortable for most theatre teams but warming blankets and the infusion of warmed intravenous fluids must be used to prevent patient hypothermia.

Special consideration is needed to ensure and maintain sterility during instrumented spine and implant surgery. This may include minimizing the number and entry of theatre personnel and using a 'no-touch technique' skin preparation, equipment sterilization, and intraoperative antibiotic prophylaxis to minimize the risks of infection are considered in detail in Chapter 94.

In 2009 the World Health Organization (WHO) published a landmark study that found that implementing a systemic process of checks can reduced safety incidents by up to a third (Haynes et al., 2009). The National Patient Safety Agency's (NPSA) launched the 'five steps to safer surgery' initiative in 2010 and all NHS healthcare organizations are now obliged to use the WHO Surgical Safety Checklist (**Fig. 4.2**). The aim of the initiative is to reduce harm associated with perioperative care and to support a change in culture within the theatre environment leading to better communication throughout the team. The five steps are: (1) preoperative team briefing; (2) sign in; (3) time out; (4) sign out; and (5) postoperative team briefing.

Surgical patient positioning

The central piece of equipment in the operating theatre is the operating table. Modern neurosurgical operating tables are radiolucent with interchangeable head and leg sections and are set on an offset column base that allows the table top to be moved cranially or caudally and tilted in all planes. Head-up positioning is used for most neurosurgical procedures as it reduces intracranial pressure and venous haemorrhage. Excessive head-up positioning however should normally be avoided because of the risks of air embolus, subdural postoperative pneumocephalus, and watershed infarction. Skull fixation is indicated in most microsurgical procedures to ensure that the head position is fixed in an optimal position with consideration given to the resulting angulation of the skull base, the desired surgical corridor, and the need to minimize brain retraction. Skull fixation is especially important when intraoperative image guidance systems are used, and it is also required for many cervical spine operations.

Skull fixation is achieved by using a pin-fixation device such as the three-point fixation Mayfield clamp. Tension rings of 20, 40, 60, and 80 lbs are marked on the rocker pin with 60 lbs of tension providing secure fixation in an adult. When positioning the pins it is important to avoid the squamous part of the temporal bone, the supraorbital ridge, implanted shunt devices, and large frontal sinuses. Skull fixation should be used with care in paediatric patients and is generally best avoided as it can result in skull perforation and extradural haemorrhage.

Various surgical positions are used in neurosurgery and each surgeon will develop their preferred position for each operation. Common surgical positions include the supine, prone, park-bench, and sitting positions (**Fig. 4.3**). Close collaboration with the anaesthetist is essential in ensuring the patient is placed in the optimal surgical position but every member of the surgical team must remain vigilant to the potential complications of improper positioning. Bony prominences are at risk of pressure damage during surgery and must be well padded, while the patient's eyes must also be covered to protect them from pressure and to avoid injury from alcoholic cleaning solutions. Peripheral nerve injuries may be caused by pressure or traction palsies with the ulnar and common peroneal nerves most at risk, especially when operating in the lateral (park-bench) position. In the sitting position there is an increased

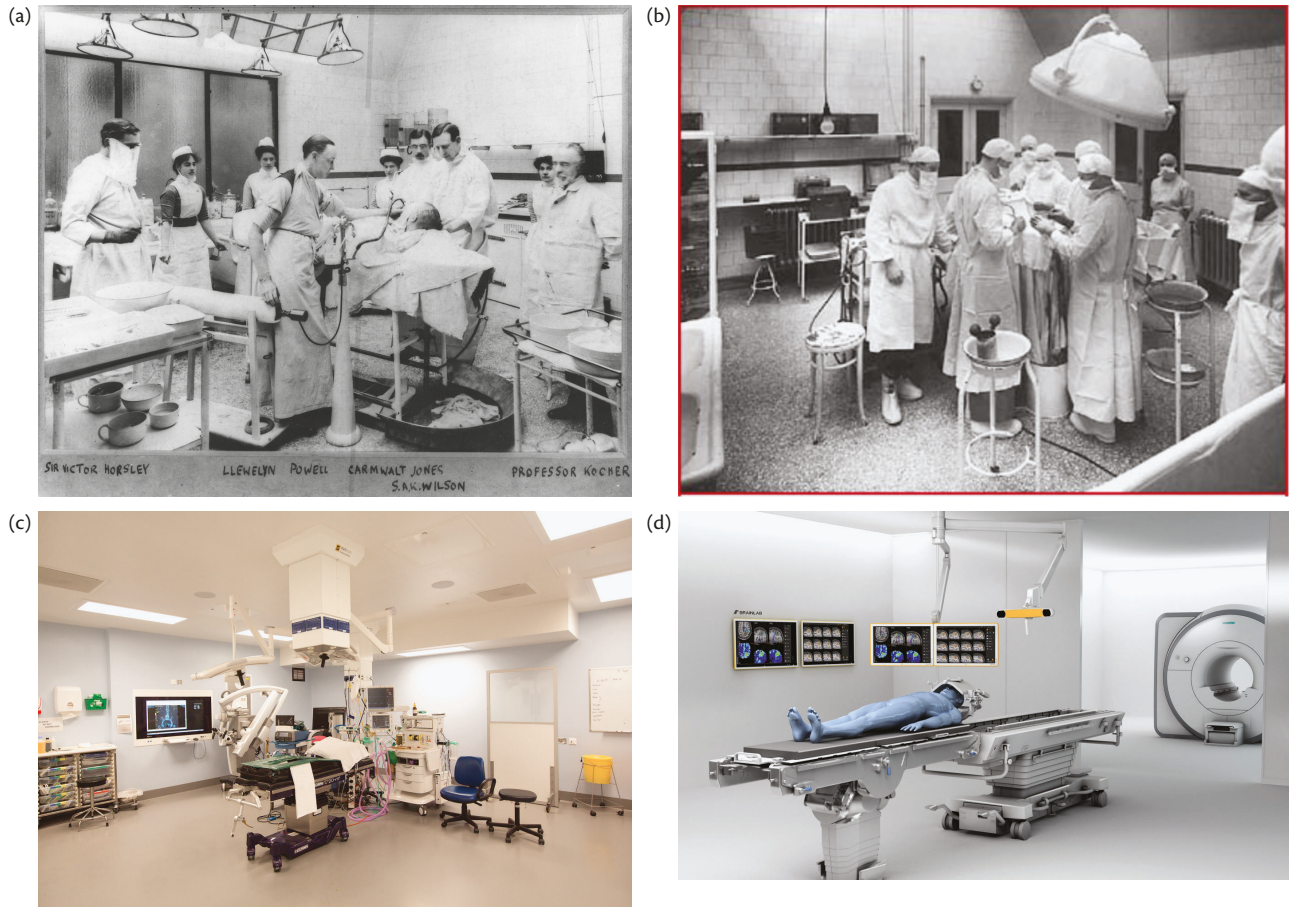

Fig. 4.1 Neurosurgical operating theatres. (A) Victor Horsley in the operating room at Queen Square Hospital, 1906; (B) 1930s operating theatre; (C) The modern neurosurgical operating theatre; (D) intraoperative MRI suite.

risk of air embolism (evidenced most rapidly by a rise in end tidal CO_2), and there is a small risk of blindness associated with surgery performed in the prone position as a result of increased intraocular pressure and reduced optic nerve perfusion pressure. Improper skull fixation can also cause scalp necrosis or local haematomas.

Positioning equipment in theatre to optimize surgical performance

The surgeon needs to consider the position of theatre personnel during a procedure. The surgical assistant should not be positioned between the surgeon and the scrub nurse, excess unused equipment should not be in theatre. Drills, ultrasonic aspirators, and bipolars must be positioned so the surgeon can use them with their dominant hand and without wires crossing the operative field. Image-guidance cameras should be positioned in such a way that the microscope and theatre staff do not obstruct the line of site to the patient. Sound levels in theatre should not be at a level where the surgeon, anaesthetist, and other theatre staff cannot communicate effectively.

Hypoglycaemia, coffee, and a full bladder may all affect a surgeon's ability to conduct microsurgery. Surgeon comfort is not a luxury but a necessity for safe surgery. Some retractor systems and chairs will allow a surgeon to rest their elbows and wrists on a firm surface and this is very useful in minimizing fatigue. Some surgical positions, notably the sitting position require that the surgeon operates with arms elevated in a way that makes fatigue problematic. Long operations may be best performed by surgical teams so that rests can be taken as required.

Theatre equipment

The neurosurgeon needs to be familiar with many types of surgical equipment and to cover all these is beyond the scope of this chapter, but the following equipment merits special consideration.

Operating microscope

There remains considerable controversy regarding who invented the first true microscope, but it is thought to have been developed in the late sixteenth century. It was Carl Zeiss, a German machinist working with the physicist Ernst Abbé who revolutionized lens making and microscope manufacturing. By the early twentieth century, the microscope was an integral part of laboratory medical research but was not used in the operating room until 1921 when Carl Nylén, a Swedish otolaryngologist, used a microscope to operate on a patient with chronic otitis media. Zeiss introduced their first series operating microscope in 1953 and in 1957 Theodore Kurze became the first neurosurgeon to use the microscope on a patient, removing a neurilemmoma of the seventh nerve in a 5-year-old

child. The first microneurovascular case was performed in 1960 by Raymond Donaghy. He also established a microsurgical training laboratory in Vermont where a young Gazi Yasgaril was sent to learn this emerging technique. More than anyone else, Yasgaril publicized the advantages of microscopic neurosurgery and made the operating microscope an integral part of modern neurosurgery (Kriss and Kriss, 1998).

The modern microscope enables the operating surgeon to see three dimensional images at high magnification. The main components of a modern microscope are the objective lens, the binocular tube, the light source, a motorized zoom system, and the suspension system. The design of the operating microscope ensures that high-quality lighting runs exactly parallel and very close to the optical path. The two eye fields are also close together, permitting binocular vision can be achieved at the bottom of a deep, narrow wound. The more a microscope is zoomed in the less depth of field the surgeon has so the surgeon should attempt to keep the microscope as close as possible to the patient. However, a good working distance between the microscope and the wound is required to allow instruments to be used without clashing with each other or the microscope. Modern microscopes have electric variable objective lenses with focal lengths from 200 to 500 mm and the focal length is virtually identical to the working distance. Eyepieces are used to re-magnify the intermediate image 10-fold and can be used to compensate for ametropia. In order to allow free movement of the microscope preoperative balancing is essential, and drapes must not restrict microscope movements.

Modern microscopes are also commonly fitted with two additional light sources; an infrared 800 nm light allows visualization of blood flow using intraoperative fluorescence and blue 400 nm light is used for fluorescence-guided tumour surgery.

Surgical endoscope

Neuroendoscopy was first performed in 1910 when urologist Victor Lespinasse used a paediatric cystoscope to treat paediatric hydrocephalus by attempting endoscopic coagulation of the choroid plexus (Abd-El-Barr and Cohen, 2013). Following this, Dandy and Mixter attempted endoscopic fenestration of the third ventricle for the treatment of hydrocephalus in the 1920s but true advances in neuroendoscopy came in the 1970s with technological developments in optics and electronics (Liu et al., 2004).

The amount of intraoperative illumination and vision under the microscope is determined by the surgical approach and may be

significantly limited in cases where the surgical corridor is long and narrow. Modern endoscopes are able to bring increased light intensity into the surgical field and provide an extended viewing angle with better magnification in close-up positions. Other potential advantages of endoscopic surgery include minimal tissue disruption and brain retraction, improved cosmetic results, shorter hospital stay, and reduced surgical morbidity.

Two main types of endoscopes are available; namely, fibreoptic flexible and rigid rod lens systems. Both types of endoscope use a xenon light source that is transmitted via a fibreoptic cable to the endoscope. Fibreoptic flexible endoscopes transmit the image through a group of tightly packed fibreoptic threads and are smaller and more malleable than rigid solid lens endoscopes. Rigid endoscopes are more expensive than fibreoptic endoscopes, but they provide superior image resolution and light transmission through a series of lenses. Some endoscopes have a working channel that allows the insertion of compatible instruments such as microforceps, endoscopic scissors, monopolar diathermy, or Fogarty balloon catheters. Irrigation channels allow the constant irrigation of fluid to clear debris from the lens and bleeding from the surgical field. Endoscopes come with a variety of lens angles (0°, 30°, 70°, and 120°) to allow visualization of hidden parts of the surgical field although intervention is usually only performed using 0° and 30° scopes.

Neuroendoscopic procedures were initially limited to the ventricles of the brain but the endoscope is now used in treating a wide spectrum of neurosurgical pathology. H.D. Jho pioneered the endonasal endoscopic approach for pituitary surgery (Jho and Alfieri, 2001) and its application to other skull base pathologies continues to expand (Paluzzi et al., 2012). The endoscope is also utilized in spinal surgery, particularly for thoracic procedures. It is important to select an appropriate endoscope with the desired characteristics for the procedure being performed. For instance, a non-channelled fibreoptic scope may be appropriate for a diagnostic ventriculostomy but a rigid solid multichannelled lens endoscope is preferable when performing endoscopic endonasal surgery. Despite endoscopy being a rapidly expanding field endoscopic surgery is still not practised routinely by all neurosurgeons and there is consequently a steep learning curve. Appropriate training is essential and collaboration with consultants from other specialties, such as otolaryngology, who are experienced in endoscopy, may shorten the difficult learning phase and reduce operative time and surgical morbidity.

Fluorescent agents

Indocyanine green (ICG)

Indocyanine green (ICG) is the commonest fluorescent agent used for intraoperative angiography. It has a peak spectral absorption at around 800 nm following intraoperative intravenous injection and due to its tight binding to plasma proteins, becomes confined to the vascular system, permitting excellent intraoperative angiography.

5-aminolevulinic acid (5-ALA)

Fluorescence-guided tumour surgery is performed following the oral administration of 5-aminolevulinic acid (5-ALA) approximately 2–4 hours before anaesthesia. Once administered patients should avoid direct sunlight due to the risk of developing a photosensitivity skin reaction. 5-ALA is a natural precursor of protoporphyrin IX (PpIX) in the haem biosynthesis pathway and excess 5-ALA provides selective and abundant accumulation of PpIX in malignant glioma cells but only slight or no accumulation in the normal brain. 5-ALA in itself is not fluorescent but PpIX is a highly fluorescent substance with maximal absorption at 440 nm, thus enabling the surgeon to differentiate between pathological tumour and normal brain intraoperatively.

Fluorescein

Fluorescein is a synthetic organic compound available as a dark orange/red powder. It is soluble in water and is widely used as a fluorescent tracer for many applications. In neurosurgery, intrathecal fluorescein administration has become an important tool in the diagnosis and localization of cerebrospinal fluid (CSF) leak and is used intraoperatively to assist in localizing the site of skull base defects. Current recommendations of fluorescein administration suggest removing 10 ml of the patient's CSF and replacing it with an equivalent injection of a 10 ml dilute solution of fluorescein into the intrathecal space. The dilute solution is bright green in colour and does not usually require visual augmentation; however, a blue light filter can assist in localization of fluorescein-coloured CSF at the skull base in equivocal cases.

Drills

Modern high-speed surgical bone drills may be pneumatically or electrically powered. The rotational speed of a drill is measured in revolutions per minute (rpm) and pneumatic drills can generate up to 100 000 rpm. Electric drills have adjustable speeds from 200 to 75 000 rpm and are smaller, lighter, and more easily manoeuvrable, although they do not provide the same level of power as pneumatic drills.

Various drill bits may be attached to the drill depending on the surgical need. **Table 4.1** illustrates some of the commonly used drill attachments and how they are used in cranial and spinal neurosurgery.

Retractors

The brain retractor was first introduced by Harvey Cushing and Victor Horsley in the early twentieth century and has since been a key neurosurgical instrument. Brain spatulas are either rectangular or tapered and are available in a variety of sizes. Articulated arms, such as the Yasargil Leyla retractor, were designed to stabilize the spatula while in use and various retractor systems have since been developed to provide a solid anchoring platform for retractors (Dujovny et al., 2010).

Inappropriate or prolonged brain retraction has the potential to cause cortical contusions, vessel injury, brain swelling, and neurological deficit and the incidence of brain retraction injury has been observed to be as high as 10% in some series (Spetzler et al., 1992). Other surgeons advocate the avoidance of retractors altogether—and certainly careful patient positioning, so that gravity assists rather than hinders the surgeon, draining cerebral spinal fluid, mannitol infusion, skilled anaesthetics, and surgical patience all contribute to make excessive retraction unnecessary. Judicious and careful use of brain retraction can minimize retraction related complications and such techniques include the placing of surgical linteens under the

Cutting burr - Rapid circumferential bone removal		Straight short/large bore attachment	
Diamond burr - Provides extra control when drilling due to slow bone removal - Generates heat for 'hot-drilling' - Can be used safely to drill bone over venous sinuses (e.g. translabyrinthine approach)		Straight variable exposure attachment (10 mm adjustment)	Acorn - Rapid vertical bone removal - Often used for creating 'mini' burr holes as part of turning a craniotomy flap		Angled short/large bore attachment	

Medtronic, Midas Rex.

retractors, avoiding firm retraction, and the use of silicon coated retractor blades.

Diathermy

Diathermy is used for cutting tissues and haemostasis. Heat is generated by the passage of high-frequency alternating current through body tissues. Currents of up to 500 mA are safe at frequencies of 400 kHz to 10 MHz and locally concentrated high-density currents can generate temperatures of up to 1000°C. There is no stimulation of neuromuscular tissue at frequencies above 50 kHz.

There are two distinct types of diathermy.

Monopolar diathermy

Monopolar diathermy uses a high-power unit (400 W) to generate high-frequency alternating current that passes from a tipped electrode (high current density), via a ground plate (with a low current density) back to the generator. The voltage used changes the mode of diathermy. Cutting diathermy uses continuous low voltage output (500–1000 V) to generate high local temperature that causes superficial tissue disruption and water vaporization but minimal vessel coagulation and haemostasis. The alternative coagulation setting generates pulsed high voltage output (up to 6000 V) of high-frequency current at short intervals resulting in tissue water vaporization and vessel coagulation. Many diathermy machines will also allow a blend of cutting and coagulation.

Monopolar diathermy does not work in a wet field and can cause heat to spread, damaging the surrounding (1–2 cm) tissues. Incorrect placement of the patient electrode plate is the most common cause of accidental diathermy burns. To minimize the risk of complications the patient electrode plate should have a surface area of at least 70 cm^2 and be placed with good contact on dry, shaved skin away from bony prominences, metal prostheses (e.g. hip replacements) and scar tissue.

Monopolar diathermy should be used with caution in patients with a history of arrhythmias and cannot be used in patients with a cardiac pacemaker due to the risk of causing cardiac arrest. There are case reports of alcoholic skin prep catching fire if not left to dry before diathermy is used.

Bipolar diathermy

Bipolar diathermy uses lower power (50 W) to generate high-frequency alternating current that passes between the two tips of diathermy forceps. It uses a 1 MHz waveform for both cutting and coagulation and because it only uses 140 V it can be used in patients with pacemakers and defibrillators. There is no need to use a patient electrode plate and bipolar diathermy can be used effectively in a wet environment.

Forceps vary in length and tip sharpness. Coagulated, charred tissue can stick to the forceps and they must be kept clean to avoid this risk. Modifications available include irrigating bipolar forceps and cooler tipped forceps that make this risk less likely.

Ultrasonic aspirators

Ultrasonic aspirators are vibrating surgical instruments which utilize ultrasound as a physical energy to fragment (cavitate), emulsify, and remove unwanted tissue. Examples of ultrasonic aspirators used in neurosurgery include the Cavitron Ultrasonic Surgical Aspirator (CUSA) (Integra) and Sonopet (Stryker). The hollow titanium tip vibrates along its longitudinal axis generating an ultrasound frequency of 20–60 kHz and all models allow the surgeon to specify the level of vibration, irrigation, and suction in order to achieve maximal control during tissue dissection. The CUSA includes a supplementary Tissue Select function that further regulates the relative

tissue fragmentation rate and some aspirators (e.g. Sonopet) permit fine bone dissection by coupling longitudinal vibration with torsional vibration.

Ultrasonic surgical aspirators provide ultrasonic cavitation, irrigation and aspiration in a single hand-held unit which helps to limit instrument traffic within the surgical field and improve the surgeon's view. The selective fragmentation of target neural tissues also reduces the risk of vessel injury, but one must be mindful of causing collateral damage from thermal injury and the risk of developing indistinct 'false' tissue planes.

Haemostatic agents

Achieving and maintaining haemostasis in neurosurgery is critical to the outcome. Various haemostatic agents have been developed and target different elements of the clotting cascade (Fig. 4.4 and Table 4.2) (Grant, 2007). Some of these agents may swell in the postoperative period and care should be taken to avoid leaving haemostatic agents in places where swelling will cause neurological compression. This is especially relevant in the spine. Some haemostatic agents may result in MR artefacts making postoperative assessment of residual tumour difficult.

Problematic bleeding can also be controlled by changing the patient position, tranexamic acid, haemostatic clips, or muscle patches. Bees wax was developed for use in neurosurgery by Victor Horsley, and is now widely used to stop bleeding from bone edges.

Neuronavigation

Imaging techniques have revolutionized the practice of neurosurgery and have become essential in guiding diagnosis, preoperative planning, and intraoperative navigation. In particular, image-guided surgery has become an indispensable modern neurosurgical technique and is applicable to numerous neurosurgical procedures including neuro-oncology, vascular, and functional neurosurgery.

The aim of stereotactic surgery is to register the anatomical or imaging space to the surgical or physical space in which the patient is located and in which surgery is to take place. Image guidance allows for smaller more precisely positioned incisions and accurate localization of lesions. Stereotactic neurosurgery may be frame-based or frameless.

Frame-based stereotactic neurosurgery

The concept of stereotactic localization was first applied in 1908 in the device of Victor Horsley and Robert Clark although the apparatus was only developed for work on small to medium sized experimental animals (Fig. 4.5A). The first successful cranial application of stereotactic surgery in humans is credited to the team of Ernest Speigel and Henry Wycis in 1947 but it was Lars Leksell, a Swedish neurosurgeon, who developed the arc-centred stereotactic frame system following a visit to Wycis in Philadelphia in 1949. Leksell's frame consisted of a rectangular base ring attached to the skull

with four pins and used three polar coordinates (angle, depth, and anterior–posterior location). The three coordinates always indicate the centre of the arc, representing the target, and the arc-centred device allows maximum flexibility in choosing the probe entry point and trajectory. The frame has been modified over the ensuing years, but remarkably remains very similar in function and appearance to the original 1949 device (**Fig. 4.5B**).

Another commonly used frame system is the Cosman-Roberts-Wells (CRW) Precision™Arc System (**Fig. 4.5C**). It has an N-shaped 'picket-fence' localizer ring and the lesion is placed at the centre of a stereotactic sphere with a fixed radius that allows free selection of an unlimited number of entry points. The CRW Precision™ Arc System also has a phantom base that can be used to confirm the target before applying the settings to the patient. Computed tomography (CT) and MRI compatible models of both Leksell and CRW Precision™ Arc Systems are available.

The advent of high-resolution MR imaging has transformed stereotactic surgical planning. Stereotaxy is no longer reliant on anatomical atlases and is usually performed on a computer workstation that allows the planning of targets and trajectories on a computer-generated 3D model. Frame-based stereotaxy has the highest degree of precision and, although largely superseded in general intracranial practice by frameless stereotactic techniques, continues to be used for cases where target placement is critical including, for example, functional lesioning and electrode or catheter placement, biopsy of small or deep lesions, and gamma knife stereotactic radiosurgery.

Frameless stereotactic neurosurgery

Frameless stereotaxy involves the use of bony landmarks, facial features, or fiducial markers to coregister the patient's skull relative to a 3D volumetric image obtained prior to surgery. Fiducials are adhesive markers, visible on both CT and MRI, and are placed on a patient's head, covering as much of the geometry of the head as possible but centred on the target lesion. For optical registration, the patient's head is fixed using a pin-fixation device and infrared reflective spheres arranged in a predetermined geometrical configuration and anchored to the same fixation device. An infrared camera detects light reflected from the spheres.

Registration is performed by the surgeon and computer software correlates the imaging studies with the defined anatomical landmarks of the patient's head. Registration remains accurate so long as the patient's head remains in same position relative to the reflectors. Registration accuracy can be enhanced by collecting as many registration points as possible, by using fiducials and by spreading anatomical registration points around the head as much as possible.

Electromagnetic (EM) registration involves generating an electromagnetic field around the patient's head in order to triangulate the position of instruments and intraoperative tools. EM navigation does not require the head to be fixed and is especially useful when the head cannot be fixed easily (e.g. shunt or paediatric surgery). EM systems track the tip of the surgical instrument and can therefore be used to track the tip of a flexible endoscope.

A registration error is a computer-generated number that denotes the degree of deviation from the ideal image-to-patient correlation. Acceptable registration accuracy depends on the size of the target lesion. Volumetric registration enables the surgeon to view images in three orthogonal planes and once registered, instruments fitted with reflective spheres may be used by the surgeon to relate the position of the instrument to the images in real time. Additional image sequences such as functional imaging and tractography can also be merged with the volumetric data enabling the surgeon to view these intraoperatively. Image-guidance systems have also been adapted for use in spinal instrumentation surgery and can be linked to operating microscopes so that the focal point of the microscope is used as the image-guidance pointer and so that image-guidance data can be overlaid in the operators view down the microscope.

Frameless image-guidance systems are a significant technological advance and an essential piece of modern neurosurgical equipment however one must be aware of their limitations. Inaccuracies in registration may occur as a result of intraoperative brain shift following loss of cerebrospinal fluid or tumour resection, because of movement of the patient, the reference frame, or fiducials, and because of a loss of line of sight between the camera and infrared reflectors. In cases where submillimetre accuracy is required and a fixed trajectory is acceptable, a frame-based system is preferable.

Intraoperative imaging

X-ray

Mobile X-ray image intensifiers are commonly used in the neurosurgical operating theatre for a variety of applications, including localization of the correct anatomical level during spinal surgery, imaging during spinal instrumentation, and for localizing other bony anatomy such as skull base foraminae or the pituitary fossa.

Mobile image intensifiers typically consist of a single unit with a low intensity X-ray source and an image intensifier positioned directly opposite each other on a mount. The mount, often referred to as a C-arm, may be rotated and translated around the patient as required. Mobile image intensifiers can provide good spatial resolution of bony anatomy and are quick and cheap to use, although the image quality is dependent on operator experience and the patient's body habitus.

Imaging during spinal instrumentation helps to ensure that the desired anatomical alignment is achieved and assists in the accurate

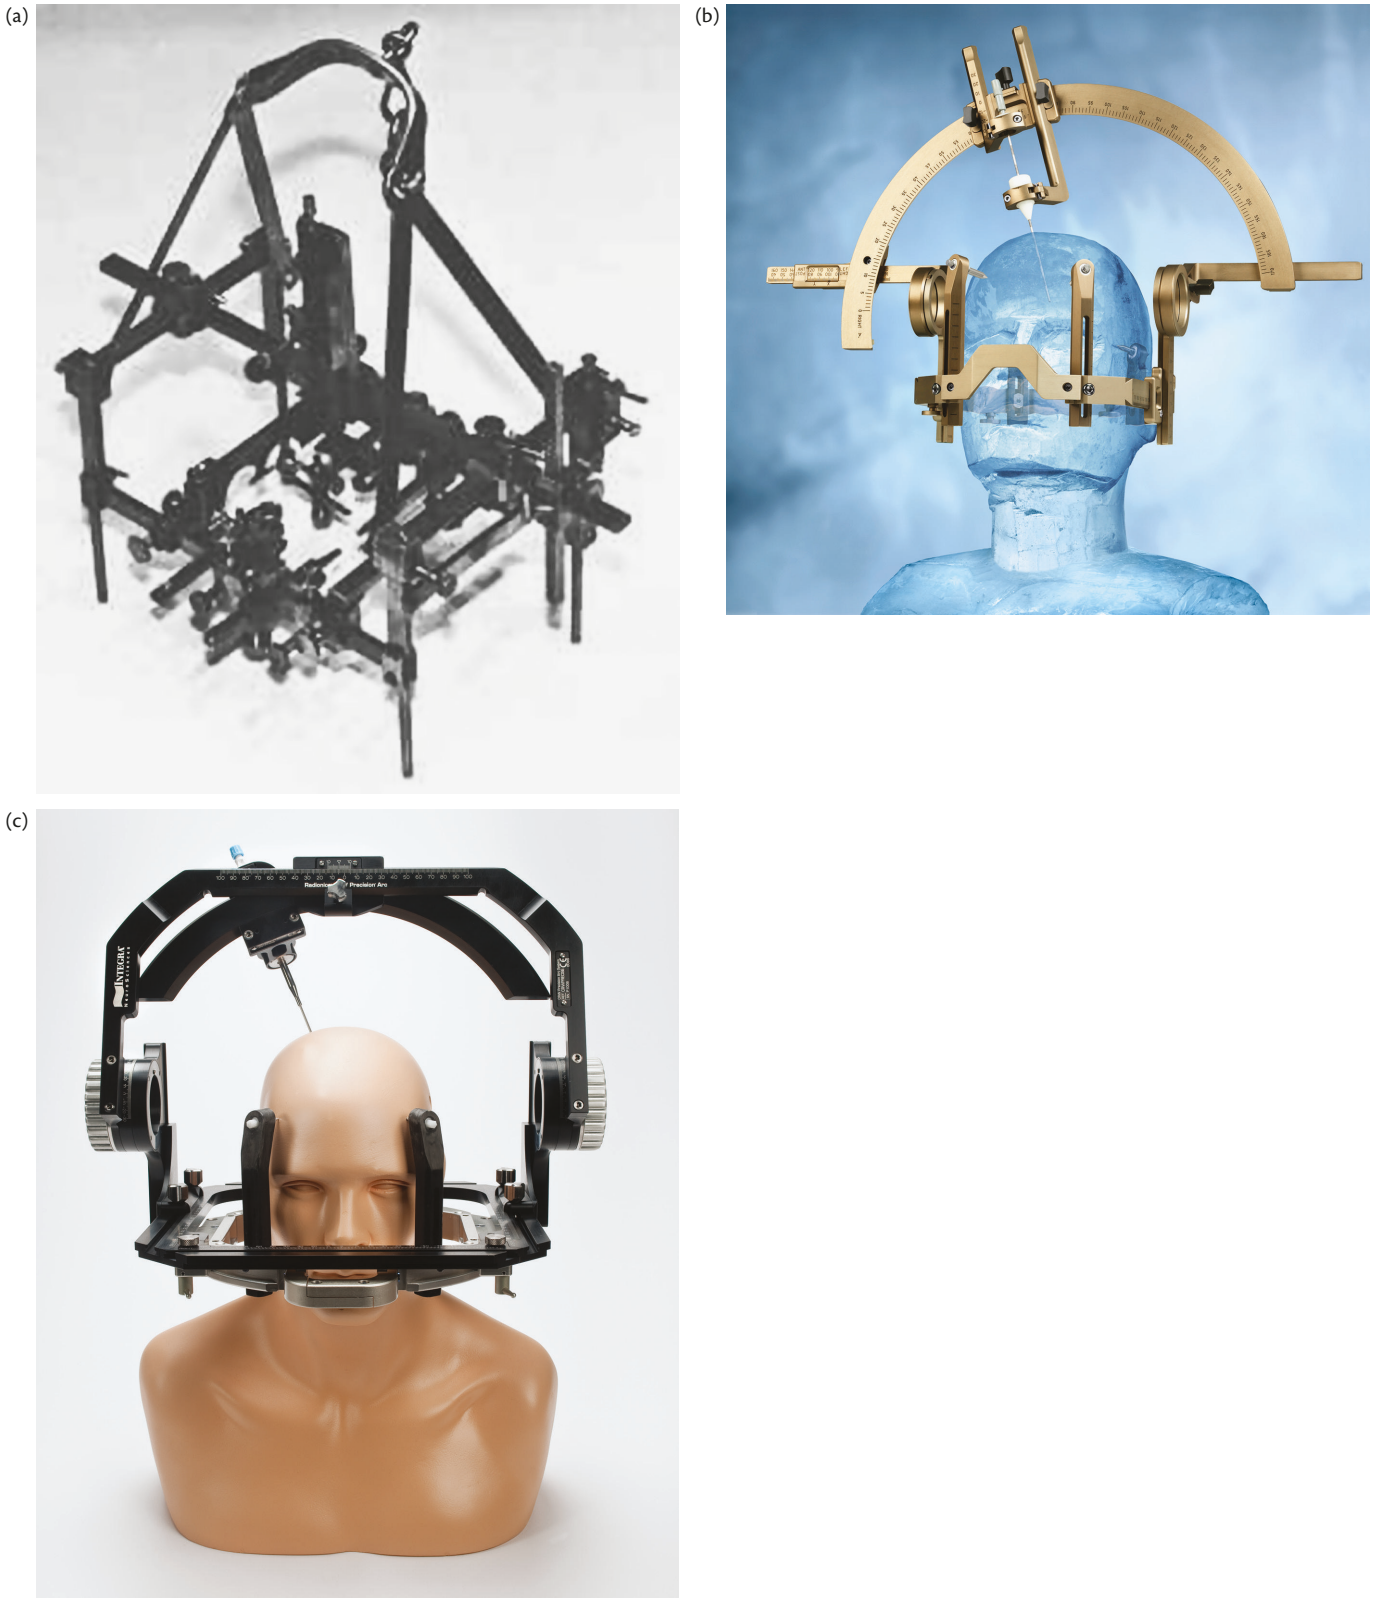

Fig. 4.5 Stereotactic frames: (A) Horsley-Clarke stereotactic frame (1908); (B) Leksell stereotactic frame; (C) CRW Precision™Arc System.

placement of implanted metalwork, such as pedicle screws. A radiolucent operating table should be used if fluoroscopic imaging is to be used intraoperatively to permit anterior–posterior views in addition to lateral views. Ensuring accurate screw positioning from 2D imaging can be difficult, particularly where there is abnormal anatomy or where complex instrumentation is used. Newer imaging

techniques are being introduced to overcome this difficulty including dedicated 3D equipment such as '3D C-arms' or the 'O-arm', and neuronavigation techniques incorporating registered fluoroscopic images with preoperative 3D CT scans.

Ultrasound

Intraoperative ultrasound is a relatively inexpensive technique that has the potential to provide surgeons with fast, real-time imaging. Ultrasound imaging relies on the use of high-frequency sound waves to image tissues. Sound is defined as mechanical energy travelling through matter as longitudinal waves producing alternating zones of compression and rarefaction. Intraoperative ultrasound uses a transducer to transmit ultrasonic waves in the range of 5–10 MHz into tissues.

Where there are interfaces of different tissue density, energy is reflected back by the tissue towards the transducer as 'echoes'. The amount of energy reflected depends on a tissue's acoustic impedance, which is proportional to the density of the tissue propagating the sound wave. Echo vibrations are then converted to electrical pulses and used to produce representative images. Greyscale or Brightness (B-mode) is the mainstay of anatomical ultrasound imaging and provides 2D greyscale images of tissues based on their relative echogenicity. Doppler ultrasound can also be incorporated into intraoperative ultrasound. The doppler effect describes a change in the frequency of sound when a sound wave encounters a moving interface, such as blood within an artery and blood flow may be mapped in colour on real-time ultrasound images.

Intraoperative ultrasound is very operator dependent and image interpretation is associated with a learning curve as most surgeons are unfamiliar with this imaging modality. Ultrasound is unable to penetrate through bone and so cannot be used for planning a craniotomy and it has limited penetration through to deeper structures meaning that careful case selection is required. Intraoperative ultrasound has been used in treating a variety of pathologies but is most frequently used during glioma surgery. Some navigation machines are now also capable of coregistering the ultrasound pictures with a reconstructed plane from the pre-op MR scan. Intraoperative doppler ultrasound has a role in neurovascular surgery and some surgeons also use ultrasound to demonstrate adequate CSF flow following foramen magnum decompression.

Intraoperative MRI (iMRI)

Neurosurgeons have become increasingly dependent on image guidance to perform optimal, safe, and efficient surgery. Routine neuronavigation systems do not allow the neurosurgeon to adjust for intraoperative brain shift and this consideration led to the development of intraoperative MRI systems (Fig. 4.1D) (Hall and Truwit, 2008). The principal feature of iMRI systems is the ability to acquire contemporaneous imaging during surgery to inform surgeons on the extent of resection achieved in order to guide further surgical decision making and most iMRI systems also allow the new images to be registered onto the neuronavigation system.

iMRI systems may be vertically or horizontally open. In vertically open systems the patient remains within a fixed position and the surgeon works within the confines of the scanner. All surgical instruments must be MR compatible and various levels of shielding of other equipment must be maintained. Images can be easily and quickly acquired at any point during the procedure without moving the patient or the magnet however vertically open systems are typically low field scanners (0.3–0.5 T) so the standard of the images obtained are not of the same quality as those generated by standard diagnostic imaging techniques.

Horizontally open iMRI systems include a high-field magnet (1.5–3.0 T) located within an integrated operating theatre (Fig. 4.1D). The table can slide or pivot out of a marked magnetic field line (5-Gauss line), allowing surgery to be performed in the usual manner using standard instruments and equipment until a scan is required. New high-field horizontally open iMRI scanners produce higher quality images allowing greater versatility and acquisition of functional MRI, MR angiography, MR venography, MR spectroscopy, and tractography. The disadvantages of this system include the significant cost required to build the intraoperative suite and the increased time spent intraoperatively manoeuvring the patient in and out of the scanner.

Intraoperative neurophysiological monitoring

Intraoperative neurophysiological monitoring offers a real-time, continuous assessment of the nervous system integrity and is considered essential for various types of neurosurgical procedure (Gonzalez et al., 2009). It is vital to consult with an expert neurophysiologist before the procedure to ensure that the most appropriate modality is selected and results must always be interpreted in the context of the surgical procedure being performed. For this reason, it is helpful to have a neurophysiologist in the operating theatre during surgery. Intraoperative monitoring can be significantly affected by anaesthetic agents so close collaboration with the anaesthetist is also essential.

Sensory evoked potentials

The visual, auditory, and somatosensory systems can be stimulated and evoked potentials can record the biofeedback response of the nervous system to these external stimuli. The recordings give information on the sensory pathway from the peripheral nerve to the level of the cortex.

Somatosensory evoked potentials (SSEP)

Somatosensory evoked potentials (SSEPs) are produced by short (0.1–1.0 msec) electrical stimulation (1–5 Hz) of a peripheral nerve and the generated responses are recorded over a proximal part of the nerve or sensory pathway. Recording electrodes are placed in named, reproducible locations. Each location is designated by a letter; N (negative deflection) or P (positive deflection) and a number that corresponds to the latency of wave. The median or tibial nerve is usually stimulated and SSEPs are monitored in terms of latency and amplitude.

The SSEP waveform is often quite variable and should therefore be monitored before surgery begins and throughout the procedure. To separate the SSEP signal from background noise a technique called signal averaging is used to combine a large number of SSEP signals. The time required to perform signal averaging means that SSEP changes may not be seen until a few minutes after the neurological injury has occurred. A decrease of about 50% in amplitude or a 10% increase in latency of the SSEP waveform is considered to be significant. Inhalational anaesthetic agents, fluctuations in blood pressure,

hypothermia, and oxygenation can all affect SSEPs to varying degrees so close consultation with the anaesthetist is needed beforehand to ensure stable anaesthesia is achieved. In thoracic spinal surgery, the upper limb SSEP signal can be used as a control. Continuous SSEP monitoring of the dorsal columns is commonly used during spinal cord and complex spine surgery and is considered essential for scoliosis surgery (Thirumala et al., 2014). Cortical mapping with SSEPs can also be used in epilepsy surgery or sensorimotor and insular cortex tumour surgery.

Visual evoked potentials (VEP) and brainstem auditory evoked potentials (BAEP)

Intraoperative visual evoked potentials (VEPs) and brainstem auditory evoked potentials (BAEPs) are less commonly used. VEPs can be evoked by patterned or unpatterned stimuli and may be used during surgery around the optic chiasm or optic tract however results under anaesthesia are not reliable. BAEPs record a waveform composed of seven discrete waves after an auditory stimulus is delivered to the external auditory canal. Each wave corresponds to a specific locus of the auditory system from the organ of Corti to the auditory cortex. BAEPs may be used during hearing preservation vestibular schwannoma surgery or during microvascular decompression for hemifacial spasm.

Motor evoked potentials

Motor evoked potentials (MEPs) are generated by stimulating the motor cortex, spinal cord, or a peripheral nerve with an electrical or magnetic stimulus. Transcranial magnetic stimulation is preferred in preoperative mapping because it is less invasive but transcranial electric stimulation using corkscrew or needle electrodes is usually performed intraoperatively. Neurogenic MEPs are recorded directly from the spinal cord or from peripheral nerves. Neurogenic MEPs generate two types of wave: direct propagation of the stimulus along the corticospinal tract generates direct waves (D waves), while indirect waves (I waves) are caused by activation of adjacent cortex. Myogenic MEPs record the muscle response (M response) of a specified muscle by using electromyography (EMG) recording. The M response reflects the motor unit action potential (MUAP) and represents the summated action potentials of the muscle fibres of one motor unit.

Inhalation anaesthetics have a significant effect on MEPs, in particular I wave responses. D waves are not affected by inhalation anaesthetics, but the α-motor neurone is blocked at higher doses, even when stimulated by transcranial electric stimulation. Intravenous anaesthetics only have a mild effect on MEPs and total IV anaesthetic using propofol and etomidate is typically preferred when using MEPs as they are less suppressive than gases at similar depths of anaesthesia. However, excessively high doses of propofol may be similarly suppressive to inhalation agents. Benzodiazepines are usually avoided because they eliminate MEP responses. Neuromuscular blocking agents do not affect neurophysiological monitoring and can actually enhance I wave recordings but MUAPs cannot be recorded when the neuromuscular transmission of acetylcholine is completely blocked. The anaesthetist observes the M-responses to evaluate the degree of neuromuscular blockade.

MEPs can monitor the dorsolateral and ventral spinal cord tracts during spinal cord and complex spine surgery and complements SSEP monitoring of the dorsal columns (Schwartz et al., 2007). Monitoring of pudendal MEPs and sacral EMG recording from the anal sphincter is used when performing selective dorsal rhizotomy for the treatment of spasticity and helps identify nerve rootlets that can be selectively sectioned.

Unlike SSEPs, MEPs are not usually monitored continuously as the patient may move following a stimulation. The surgeon and neurophysiologist also need to work together to ensure frequent MEPs are obtained without disrupting the surgery.

Electromyography

A recording electrode is placed inside a needle and inserted into a muscle to record the MUAP of that muscle. Signals are then converted into sound to demonstrate muscle activity. Evoked EMG uses electrical stimulation to identify specific nerves whereas free-running EMG is used to identify any interruptions to the nerve's normal electrical discharge. Spontaneous benign discharges produce short non-sustained discharges (likened to the sound of 'popcorn') and indicate proximity of the stimulus to the nerve whereas a neurotonic discharge is prolonged and indicates ongoing nerve injury.

Facial nerve monitoring is the commonest type of intraoperative EMG used in cranial neurosurgery whereby recording electrodes are placed in the orbicularis oris and orbicularis oculis muscles. Muscle activity is recorded either during a surgeon's intentional stimulation of the nerve or by inadvertent nerve stimulation during manipulation, mechanical, or thermal injury. Optimal facial nerve EMG recordings are obtained when neuromuscular blockade is avoided but facial muscles appear relatively resistant to the effects of muscle relaxants. Hartman's solution irrigation should be used instead of saline irrigation to avoid stimulation of the facial nerve. EMGs are also used to monitor muscle group activity during selective dorsal root rhizotomy for spasticity and spinal root monitoring is considered a key component of multimodality spinal monitoring used during spinal instrumentation.

Intraoperative cortical mapping (brain mapping)

Intraoperative brain mapping is typically used to locate the motor, sensory, or speech cortex during epilepsy or tumour surgery in and around eloquent areas. Phase reversal SSEPs may be utilized in anaesthetised patients to localize the primary sensory or motor cortex whereby a strip grid is placed on the surface of the brain perpendicular to the anticipated orientation of the central sulcus. A phase reversal of the N20/P20 peak indicates that those electrodes straddle the central sulcus. In awake patients, direct cortical stimulation may be used to map the motor cortex.

For speech mapping in the temporal lobe, a recording electrode strip is placed on the brain surface and the cortex is then stimulated using a bipolar cortical stimulator. The stimulating current is increased in small 2 mA increments, up to a maximum of 10 mA, while observing for any after discharges (akin to focal seizures). Once the patient's threshold for after discharges has been established, patients are asked to name objects shown on picture cards while the cortex continues to be stimulated and any paraphasic errors or speech arrest are noted. The aforementioned steps are then repeated so that the patient's speech area may be mapped out on the brain's surface. Awake craniotomy is usually required for brain mapping, especially for the speech areas.

The key to a successful awake procedure is patient preparation. Good patient cooperation is required, and careful patient selection

is needed to ensure the patient fully understands what will happen during surgery. Various anaesthetic and surgical techniques have been described in the context of performing awake craniotomy but a successful procedure mandates anticipation of specific problems and clinical vigilance (Erickson and Cole, 2012). Fully awake surgery is performed after the infiltration of local anaesthetic into the scalp or following regional nerve block of the scalp. The asleep-awake-asleep (AAA) technique uses general anaesthesia, with or without the use of an airway, during the opening and closing portions with emergence of patients from anaesthesia in the interim. However, the more commonly advocated anaesthesia technique for the opening and closing portions is termed monitored anaesthesia care (also called conscious sedation). The same medications used in the AAA technique are given (propofol and fentanyl) but they are given in pulses and at lower doses with the goal of providing a smooth transition to alertness and obviating the difficulties of airway intervention (Erickson and Cole, 2012).

Perioperative care of the neurosurgical patient

Karol P. Budohoski, Alessandro Scudellari, Sylvia Karcheva, and Derek Duane

Introduction

Multidisciplinary involvement in the care and planning of patients for neurosurgical procedures is now a common and necessary requirement to limit complications and promote better neurological outcomes. In the perioperative period, failings in clinical management can be devastating and cause severe disability or death (Wacker and Staender, 2014). The shared goal of the neurosurgeon along with the neuroanaesthetist acting as perioperative physician, is to facilitate optimization of the patient's clinical and psychological readiness for the operative intervention and subsequent recovery while preventing avoidable harm. To enable this, an established perioperative pathway is followed that includes performing a preoperative evaluation, completing appropriate investigations, communicating risk, complying with patient safety measures, promoting teamwork, and pursuing specific intra- and postoperative management strategies. These processes will be discussed in detail in the following sections, while highlighting their importance in the preservation of normal neurological function.

Preoperative anaesthetic evaluation

The purpose of the preoperative assessment is to optimize a patient's comorbidities and formulate a perioperative management plan. This review should follow the time-honoured tradition of history taking, examination, deciding on necessary investigations, risk assessment analysis, information sharing, and seeking informed consent. When assessing patients preoperatively, use is made of the American Society of Anesthesiologists (ASA) physical status classification system. This is one accepted method used for the stratification of a patient's pre-existing health status (**Table 5.1**).

Airway

Airway difficulty resulting in hypoxia and hypercarbia is the single most important cause of anaesthesia related morbidity and mortality. Therefore, it is vital to conduct a comprehensive examination of the airway preoperatively. Many tests to predict a difficult airway assess parameters such as mouth opening with grading of pharyngeal structures, neck mobility, and anatomical oropharyngeal measurements but none has the desired specificity and positive predictive value to be consistently useful. In the neurosurgical population, patients with cervical spine disease leading to limited movement, instability requiring a cervical collar or traction weights and those with acromegaly can all cause potential airway difficulty for the anaesthetist. To ensure adequate preoperative hydration and to help avoid gastric contents aspiration during intubation, recent guidelines encourage anaesthetists to allow adults and children to drink clear fluids up to 2 hours before elective surgery, while solid food should be prohibited for 6 hours (Smith et al., 2011).

Respiratory system

Optimizing pulmonary function is important to ensure the patient can be adequately oxygenated and ventilated intraoperatively, thus permitting respiratory manipulation of cerebrovascular physiology. Patients with neurological disorders have a higher risk of suffering aspiration pneumonia and neurogenic pulmonary oedema, both of which can adversely affect neurological outcome and survival.

Patients with a smoking habit should stop at least 6–8 weeks prior to surgery allowing for improvement in lung function and a better perioperative outcome. Acute exacerbations of infective or inflammatory airway diseases will need treatment and deferment of anaesthesia for up to 6 weeks to permit airway sensitivity to resolve. Chronic pulmonary diseases should be assessed clinically and where there is evidence of worsening impairment, further imaging and functional testing will sometimes be necessary to help clarify the risk of complications which can include postoperative ventilation. Patients who suffer from obstructive sleep apnoea especially those with acromegaly or Cushing's disease are often very sensitive to opioid analgesics and sedative agents. These patients can develop impaired respiratory gas exchange, atelectasis, and pulmonary infections without the routine use of continuous positive airway pressure prior to surgery.

Cardiovascular system

The prevalence of heart disease is common in neurosurgical patients and a careful assessment of the functional state of the cardiovascular system is necessary to reliably predict perioperative and long-term

Table 5.1 American Society of Anesthesiologists (ASA) physical status classification system

ASA grade	Definition
I	A healthy patient with no systemic disease
II	Mild to moderate systemic disease
III	Severe systemic disease imposing functional limitation on patient
IV	Severe systemic disease which is a constant threat to life
V	Moribund patient who is not expected to survive with or without the operation
VI	A declared brain-dead patient whose organs are being removed for donor purposes
	For emergency cases the suffix 'E' is used

ASA Physical Status Classification System is reprinted with permission of the American Society of Anesthesiologists, 1061 American Lane, Schaumburg, Illinois 60173–4973.

cardiac complications (Fleisher et al., 2014). In patients with the usual risk factors and a history of shortness of breath, fatigue, or chest pain while performing daily living activities, usually have poor cardiovascular reserve requiring further investigation. The revised cardiac risk index (Table 5.2) using six independent variables is helpful in assessing the neurosurgical patient's risk of cardiac complications and mortality (Ford et al., 2010).

Poorly controlled hypertension (systolic >180 mmHg and mean arterial pressure (MAP) over 110 mmHg) increases cerebrovascular resistance and causes a right shift of the cerebral blood flow autoregulatory curve resulting in poor tolerance to acute hypotension. If surgery can be postponed, weeks to months of treatment may be needed to adequately control the blood pressure otherwise perioperative management by intravenous agents can be instituted for emergency surgery albeit with increased risk of complications.

Patients who have had a recent myocardial infarction or coronary stent intervention are at a higher risk of further myocardial damage if operated on within six months. Heart failure, in particular, is a significant risk for perioperative morbidity and mortality and requires optimal treatment prior to surgery in line with international guidelines and local cardiology advice to ensure a good outcome (Yancy et al., 2013).

Patients with a newly suspected heart valve lesion need echocardiography evaluation to quantify its severity. Some patients may need a valvular intervention before their elective neurosurgical procedure to reduce their perioperative cardiac risk. In general, knowing the severity of the valvular heart disease allows choice of the appropriate anaesthetic technique as well as deciding on the best perioperative monitoring and level of postoperative care for the patient.

Cardiac dysrhythmias and conduction disorders occur more frequently with increasing age such that all patients over the age of 55 years should have a routine electrocardiograph prior to surgery. The presence of a dysrhythmia in the preoperative setting should prompt investigations into the underlying cause. Atrial fibrillation (AF) is the most common tachydysrhythmia. Patients with rate-controlled AF who are clinically stable generally do not require special evaluation in the perioperative period other than adjustment of anticoagulation. Patients who develop conduction abnormalities leading to bradydysrhythmias, or episodes of supraventricular or ventricular tachycardias require referral to a cardiologist for further evaluation and possible cardioversion to sinus rhythm or insertion of a permanent transvenous pacing device. Those patients who present for neurosurgery with implanted cardiac pacemakers or defibrillators will need their device checked for any signs of malfunction after surgery if electrocoagulation is used during the procedure.

Table 5.2 Revised Cardiac Risk Index

Revised Cardiac Risk Index	
1	High risk type of surgery
2	Ischaemic heart disease (includes any of the following: history of MI, positive exercise test, current chest pain, nitrate use, or electrocardiography with Q waves)
3	Congestive heart failure
4	History of cerebrovascular disease
5	Preoperative treatment with insulin
6	Preoperative serum creatinine >2.0 mg/dl

Neurological system

A preoperative record of the patient's neurological state using the Glasgow Coma Scale (GCS) score should be made to identify pre-existing deficits. Pupil size and reaction to light should be noted. Assessment of cranial nerve integrity is important to establish problems with bulbar function along with gag and cough reflexes. Examination of sensory and motor function will establish the presence of any anomalies. This baseline neurological examination is essential to allow comparison with a patient's postoperative state for detection of any possible deterioration in function.

Other medical conditions

Other medical disorders affecting the endocrine, renal, hepatic, neuromuscular, and metabolic systems will need to be optimized prior to neurosurgery. Electrolytes, (especially sodium and potassium) and water disturbances resulting from conditions such as cerebral salt wasting (CSW) syndrome, or inappropriate antidiuretic hormone secretion (SIADH) and diabetes insipidus (DI) will need appropriate management preoperatively to ensure anaesthesia can be administered safely. Hyperglycaemia, a commonly encountered problem in neurosurgical patients mainly due to corticosteroid treatment, has well documented adverse effects on injured brain tissue (Kramer et al., 2012). Insulin therapy instituted preoperatively according to local guidelines may be necessary to achieve adequate glycaemic control.

Prehospital medications and allergy status

The continuation of a patient's prehospital medications is usual up to the day of surgery. However, depending on neurosurgical advice, specific recommendations in relation to corticosteroids, and anticonvulsants are often made. Most antihypertensive agents and analgesic drugs for chronic pain should also be continued. Diabetic patients can sometimes omit oral hypoglycaemic agents but to optimize their blood glucose they may need an insulin sliding-scale regimen preoperatively. Anticoagulant and antiplatelet agents should be stopped at the appropriate time to allow clotting and platelet function to return to normal. This decision should be informed by haematology

or cardiology advice and based on a consideration of procedure urgency, along with the risks associated with the potential for haemorrhage and thrombosis.

A patient's history of drug allergies should be documented prior to anaesthesia. Any record of anaphylaxis, facial swelling, bronchospasm, hypotension, or profound cutaneous erythema related to a particular agent are all highly significant and warrant avoidance. Drug allergies are often readily documented to antibiotics, intravenous contrast, and anaesthetic agents but enquiry should also be made about reactions due to latex, iodine, chlorhexidine, adhesive tapes, and other substances used during the surgical procedure.

Preoperative investigations

Guidelines from both the ASA and the National Institute for Health and Care excellence (NICE) do not advocate routine preoperative investigations but rather tests based on the type of procedure (minor to complex major) and the functional impairment imposed by comorbidities. Biochemical, haematological, and electrophysiological testing along with imaging evaluate the degree of pathology and dysfunction of a particular organ system thus providing information on physiological reserve and the potential response to anaesthetic agents.

A risk factor assessment based on a patient's history and examination should indicate the need to check the haemoglobin level preoperatively. When significant blood loss is anticipated, blood group type and cross-matching will be required. Establishing a history of familial bleeding disorders or other risk factors for coagulopathy necessitates preoperative coagulation testing. However, there is little evidence that abnormal tests are predictive of perioperative haemorrhage (Seicean et al., 2012).

Comorbidities affecting the renal and hepatic systems either directly or indirectly require testing for sodium, potassium, creatinine, urea, estimated glomerular filtration rate, and liver enzyme levels. In patients with convulsive disorders, assessment of magnesium, calcium, and anticonvulsant drug levels may be appropriate. When endocrine abnormalities are suspected, baseline investigation of the hypothalamic-pituitary-end-organ axis should be established. Other blood investigations should be guided by the severity of a patient's comorbidities and the associated functional impairment.

An electrocardiogram is useful as a baseline investigation in patients with signs and symptoms of ischaemic heart disease. It may highlight hypertensive heart disease, rhythm abnormalities, or occult ischaemia. Further investigation of the cardiovascular status of the patient using a combination of exercise stress testing, echocardiography, nuclear imaging studies, and coronary angiography is usually indicated with findings of exertional dyspnoea and chest pain. Preoperative chest radiographs and pulmonary function testing are necessary only in patients whose symptoms and underlying lung disease is progressive.

Intraoperative anaesthetic management

Induction and maintenance of anaesthesia

The basic principles of neuroanaesthesia for cranial neurosurgery are essentially twofold; (1) the provision of a relaxed brain to enable good operative surgical conditions, and (2) the maintenance of cerebral perfusion pressure (CPP) and cerebral oxygenation. Controversy remains regarding the best practice to enable these overall goals such that interventions are often empirical rather than evidence-based.

Venous access

Once a patient is deemed fit for surgery their pathway from induction to emergence follows specific anaesthetic interventions. An inhalational induction is more usual in children and uncooperative or needle phobic adult patients but more commonly, an intravenous induction is used after initial venous access has been obtained. In general, both arterial and venous access can be achieved under local or general anaesthesia. Depending on the type of surgery and the severity of the patient's comorbidities, a central venous catheter is sometimes indicated.

Type of induction and drugs used

Intravenous induction of anaesthesia is commonly performed using short-acting agents such as propofol, thiopentone, etomidate, or ketamine (see **Table 5.3** and **Fig. 5.1**). Each agent has their own benefits and drawbacks but there is little to choose between them. In general, propofol and thiopentone are fast-acting but cause significant hypotension. Etomidate and ketamine cause less haemodynamic instability but the former agent can suppress adrenocortical activity for many hours and the later drug can cause postoperative hallucinations and nightmares. If intravenous access is not initially possible, there is concern over possible airway control or if the patient is a child, then an inhalational induction with a volatile agent and a mixture of oxygen and air is performed (see **Table 5.4**). This form of induction generally takes longer, is associated with excitatory phenomena, and if airway issues arise there is no immediate intravenous access to allow the administration of neuromuscular blocking agents.

Airway management

After induction of anaesthesia, intubation or the insertion of a supraglottic airway device is facilitated using a non-depolarizing neuromuscular blocking agent such as atracurium or rocuronium. Depending on the dose, these agents can take 1–3 minutes to reach peak effect and they are more commonly implicated in causing histamine release or rarely anaphylaxis. Securing the airway with a plain or reinforced cuffed endotracheal tube (ETT) is commonplace for most neurosurgical procedures. The ETT should be taped with care to avoid inadvertent dislodgement, especially for patients in the prone position. If a difficult airway is predicted from the scoring systems used in the preoperative assessment and the patient has cervical spine pathology, then a fibreoptic-assisted awake or asleep intubation may be required. An unpredicted difficult airway is no more common than in the general surgical population and the standard management algorithms for this clinical scenario should be followed. After intubation, patients are ventilated using an air/oxygen mixture of gases and an inhalational agent is added if required.

In emergency situations, a rapid sequence ('crash') induction is commonly performed. This involves using 100% oxygen for up to 5 minutes to preoxygenate the patient, the administration of a short-acting intravenous sedative agent (e.g. propofol or thiopentone) and simultaneous application of cricoid pressure to help avoid aspiration of the contents of a presumed full stomach. Once the patient is unconscious, a rapid administration of a depolarizing neuromuscular

blocking agent (e.g. suxamethonium) or a higher dose of a non-depolarizing agent is given. The time to adequate intubating conditions is usually 90-seconds following this regimen.

Monitoring

Standard physiological parameters are monitored during neuroanaesthesia. These include: heart rate; three or five lead electrocardiography; pulse oximetry; non-invasive or invasive blood pressure; respiratory rate; end tidal carbon dioxide; nasopharyngeal temperature; and the concentrations of oxygen and inhalational agent. Ventilation parameters (i.e. tidal volume, peak inspiratory pressure, and positive end-expiratory pressure (PEEP)) are adjusted to achieve an arterial oxygen level of greater than 13 kPa and a carbon dioxide level of between 4.5 and 5 kPa. A urinary catheter is

sometimes inserted to measure renal output during protracted surgery, for anticipated significant blood loss or where hyperosmolar therapy is used. Neuromuscular junction monitoring is essential in all cases where muscle paralysis is maintained throughout anaesthesia.

In certain circumstances, electroencephalography (EEG), electrophysiological monitoring of cranial nerves, and the measurement of motor or sensory evoked potentials can help prevent postoperative neurological deficits. Processed EEG-based depth of anaesthesia monitoring using the bispectral index or spectral entropy is recommended as an option in patients undergoing total intravenous anaesthesia (TIVA) with muscle relaxants, deep anaesthesia without the use of muscle relaxants and those at a higher risk of unintended awareness (Escallier et al., 2014).

Positioning

After induction of anaesthesia, potent stimuli resulting from laryngoscopy, insertion of a bladder or central vascular catheter, the application of skull pins, and positioning can cause a hypertensive response that must be obtunded to avoid an unexpected rise in intracranial pressure. This complication may also arise in patients positioned without a 15- to 30-degree head elevation, when the neck is flexed or turned resulting in obstruction to cerebral venous outflow, when PEEP greater than 10 cm H_2O is used and in the prone position which obstructs adequate ventilation. Hyperflexion of the neck should also be avoided as it may result in tongue and airway oedema thus preventing safe extubation at the end of surgery.

The sitting position is well known for its complications of hypotension, venous air embolism (VAE), macroglossia, pneumocephalus, and nerve injuries. Despite this, if a strict team protocol is followed the position is generally well tolerated and excellent operative conditions are ensured. In prone positioning, it is the responsibility of both surgical and anaesthetic teams to adopt strategies to minimize the risk of organ system pressure-injuries, myocutaneous necrosis, peripheral neuropathies, and ophthalmic complications (DePasse et al., 2015).

Maintenance of anaesthesia

General anaesthesia comprises a triad of hypnosis, analgesia, and muscle relaxation. In general, intravenous anaesthetic agents couple the reduction in cerebral metabolic rate of oxygen consumption ($CMRO_2$) and cerebral blood flow (CBF), preserve cerebral autoregulation (CAR) and carbon dioxide reactivity while reportedly inhibiting excitotoxicity and free radical-mediated lipid peroxidation. However, they can lower the MAP and CPP with resulting potentially harmful effects on cerebral oxygenation and intracranial pressure (ICP). In comparison, inhalational agents, to a varying degree, suppress $CMRO_2$ in a dose-dependent manner but cause cerebral vasodilatation (desflurane ~ isoflurane > sevoflurane) which may promote an increase in CBF and hence ICP unless compensated by hypocapnia induced vasoconstriction. These agents also cause a dose-dependent decrease in CPP, CAR, and carbon dioxide reactivity.

Despite the difference in the effects of both intravenous and inhalational agents on cerebral haemodynamics, there is not yet a consensus as to the best anaesthetic technique for neurosurgical procedures (Chui et al., 2014). However, in patients with known intracranial hypertension, intravenous-maintained anaesthesia would seem to have the theoretical advantage while inhalational agents should be used by those more experienced. In procedures where electrophysiological monitoring of the brain and spinal cord are undertaken, TIVA, rather than inhalational agents, has only a minimal influence on measured potential. During operations on the vertebral column and spinal cord, the anaesthetic considerations should be the same as for cranial interventions.

Intraoperative events and anaesthetic emergence

Respiratory and cardiovascular

The ability to control arterial oxygen and carbon dioxide levels by altering the patient's ventilation is essential in the management of intracranial hypertension. Important causes that can prevent adequate ventilation and require immediate remedy include: (1) inadvertent endobronchial intubation; (2) sputum blocking or kinking of the ETT; (3) bronchospasm; (4) faulty prone positioning; and (5) an unrecognized pneumothorax after central venous access or tunnelling during a cerebrospinal fluid (CSF) diversion procedure.

Intraoperative arterial hypotension (systolic blood pressure <90 mmHg), known to be associated with a poor outcome in patients with traumatic brain injury (TBI) often requires a reduction in anaesthesia dosing as well as fluid and inotropic support. Cardiac rhythm disturbances can be evoked by ICP-mediated vagus nerve stimulation, trigeminal cardiac reflex activation, brainstem manipulation, and lidocaine toxicity. Cessation of the stimulus is usually sufficient to terminate the disturbance or restoration to sinus rhythm may be pharmacologically assisted. In the event of a cardiac arrest during neurosurgery the usual advanced life support protocols should be followed, as well as consideration given to early removal of the patient from the head-fixation clamp and adoption of the supine position (Resuscitation Council (UK), 2014).

Intraoperative fluid management

In general, maintenance intraoperative fluids should be kept to a minimum unless there is significant bleeding or haemodynamic instability. Glucose-free iso-osmolar crystalloid fluids are most often used. Fluid and electrolyte balance can be significantly affected by the use of hyperosmolar agents and other diuretics and aggressive replacement to avoid metabolic derangement is sometimes needed.

Perioperative blood loss during neurosurgery can be unpredictable and significant resulting in hypotension, reduced cerebral oxygenation, coagulopathy, and anaemia. Prompt restoration of blood volume is mandatory using crystalloid fluids and blood products. Coagulation testing and haematology advice should guide the administration of clotting factors. The optimal haemoglobin trigger for transfusion is contentious. Reports from several studies have shown both anaemia and red blood cell transfusion to be associated with worsening patient outcomes (Alan et al., 2014; Gruenbaum and Ruskin, 2014).

Other unexpected events

Catastrophic unexpected events can occur during neurosurgical procedures requiring action to be taken collaboratively by both surgeon and anaesthetist. Such events include; anaphylaxis, seizures, acute brain swelling, aneurysm rupture, and VAE. The underlying principles in the management of these critical events include identification and removal of the cause followed by treatment to prevent or limit any adverse outcome for the patient. In all events, efforts are directed towards (1) optimizing cerebral oxygenation by restoring CPP using fluids and inotropic agents; (2) attempting a neuroprotection strategy by reducing $CMRO_2$ with anaesthetic drugs, anticonvulsants, and hypothermia; and (3) lowering ICP with hyperosmolar agents and short-term hyperventilation.

Prophylactic antiepileptic medication has been variably recommended for use during neurosurgical, especially neuroncology procedures. The incidence if seizures in the first postoperative week is reduced by approximately 40–50%, but with little or no effect on the incidence of late seizures (Temkin, 2002).

Anaesthetic emergence

Emergence from anaesthesia at the end of surgery should be a managed process. The aim is to preserve haemodynamic stability, avoid excessive coughing and bucking on the ETT while achieving a rapid and smooth transition to normal cognitive function. This allows a prompt neurological assessment and early detection of deficits that may require urgent intervention. There is no difference in the timing of return to normal cognition when either intravenous or inhalational anaesthesia is used for neurosurgery (Chui et al., 2014).

A poorly managed emergence may result in haemodynamic instability and possibly cause intracranial bleeding, cerebral hyperperfusion syndrome, or ischaemic myocardial dysfunction. Antihypertensive agents may be needed to control the systolic blood pressure to below 160 mmHg usually. In general, most patients should be delivered to the postanaesthesia care unit without the need for airway support, breathing spontaneously, haemodynamically stable, conscious, alert, normothermic, and comfortable.

Postoperative anaesthetic care and complications

Respiratory

At the end of surgery, patients are usually extubated in the operating room or in a high-dependency care area. Early postoperative respiratory complications following cranial procedures have an incidence of up to 20% (Ali, 2015). They manifest as hypoxia and hypercarbia secondary to a pneumothorax, atelectasis, sputum retention, aspiration pneumonia, bronchospasm, or neurogenic pulmonary oedema. Supplementary oxygen, physiotherapy, antibiotics, bronchodilators, diuretics, non-invasive ventilation, and tube thoracostomy after imaging may be required as treatment options. If measured arterial oxygen and carbon dioxide levels continue to deteriorate, early reintubation and ventilation to avoid secondary brain injury should be instituted without delay.

Cardiovascular

Transient hypertension on extubation is not uncommon but it may persist into the postoperative period. Treating postoperative pain may be sufficient to lower blood pressure to within the patient's normal range. However, persistent systolic hypertension can lead to intracerebral bleeding or a cerebral hyperperfusion syndrome and may require prompt treatment with short-acting antihypertensive agents. Overaggressive management should be avoided as it can risk cerebral ischaemia. Hypotension in the postoperative period usually responds to fluid management unless myocardial dysfunction is suspected when further investigations are required.

Delayed neurological recovery

A delayed neurological recovery may be related to the residual depressant effect of anaesthetic drugs, inadequate reversal of muscle relaxants, hypoglycaemia, or hypothermia. Patients who have a depressed conscious level or signs of abnormal neurology on examination within a reasonable period after stopping anaesthesia, warrant a computer tomography (CT) brain scan. Pneumocephalus may be revealed as the cause and treatment with high oxygen concentration for up to 12 hours will usually bring about improvement. In the absence of any abnormality on the scan to account for a delayed recovery, a diagnosis of a subclinical seizure by exclusion is often made. Patients should be loaded with intravenous anticonvulsants and investigated further with electroencephalography. In all cases and especially where seizure activity accounts for the altered state of consciousness, there may be a need to provide ventilatory support and admit the patient to the neurocritical care unit.

Postoperative nausea and vomiting

The incidence of postoperative nausea and vomiting (PONV) after surgery is about 30–50% exceeding 70% in high risk patients. Persistent PONV after a neurosurgical procedure may cause intracranial bleeding and brain swelling. Risk factors include female gender, younger age, previous history, intracranial pathology, infratentorial surgery, use of nitrous oxide, sensitivity to opioids, and postoperative hypotension. Various antiemetics ranging from anticholinergics, antihistamines, dopamine receptor antagonists, 5-HT3 antagonists, steroids, and neurokinin-1 receptor antagonists have all been studied but no one agent is favoured over another.

Most anaesthetists take a multimodal approach using two or three agents when attempting to prevent or treat PONV (Kranke, 2015).

Pain management

Two-thirds of patients experience moderate to severe pain in the first 24–48 hours after a neurosurgical procedure. There are no large-scale studies to provide level one evidence for any particular postoperative analgesic regimen in these patients due perhaps to the multiple postulated pain mechanisms involved. A multimodal approach to pain management is necessary with the goal of targeting several of these pain-signalling pathways. Opioids are the main stay of treatment for moderate to severe pain after either cranial or spinal procedures. Fear of use related to the side effects of increased PONV, urinary retention, pupillary changes, sedation, and respiratory depression must be balanced against the patient's pain scores, agitation, altered cerebral haemodynamics, and raised intracranial pressure as a result of inadequate analgesia.

Codeine-based agents, paracetamol, non-steroidal anti-inflammatory drugs (NSAIDs), gabapentinoids, centrally acting alpha-2 agonists, ketamine, lidocaine infusions, and magnesium are less effective as monotherapy but more successful in opioid sparing and providing pain relief when used within a multimodal treatment protocol (Devin and McGirt, 2015). The use of NSAIDs must be considered against the risk of haemorrhage, gastric ulceration, renal toxicity, impaired bone fusion, and coronary vascular thrombosis. Ketamine may cause hallucinations, sedation, and diplopia while gabapentin is associated with sedation, dizziness, headache, and visual disturbances. Infratentorial surgery is often associated with more pain and the efficacy of patient-controlled analgesia has been shown is some studies.

Scalp infiltration with local anaesthetic agents in the form of a regional scalp block should be considered in all patients undergoing a craniotomy procedure. Evidence exists for reduced opioid requirements and postoperative pain scores are lower in the first 24 hours (Guilfoyle et al., 2013). Epidural and intrathecal neuraxial analgesia using a combination of drugs has its advocates for postsurgical pain relief after spinal operations. However, the literature provides little evidence with respect to the optimum route or dose of agent to use in relation to the type of surgery (Sharma et al., 2012).

Fluid and electrolyte management

Most patients who have undergone an uneventful neurosurgical procedure do not require regular intravenous postoperative fluid replacement. Clinical problems that may necessitate a postoperative fluid prescription to maintain normovolaemia include; a delayed return to consciousness, cerebral vasospasm, disturbed bulbar function, persistent PONV, significant blood loss during surgery, large volume diuresis from hyperosmolar therapy, haemodynamic instability, and endocrine issues such as diabetes mellitus, DI, and CSW syndrome. Iso-osmolar crystalloid fluids sometimes supplemented with potassium chloride are generally used. Glucose containing fluids may exacerbate neurological damage and increase brain free-water content.

Disorders of water balance causing hypo- or hypernatraemia (136 mmol/litre >Na^+ >150 mmol/litre) are common in patients after subarachnoid haemorrhage, traumatic brain injury, intracranial tumours, and pituitary surgery. Patients with these conditions usually benefit from measuring urine output and serum sodium for 24–48 hours postoperatively. A rising plasma sodium in the presence of hypotonic polyuria is robust evidence of acute DI and warrants decisive action usually in the form of desmopressin and fluid resuscitation guided by endocrinology advice.

Hyponatraemia is more common in neurosurgical patients caused by SIADH or cerebral salt wasting syndrome (CSWS). The diagnosis of SIADH can be considered if the plasma sodium and urea are falling in a euvolaemic patient with a low urine output after the exclusion of hypoadrenalism and hypothyroidism. Where there is hyponatraemia, an increase in urine volume, hypovolaemia, a fall in blood pressure, and a rise in blood urea (in the absence of diuretic therapy), the diagnosis of CSWS should be considered. Total 24-hour urinary sodium loss may help distinguish between SIADH and CSWS.

Treatment for CSWS involves sufficient intravenous sodium chloride to keep pace with urine losses and fludrocortisone in refractory cases. However, SIADH in the neurosurgical setting should involve expert advice on the limits of fluid restriction and the use of hypertonic saline, demeclocycline, and selective vasopressin-2 receptor antagonists. The rapidity of correction of hyponatraemia must be carefully monitored, to avoid neurological complications such as central pontine myelinolysis. A rate of correction no more than 12 millimoles/litre/day is generally considered safe.

Neurosurgical patients often present with disorders of potassium homeostasis because of perioperative osmotic therapy, associated renal failure, or trauma. Hypokalaemia (K^+<3.5 mmol/litre) and hyperkalaemia (K^+>5.5 mmol/litre) should be treated promptly to avoid life-threatening arrhythmias and haemodynamic instability.

Postoperative care facilities

It is crucially important that all neurosurgical patients are cared for postoperatively in an area dedicated to the monitoring, assessment, and recognition of neurosurgical complications. Expertise is required for a multitude of tasks that include; continuous neurological assessment, the maintenance of haemodynamic targets, interpretation of gas exchange parameters, observation for wound haematomas, the management of external ventricular drains, timely administration of medications for extrapyramidal disorders and the administration of antithrombotic agents after neuroradiological interventional procedures. Evidence suggests that as well as being cost-effective, the care of elective neurosurgical patients in these postoperative care areas rather than on a neurointensive care unit is safe (Smith, 2015).

Anaesthesia for specific neurosurgical interventions

Traumatic brain injury

The main role of the anaesthetist during surgery for traumatic brain injury is to protect the brain from further secondary injuries. Intraoperative management involves maintenance of an adequate cerebral perfusion pressure, while keeping oxygen and carbon dioxide levels, along with temperature and glucose, within normal range.

Many patients are the victims of accidents resulting in polytrauma and may already be intubated and ventilated when received in the

operating room. Life-threatening injuries are managed as a priority for cardiopulmonary stability before neurosurgical intervention. Every attempt should be made to assess and document GCS score, pupil size, reactivity, pre-existing neurological deficits, axial spine stability, and any other available relevant medico-social history. Aside from routine biochemical and haematological tests, analysis of clotting function and the availability of blood products must be ensured prior to any intervention.

Induction of anaesthesia is usually with propofol or thiopentone, as both significantly reduce $CMRO_2$ and therefore ICP. However, most anaesthetic agents, except ketamine and etomidate, cause a degree of hypotension which can be offset with vasopressors. Suxamethonium, a depolarizing neuromuscular blocking agent, is often used to facilitate airway management as part of a rapid sequence induction. Neither depolarizing or non-depolarizing agents have significant effects on ICP. Intubation can be difficult in neurotrauma patients who require a cervical collar and manual in-line stabilization for possible cervical spine injury. It is essential to have a backup plan for a failed intubation to avoid any rise in ICP due to hypoxia and hypercapnia.

During surgery, standard monitoring is augmented with measurements of temperature, urine output, and neuromuscular function. Invasive arterial blood pressure monitoring is essential and it allows regular blood gas measurements. Large-bore peripheral venous access is sufficient in most cases while central venous access, unless essential, should not delay surgery.

Total intravenous anaesthesia using infusions of propofol and remifentanil is a widely used technique for the maintenance of anaesthesia in brain injured patients. Inhalational agents can be used but in low concentrations (<1MAC) and nitrous oxide should be avoided. A PaO_2 of more than 11 kPa achieved using PEEP less than 8 cmH_2O and a $PaCO_2$ of 4–4.5 kPa is preferred. Prolonged hypocapnia can cause cerebral ischaemia and should be avoided. In adults, a CPP of more than 60 mmHg is maintained with fluids (blood products or glucose-free crystalloids) and vasopressors, as needed. Hyperosmolar therapy in the form of mannitol (0.25–1 g kg^{-1}) and/or hypertonic saline (5%, 2–3 ml kg^{-1}) is used to reduce brain swelling. Otherwise, patients are maintained normoglycaemic, normothermic, euvolaemic, electrolytes within normal range, and metabolically stable.

Postoperatively, severely injured patients will have ICP monitoring sited and require a period of sedation and ventilation on a neuro-critical care unit. Some patients may be suitable for extubation and require high-dependency, level II care for neurological observation, analgesia, as well as fluid and electrolyte management. Anticonvulsive therapy and pharmacological thromboprophylaxis should be administered on the advice of the neurosurgical team.

Brain swelling and neuroprotection

The aetiology of severe intraoperative brain swelling is multifactorial and is a recognized complication during surgery for TBI. In many cases, medical treatment is unsatisfactory and without immediate effect such that bone replacement is impossible and urgent scalp closure over the herniating brain is required. Implementing measures to manipulate basic neurophysiological parameters will eventually yield some benefit. CPP should be optimized with the use of fluids or vasopressors, hypoxia corrected and mild transient hypercapnia (4–4.5 kPa) instituted. Patients should be placed in a 30° head-up tilt, anaesthetic depth increased with boluses of propofol, thiopentone, or opiates, neuromuscular blockade established, and hyperosmolar or diuretic therapy started. Hyperthermia should be treated aggressively by ambient air cooling and cold intravenous crystalloid fluids while consideration should be given to instituting mild hypothermia (35–36°C). Intravenous insulin will be required for hyperglycaemia and anticonvulsant agents can be useful if seizure activity is a precipitating cause. A thiopentone infusion to achieve EEG burst suppression and surgical CSF drainage may add some benefit to the treatment regimen.

Cerebral aneurysm surgery

In the perioperative period, anaesthetic management for patients undergoing neurovascular surgery aims to optimize outcomes which are defined by the risks associated with neurological, systemic, anaesthetic, and neurosurgical complications.

A comprehensive preoperative assessment for emergency neurovascular surgery is often not possible. However, it is essential to establish baseline neurological function and optimize the patient's condition in relation to complications associated with hydrocephalus, cardiopulmonary dysfunction, and electrolyte abnormalities. This may involve treatment of dysrhythmias, hypovolemia, hypotension, hypoxia resulting from neurogenic pulmonary oedema, and dysnatraemias caused by SIADH or CSW. Baseline investigations should include a complete blood count, electrolyte studies, cardiac troponin levels, coagulation profile, blood group determination, 12-lead electrocardiograph, echocardiography when indicated, and a chest radiograph. Medical therapy for coexisting conditions should be continued along with nimodipine and anticonvulsant medications. For elective neurovascular surgery, a comprehensive preoperative assessment is performed focusing on associated comorbid conditions. Prior to surgery, a review of anticoagulant and antiplatelet medications should help formulate a management plan in consultation with haematological advice.

During anaesthesia, in addition to routine cardiac, respiratory, urine output, and nasopharyngeal temperature monitoring, more specialized haemodynamic assessment of cardiac output may be necessary to guide vascular filling, especially if myocardial dysfunction is suspected. Central venous access may be necessary for the delivery of vasoactive agents. Intravenous induction of anaesthesia should aim to avoid wide swings in mean arterial and intracranial pressures which may alter the transmural pressure gradient (TPG = MAP-ICP) across the aneurysm and cause it to rupture. Laryngoscopy, intubation, and the application of skull pins are potent hypertensive stimuli which should be anticipated and prevented. MAP should then be maintained within 20% of the patient's normal preoperative level to achieve an adequate CPP.

Cerebral aneurysm surgery can be performed under inhalational anaesthesia or TIVA. Short-acting intravenous drugs such as propofol, fentanyl, remifentanil, or sufentanil are commonly used. Volatiles agents, if used, should not exceed a minimum alveolar concentration of one (MAC <1) because of their potential to cause cerebral vasodilatation thus increasing cerebral blood volume and therefore ICP. Short-acting neuromuscular blocking agents can be used to help facilitate adequate ventilation. Hypercapnia should be avoided and the $PaCO_2$ should be kept between 4.5 and 5 kPa. A PaO_2 of more than 11 kPa should be maintained along with normothermia and normoglycaemia. Hyperosmolar agents such as

mannitol (0.5–1 g/kg) or hypertonic saline (2 ml/kg of 5% NaCl), should be initiated slowly and, ideally, delayed until the dura is open.

During surgery, more than 15–20 min of temporary arterial occlusion risks ischaemia and therefore the MAP is usually augmented to improve collateral circulation. Unfortunately, good evidence is lacking for the use of inhalational agents, hypothermia, barbiturates, propofol, and extra doses of mannitol to safely extend the duration of occlusion. Once the aneurysm has been clipped, mild to moderate hypertension using metaraminol, norepinephrine, or phenylephrine, is permitted to improve cerebral perfusion. At the end of uneventful aneurysm surgery, patients should be extubated with minimal coughing and haemodynamic fluctuations and a rapid return of consciousness allows for early neurological assessment. Neurovascular patients should be managed in a neurosurgical high-dependency or intensive care unit to ensure appropriate analgesia, continued haemodynamic monitoring, adequate oxygenation, optimum fluid and electrolyte management, and early detection of complications.

Management of intraoperative aneurysm rupture

The incidence of intraoperative aneurysm rupture for urgent cases is between 5% and 10%. The patient's survival depends on rapidly controlling the bleeding while maintaining adequate cerebral perfusion. Effective communication with the neurosurgical team is essential. The patient should be ventilated with 100% oxygen. Adenosine-induced transient asystole or short-term hypotension using anaesthetic agents or vasoactive drugs may allow surgical control of the bleeding. Restoration of intravascular volume with blood, clotting products, and crystalloid solutions should enable maintenance of a safe minimum CPP. Further doses of propofol, thiopental or etomidate can be used to achieve electroencephalographic burst suppression thereby reducing cerebral metabolic rate to a minimum. Cerebral oedema can be treated with hyperosmolar agents and inducing mild hyperthermia (34–35°C) may be considered, although without good evidence. Once the aneurysm is secured, CPP should be restored to normal levels.

Posterior fossa surgery

The risk of arrhythmias, complications associated with positioning and the potential occurrence of a VAE are fundamental considerations in the perioperative management of patients undergoing posterior fossa surgery.

In addition to the usual preoperative assessment, a detailed neurological examination is crucial to plan perioperative management. In particular, signs of raised intracranial pressure and dysfunction associated with pathology of the brain stem, cranial nerves, and cerebellum should be sought. Relevant imaging should be discussed with the neurosurgeon and a plan formulated for positioning, CSF drainage, neurophysiological monitoring, and any potential significant complications.

In addition to standard monitoring, an intra-arterial catheter is recommended while insertion of a central venous catheter may prove useful in the event of a VAE. Electrophysiological monitoring should be tailored to the site of surgery and the location of the lesion. Use of the sitting position for posterior fossa surgery has declined due to the increased risks of haemodynamic instability, VAE, and spinal cord compression from severe neck flexion. Surgery is now commonly performed in the prone or semi-prone positions which requires careful attention to avoid complications associated with airway oedema along with skin, peripheral nerve, and abdominal organ damage.

There is no evidence for improved outcomes in relation to a specific anaesthetic technique for posterior fossa surgery. The general goals of adequate anaesthesia, analgesia, maintenance of CPP, haemodynamic stability, and avoidance of coughing remain self-evident. Brain stem manipulation can cause cardiac dysrhythmias, particularly bradycardia as well as ventricular and supraventricular tachycardias. Most terminate with cessation of surgical stimulation and it is rare for pharmacological intervention or rarer still, for external cardiac massage, to be required. Stimulation of the trigeminocardiac reflex can also cause marked intraoperative hypertension which can be treated by deepening anaesthesia.

As with all neurosurgery, early postoperative neurological evaluation of the patient is essential. However, after prolonged surgery in the prone position, some anaesthetists perform a 'leak test' on the endotracheal tube with the cuff deflated to check if airway oedema will delay extubation. If this is the case, or airway reflexes are slow to return, patients may be kept intubated and require ventilation on the intensive care unit until extubation can be safely completed. Hypertension should be avoided in the early postoperative period to limit the risks of brain oedema and intracranial haemorrhage.

Venous air embolism

The incidence of haemodynamically significant VAE in posterior fossa surgery is 8% to 15% in the sitting position and 3% to 5% in the prone or park-bench position. Risk factors include operative site above the level of the heart and the presence of non-collapsible veins. Almost 25% of the adult population have a patent foramen ovale which increases the risk for paradoxical air embolism that can lead to myocardial and cerebral ischaemia. The intraoperative clinical presentation for a VAE can vary between minimal air entrainment with low morbidity to sudden cardiac arrest and death with larger air volumes.

The pathophysiology of a VAE involves; impaired right ventricular outflow, mechanical obstruction of pulmonary capillaries, increased intrapulmonary shunting leading to hypoxia and hypercarbia, raised pulmonary artery pressure, bronchoconstriction, a decrease in cardiac output, hypotension, arrhythmias, myocardial failure, and cardiac arrest. Precordial doppler ultrasound and capnography remain the recommended monitors for VAE during posterior fossa surgery and will allow detection before clinical signs occur. In the event of a VAE, inform the surgeon to prevent further air entrainment by flooding the wound with saline. Compressing the jugular vein can temporarily increase venous pressure and allow localization and repair of the site of entrainment. Decrease the gradient between the heart and the operative site. Administer 100% oxygen and stop nitrous oxide. Attempt to aspirate air through a central venous catheter and provide haemodynamic support if required. If the patient remains in a precarious cardiopulmonary state, surgery may need to be abandoned, the patient turned supine, and further resuscitation measures instituted as necessary.

Neurosurgical oncology

Preoperative assessment of patients presenting with primary or metastatic brain tumours involves an assessment of symptoms, history of seizures, an evaluation of premorbid conditions and a review of preadmission medication. Patients should be examined for level

of consciousness, peripheral neurological deficits, in addition to speech and language abnormalities. Laboratory tests should rule out significant biochemical, haematological, and coagulation disorders. Imaging of the primary cerebral lesion is checked for site, size, signs of raised ICP, and vascularity while the spread of metastatic disease in those with secondary tumours needs careful evaluation. Up to 4 hours before induction of anaesthesia 5-aminolevulinic acid (5-ALA), which improves the likelihood of complete tumour resection, is sometimes administered. At this stage, a postoperative plan to manage the patient in a high-dependency or critical care setting should be considered if needed.

Induction of general anaesthesia usually proceeds with an intravenous agent combined with an opiate and a non-depolarizing muscle relaxant. Obtunding haemodynamic responses to laryngoscopy and head-pin insertion will help maintain a stable CPP and avoid excessive rises in ICP. Along with standard monitoring, an intra-arterial catheter, central venous access, temperature, and urine output measurement, in addition to more advanced methods to assess haemodynamic function, may be required for prolonged complex procedures or when comorbidities dictate. In specific circumstances, electrophysiological monitoring is required. Patients may receive hyperosmolar agents during the craniotomy procedure and subsequent blood analysis for monitoring of electrolyte imbalances. Appropriate head-up positioning and avoidance of venous obstruction during positioning can limit elevations in ICP, while minimizing neck flexion will help avoid airway oedema postoperatively.

Anaesthesia is usually maintained by a total intravenous or inhalational technique, supplemented with opiates and sometimes neuromuscular blocking agents. Propofol reduces cerebral blood volume (CBV) and preserves autoregulation and CO_2 reactivity, while volatile agents can increase ICP because they cause cerebral vasodilatation. When electrophysiological monitoring is employed, intravenous anaesthesia interferes less with signal characteristics. Glucose-free iso-osmolar crystalloid solutions should be administered during surgery unless blood loss requires a transfusion to maintain haemodynamic stability and adequate brain oxygenation. In general, the principal aims during anaesthesia for craniotomy procedures is to avoid hypoxia, hypercapnia, hypothermia, hypoglycaemia, ICP rises, and maintain CPP while improving brain compliance. The management of complications related to neurosurgical oncology can involve blood products and clotting factors for acute haemorrhage, intravenous anaesthetic, and anticonvulsant medication for seizure control and imaging with possible evacuation of blood clot for postoperative haemorrhage. The treatment of VAE and acute cerebral oedema have been referred to in other sections.

Emergence from anaesthesia with minimal coughing and straining avoids an increase in ICP. Early neurological assessment is facilitated by a prompt return to consciousness if cessation of anaesthesia is timed appropriately. Pneumocephalus, if significant, can delay wake-up and benefits from early recognition to allow treatment with high oxygen concentrations. Hypertension in the postoperative period is usually treated to a MAP less than 160 mmHg with short-acting beta-blockers. The analgesic effects of strong opiates need to be balanced against their sedative properties, but less use of these drugs may be required if a local anaesthetic block of scalp nerves is performed prior to waking the patient.

Anaesthesia for awake craniotomy

Developments in neurosurgery have placed a greater focus on awake procedures which are now routinely used in epilepsy surgery and for removal of lesions involving eloquent brain areas. These procedures can be performed awake under local anaesthetic with or without sedation, under general anaesthesia initially (intubated or use of supraglottic airway device), then awake (asleep-awake), or reanaesthetized (asleep-awake-asleep). Patients need to be carefully chosen, counselled, and fully consented to ensure success of these procedures. The role of the anaesthetist is crucial to ensure; (1) maintenance of airway patency and ventilation, (2) haemodynamic stability, (3) adequate analgesia and sedation as required, (4) patient cooperation for continuous neurological assessment and (5) timely treatment of any seizure activity. Constant anaesthetic presence and vigilance is essential to help avoid potential complications injuring the brain and risking the patient's life.

Spinal surgery

Anaesthesia for spinal surgery involves consideration of a combination of specific issues to ensure a good outcome. These include, managing a potential airway problem due to traumatic or degenerative cervical spine disease, dealing with the complications of the prone position, adapting anaesthetic techniques to facilitate accurate neurophysiological monitoring, dealing with blood loss and coagulation matters and providing effective multimodal postoperative analgesia to enable early mobilization and hospital discharge (Bajwa and Halder, 2015).

Due to the age range of people presenting for spinal surgery, only a systematic approach to the preoperative assessment will ensure the identification of any pre-existing focal neurology or altered physiological reserve resulting from recent trauma or chronic comorbid diseases. Procedures required to manage a difficult airway are not uncommon in patients needing cervical or upper thoracic surgery. Previous cervical fixation surgery or arthritis leading to limited neck movement, cervical spine instability, and cord compression will often necessitate an awake or asleep fibreoptic intubation or the use of other videolaryngoscopy instruments to permit intubation without causing further damage to the spinal cord. Respiratory function (e.g. reduced volume and compliance parameters) can be compromised in patients needing surgery for scoliosis or other neuromuscular conditions. Chest trauma, resulting in multiple rib fractures, flail segments, pneumothoraces, and pulmonary contusions, can make adequate oxygenation and ventilation problematic intraoperatively, especially in those patients positioned prone who may also need further postoperative critical care management.

Patients presenting for spinal surgery to stabilize a spinal cord injury can be haemodynamically unstable due to spinal shock or autonomic dysreflexia and require vasoactive agents to ensure an adequate heart rate and MAP. Patients with cardiac disease but limited mobility due to degenerative spinal conditions often need stress echocardiography prior to surgery. Acquired coagulation abnormalities due to medications or trauma need to be normalized to avoid bleeding and haematoma formation potentially causing spinal cord compression. Blood loss should be anticipated in major spinal surgery such that blood and coagulation factors are made readily available while cell salvage and the use of tranexamic acid help reduce homologous transfusion requirements (Cheriyan et al., 2015).

The principal anaesthetic objective during spinal surgery is maintaining adequate spinal cord perfusion at all times. The conduct of anaesthesia usually involves (1) large-bore venous access; (2) standard monitoring; (3) measurements of invasive arterial and/or central venous pressures, temperature, and urinary output; (4) intravenous induction; (5) appropriate airway management with the use of a double-lumen endotracheal tube if transthoracic procedures are planned; (6) maintenance with an inhalational agent or total intravenous anaesthesia if neurophysiological monitoring is used to avoid amplitude reduction in the evoked potential signals; (7) use of a forced-air warming device; and (8) cell salvage usage if major blood loss is anticipated.

Emergence from anaesthesia should be planned and attention paid to identifying airway oedema after prolonged prone positioning. Patients should be turned carefully supine, placed more than 30° head-up and extubated with minimal coughing and when responding to command. Blood pressure should be expectantly managed avoiding systolic hypertension more than 160 mmHg with beta-blockers or another vasoactive agent. Any new motor deficit requires immediate neurosurgical review, urgent imaging, and possibly exploratory surgery. Pain management should be multimodal involving the use of epidurals, patient-controlled analgesia, intermittent intravenous or oral opioid analgesics, non-steroidal anti-inflammatory drugs, gabapentinoids, alpha-2-agonists (e.g. clonidine), and ketamine.

Prone positioning

Prone positioning requires the correct equipment and sufficient staff for moving and handling the patient. A minimum of six people is required for log-rolling to maintain spinal alignment. Patients can be positioned on various frames (e.g. Wilson, Allen), tables (e.g. Jackson) and mattresses (e.g. Montreal). There should be no constriction of the abdomen thus allowing free excursion of the diaphragm, permitting ventilation with the lowest possible intrathoracic pressures, and avoiding venous congestion which can cause a bloody surgical field. Abdominal organ ischaemia, resulting in an unexplained metabolic acidosis can result from poor positioning. Due to diminished preload, cardiac output usually falls on turning prone which often requires fluids and vasopressor agents to restore haemodynamic stability. The head and neck should be in a neutral position either in a Mayfield clamp or a foam cushion. There should be no pressure on the eyes which are usually taped and padded. The arms should be kept at the patient's side or abducted to no greater than 90 degrees. All extremities and pressure points need to be padded to avoid injuries to the brachial plexus, ulnar, median, lateral cutaneous, common peroneal and sciatic nerves. The incidence of visual loss after spinal surgery is 1 in 30 000 and is likely due to ischaemic optic atrophy, cortical ischaemia, or central retinal artery occlusion. Factors involved in the aetiology of this complication include, surgery more than 6 hours duration, significant intraoperative blood loss and hypotension, non-neutral head positioning, and incorrect use of head supports, and other possible patient-related factors (Shmygalev and Heller, 2011).

Pituitary surgery

The management of the consequences of pituitary pathology in relation to raised ICP, mass effects, and disruption of hormonal secretion is the focus of perioperative assessment for these patients. Preoperatively, imaging defines the extent of the lesion while other tests identify if patients have developed electrolyte disturbances, abnormal hormone secretion syndromes, reduced cardiopulmonary reserve, and dysfunction of upper airway structures.

Acromegaly, caused by hypersecretion of growth hormone from a functioning pituitary macroadenoma, can cause anaesthetic concerns in relation to upper airway changes. These include prognathism, macroglossia, tissue hypertrophy reducing glottic opening and hoarseness from possible recurrent laryngeal nerve injury. This disease is also associated with obstructive sleep apnoea (OSA), hypertension, cardiac muscle and conduction abnormalities, diabetes mellitus, kyphoscoliosis, and proximal myopathy. These patients may need preoperative transthoracic echocardiography to assess left ventricular function, respiratory function testing, and consideration given to performing an awake fibreoptic intubation for a potentially difficult airway.

Hypersecretion of adreno-corticotropic hormone from a pituitary adenoma resulting in excess glucocorticoid is called Cushing's disease. Patients often have truncal obesity, moon facies, thin extremities, OSA, cardiac dysfunction, coagulation abnormalities, osteoporosis, thin skin, and diabetes mellitus. With this condition, anaesthetic concerns include possible airway difficulties and intraoperative cardiorespiratory instability.

Hyperthyroidism caused by thyroid stimulating hormone producing adenomas will require treatment as indicated before surgery with somatostatin analogues, antithyroid medications, and beta-blockers. Certain patients will need steroid supplementation at induction to cover the metabolic stress of anaesthesia and surgery.

The most important anaesthetic concerns in patients presenting for pituitary surgery are related to airway management and haemodynamic instability. Expertise in a variety of intubation techniques, including video laryngoscopy and awake fibreoptic intubation, should be available. Reinforced or south-facing oral endotracheal tubes are frequently used for endonasal pituitary surgery. The oropharynx if usually packed with gauze to help prevent blood entering the airways and it must be removed prior to extubation. Cardiovascular disease is common in patients presenting with hormone-secreting tumours. Intraoperative haemodynamic instability from hypertension, dysrhythmias, myocardial ischaemia, and ventricular dysfunction may require invasive arterial monitoring and vasoactive agents to maintain an adequate cerebral perfusion pressure.

The anaesthetic technique for this surgery can be either intravenous or inhalational. Standard monitoring supplemented with measurements of invasive arterial pressure, temperature, and urine output is customary. Painful stimulation, resulting in hypertension, is common during nasal/transsphenoidal dissection but minimal during surgery on the sellar lesion itself. Haemodynamic parameters can be further adversely affected by application of adrenaline-containing local anaesthetic to the nasal mucosa. The use of remifentanil, short-acting beta-blockers, and vasodilators are used to preserve cardiovascular stability. Controlled hypercapnia and temporary increases in ICP via a lumbar intrathecal catheter can be used to push the tumour into the surgical field. Fluid loss is replaced with glucose-free crystalloid solutions to maintain a neutral balance while avoiding electrolyte disturbances. Blood loss is usually minimal unless there is injury to the cavernous sinus when transfusion if often required. A sellar CSF leak, sometimes identified by a Valsalva manoeuvre, is usually surgically sealed with autologous abdominal or thigh fat and facia.

Prior to emergence from anaesthesia, the oropharynx is suctioned and any gauze pack removed. Smooth emergence prevents dislodgement of surgically-placed nasal packs. Patients with known airway difficulties should be positioned with head-up tilt and safely extubated when responding to commands. Myopathic patients may be too weak to extubate and require a period of postoperative ventilation on a critical care unit. Adequate analgesia and antiemetics should be prescribed for all patients during their stay on the postanaesthesia care unit. When discharged to the ward, combined care with endocrinologists provides guidance on further steroid and hormone replacement therapy in addition to assisting the early recognition and treatment of other neuroendocrine complications.

Coagulation disorders and venous thromboembolic disease

Pathophysiology of coagulation

Cascade model

The concept of coagulation as a proteolytic enzyme cascade was described by two groups in 1964 (Davie and Ratnoff, 1964; Macfarlane, 1964). Schematically, the coagulation pathway can be divided into the extrinsic and intrinsic pathways (Fig. 5.2). The extrinsic pathway is activated when blood comes into contact with tissue factor (TF) on the surface of extravascular cells (e.g. fibroblasts within the vascular wall). The role of the intrinsic pathway is less clear *in vivo*. It is activated with internal damage to vessel wall and when mechanical devices come into contact with blood. Nevertheless, both the extrinsic and intrinsic pathways are extremely useful in understanding the biochemical reactions underpinning common coagulation assays, such as the prothrombin time (PT) and partial thromboplastin time (Table 5.5).

Both the extrinsic and intrinsic pathway ultimately lead to the conversion of factor X to Xa (factor X being the first factor of the common pathway), which is an essential component of the prothrombinase complex. This consists of factors Xa and Va bound together on a phospholipid membrane by calcium ions. The prothrombinase complex acts to convert prothrombin (factor II) to thrombin (factor IIa), which in turn activates factor XIII. This allows stabilization of the clot by creating covalent cross-links between fibrin molecules.

Cell-based model

While the classical model explains the function of laboratory assays of coagulation and the interactions between specific clotting factors, it is not sufficient to allow a full understanding of coagulation *in vivo*. The cell-based model has been developed to fill that niche and better describe some of the coagulation disorders seen clinically, such as the failure of the extrinsic pathway to compensate for factor deficiencies of the intrinsic pathway observed in haemophilia (Hoffman and Monroe, 2001; Hoffman, 2003).

The new model places emphasis on specific cells and their cell surface receptors in the process of coagulation which occurs in three overlapping stages of initiation, amplification, and propagation. Initiation occurs on TF-containing cells (e.g. stromal fibroblasts, which normally lie outside the vasculature), blood mononuclear cells, or endothelial cells in states of inflammation. A breach in the vessel wall exposes TF-containing cells to plasma. Factor VII binds to TF on the cell surface and is then activated to factor VIIa. The VIIa/TF complex activates factor X and factor IX. When confined to the cell surface, factor Xa binds with factor Va and leads to the production of thrombin from prothrombin, beginning the amplification process. Importantly, factor Xa is rapidly inhibited when dissociated from the cell surface by tissue factor pathway inhibitor and antithrombin III (ATIII).

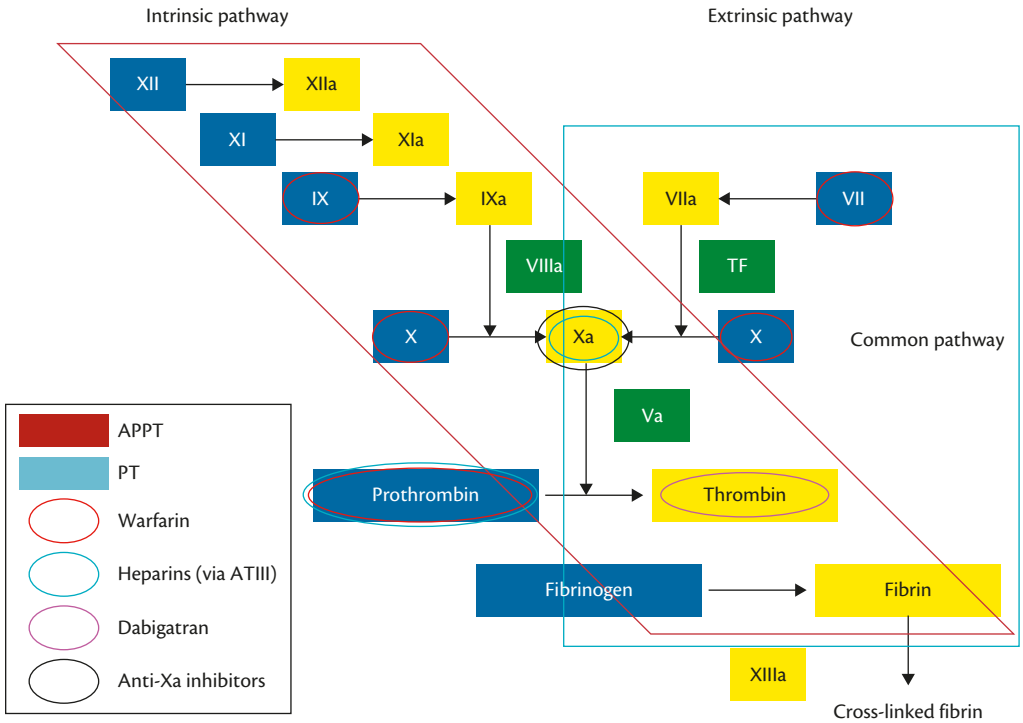

Fig. 5.2 Coagulation cascade pathways including mechanisms of action of commonly used anticoagulants.

Table 5.5 Coagulation assays, related clotting factors, and clinical use

Test	Inherited	Acquired	Pathway	Clinical
aPTT	vWF, VIII, IX, XI, XII factor deficiencies (haemophilia)	Heparin; antiphospholipid antibodies	Intrinsic, and common pathway	Factor deficiency about 20–40% before abnormality seen; monitoring heparin therapy
PT	VII deficiency	Warfarin; factor VII inhibitor; Vit K deficiency; liver disease;	Extrinsic and common pathway	Screen for factor VII deficiency; Screen for factor X, V II, I (together with aPTT); monitor warfarin use (INR); INR not appropriate for liver disease
TEG			Whole process of coagulation including platelet function	Used differentiate surgical bleeding from coagulation disorder

Thrombin produced on TF-containing cells and acting via protease-activated receptors, leads to platelets activation, which in states of tissue damage are already adherent to extravascular matrix. These activated platelets, lead to the production of activated factors V and VIII. Factor Va is released from platelet alpha granules while factor VIIIa is released from the von Willebrand factor (vWF). Together these lead to large-scale thrombin production, which constitutes the amplification phase of coagulation. The propagation phases relate to formation of a stable fibrin clot with the help of enzymatic complexes on the surface of activated platelets. Instrumental in this is the factor VIIIa/IXa complex, which activates factor Xa.

In the cell-based model of coagulation, platelet cell surface is essential in the amplification and propagation phases of coagulation. The special function of platelets is related to their ability to adhere to injured surfaces using multiple receptors and pathways. Platelets express glycoprotein Ib/IX and vWF, which help localize platelets to the site of injury. It is important that the initiating and propagating steps of anticoagulation are normally sequestered to different cell surfaces to limit the undesired activation of coagulation. Table 5.5 demonstrates the mechanism of action of commonly used anticoagulants.

Management of deranged coagulation prior to neurosurgery

Deranged coagulation in neurosurgery is frequently related to the preoperative use of antiplatelet or anticoagulant medications for the prevention of primary or secondary cardiovascular disease. In addition, the use of fibrinolytic agents for the management of cerebrovascular and cardiovascular emergencies, increases the incidence of intracranial haemorrhage which may necessitate neurosurgical intervention.

Elective neurosurgery

In elective cases, suspected or known coagulation disorders should be adequately diagnosed and treated with the appropriate factor replacement. Coagulation dysfunction related to preoperative administration of antiplatelet or anticoagulant medications should be normalized by stopping these agents before surgery (Table 5.6). In dealing with perioperative anticoagulation, a balance must be had between the risk of surgical bleeding, the likelihood of any pre- and postoperative venous thromboembolism (VTE) event and the shortest and safest time interval for the discontinuation and recommencement of anticoagulant agents.

Antiplatelet agents are given orally or intravenously for the prevention of cerebral, coronary, or carotid thromboembolic disease, and reversibly or irreversibly inhibit cyclooxigenase-1 (COX-1) and thromboxane A2 (subscript) synthesis and the P2Y12 receptor affecting platelet function for up to ten days. To allow regeneration of the platelets prior to surgery, antiplatelet medication should be stopped until new platelets can be made (typically 20 000 platelet as made per day, i.e. 5 days are required to generate 100 000 new platelets). Certain neurosurgical procedures are commonly performed without discontinuation of antiplatelet medication (e.g. carotid endarterectomy or low flow extracranial-to-intracranial bypass) to minimize the risk of perioperative stroke and/or vessel occlusion.

In relation to cardiovascular disease, most guidelines agree that the risk of thrombosis is at its highest for up to six weeks after insertion of a bare metal cardiac stent, six months for a drug-eluting stent and three months after a myocardial infarction, stroke, or deep venous thrombosis (DVT) (Rabbitts et al., 2008). The risk diminishes considerably after 12 months. In these patients, even short periods without dual antiplatelet therapy increases the risk of instent thrombosis and cardiac events. Therefore, any elective surgery should be postponed in this group of patients. Patients whose thrombotic risk is high, such as those with mechanical heart valves, require discontinuation of warfarin 3 days prior to surgery. Bridging therapy using therapeutic doses of low molecular weight heparin (LMWH) until 12–24 hours before the operation is usually needed. Recommencement of antithrombotic medication should usually begin within 24–48 hours postoperatively.

Table 5.6 Duration of cessation for antiplatelets and anticoagulants before elective surgery

Drug	Time	Pre-op tests	T1/2
Aspirin	5 days		20 K platelets produced per day. 5 days = 100 K platelets
Clopidogrel	5–7 days		20 K platelets produced per day. 5 days = 100 K platelets
Warfarin	3–5 days	INR day of operation	36–42 h
LMWH	12 h	Anti Xa assay	4 h
UH	4 h	Check APTT ratio	1 h
NOAC	2 days		9–17 h (approx. 12 h)

LMWH, low molecular weight heparin; NOAC, new oral anticoagulants; UH, unfractionated heparin.

Emergency neurosurgery

The management of coagulopathies, either iatrogenic or disease-related, in patients undergoing emergency neurosurgery has minimal good evidence to support best practice. Rarely, urgent operations may need to be performed despite a coagulopathy, but in general, there is usually time for patient assessment, laboratory testing, and the institution of appropriate treatments.

Anticoagulation-associated intracerebral haemorrhage

The need for neurosurgical interventions is sometimes the result of prior anticoagulation and antiplatelet medication use. The most common problem encountered is anticoagulation-associated intracerebral haemorrhage (AAICH). The use of oral anticoagulants such as vitamin K inhibitors has increased the incidence of AAICH to 15% of all ICH while these patients have an 11-fold higher risk of developing this complication (Wintzen et al., 1984; Flaherty et al., 2007). Furthermore, patients on oral anticoagulants are at significantly higher risk of haematoma expansion and worse outcomes (Flibotte et al., 2004). Management of AAICH is based on four principals: the need to stabilize the bleed (i.e. prevent expansion); addressing the safety of performing any intervention; emergency reversal of anticoagulation; and monitoring the effect and prevention of thromboembolic complications.

Prevention of haematoma expansion is mainly achieved through strict systolic blood pressure management. A recent meta-analysis of four large randomized trials evaluating blood pressure targets for management of ICH (rapid blood pressure reduction in acute intracerebral haemorrhage; INTERACT; ICH ADAPT; INTERACT2) demonstrated that lowering the systolic blood pressure target to less than 140 mmHg was associated with reduced haematoma growth in the first 24 hours and improved outcomes at 3 months (Tsivgoulis et al., 2014). Therefore, current guidelines recommend systolic blood pressure targets of less than 140 mmHg (Hemphill et al., 2015).

Reversing anticoagulants and antiplatelet agents

Urgent reversal of anticoagulation is frequently difficult to achieve with certainty, takes time to implement, and usually requires transfusion of specific blood products. There is limited evidence regarding the efficacy of specific interventions, nevertheless certain principals are widely accepted. **Table 5.7** summarizes the strategies used to reverse commonly used anticoagulants and antiplatelet agents.

Warfarin

Warfarin is the commonest agent implicated in AAICH. In patients with an international normalized ratio (INR) more than 1.4, vitamin K should be administered. Importantly, vitamin K can take up to 24 h to full effect and therefore, additional measures should be taken. Current recommendations include, transfusion of fresh frozen plasma (FFP) or prothrombin complex concentrate (PCC). FFP contains all clotting factors, however, it requires time to cross-match and large transfusion volumes may lead to lung injury, volume overload as well as allergic reactions. Three (II, IX, and X) and four (II, IX, X, and VII) factor PCC are available. In a study of 202 patients with warfarin-associated bleeding, PCC was shown to normalize the INR within 30 min in approximately 60% of cases, as opposed to 10% of cases who received FFP (Sarode et al., 2013), making PCC the treatment of choice in most centres.

Table 5.7 Emergency reversal of anticoagulation in neurosurgery

Agent	Test	Treatment
Aspirin	PFA-100	1–2 U of platelets; DDAVP 0.4 mcg/kg over 30 min
Clopidogrel	Platelet aggregation test	1–2 U of platelets; DDAVP 0.4 mcg/kg over 30 min
Ticagrelor		1–2 U of platelets; DDAVP 0.4 mcg/kg over 30 min
UH	APTT ratio	Protamine 1 mg per 100 U of UH in last 2–3 h (repeat dose of 0.5 mg per 100 U of UH if APTT remains elevated)
LMWH	Anti-Xa assay	protamine 1 mg per 1 mg (enoxaparin) 100 U (dalteparin). Half dose if >8 h since LMWH administration
Pentasaccharides	Anti-Xa assay	4 factor PCC 20 U/kg; rfVIIa 90 mcg/kg
Warfarin	INR	Vit K 5–10 mg; FFP 15 ml/kg; 4 factor PCC 20 U/kg; rfVIIa
Direct thrombin inhibitors	APTT/TT	Dabigatran—idarucizumab 5 mg in two doses every 15 min; haemodialysis; TXA, 4 factor PCC activated charcoal 50 g if taken within 2 h
Factor Xa inhibitors	Anti-Xa assay	Four-factor PCC 50 U/kg; activated charcoal 50 g if taken within 2 h

LMWH, low molecular weight heparin; NOAC, new oral anticoagulants; PCC, prothrombin complex concentrate; TXA, tranexamic acid; UH, unfractionated heparin.

New anticoagulants

Non-vitamin K oral anticoagulants (NOACs) - also referred to as DOACs (direct oral anticoagulants), are a diverse group of medications which include factor Xa inhibitors (rivaroxaban, apixaban, edoxaban) and direct thrombin (factor IIa) inhibitors (dabigatran). These agents have a rapid onset of action, a close dose-dependent effect, shorter half-lives (average: 5–15 hours), undergo renal and hepatic metabolism, and have a more predictable pharmacokinetic profile. Therefore, the major advantage is a much lower requirement for routine drug monitoring. If a patient is on a NOAC agent, has normal renal and liver function, and there is a low surgical bleeding-risk compared to a VTE event, then a discontinuation for 2–3 half-lives of the drug would suffice or 4–5 half-lives when the bleeding-risk is high. On average, the half-life of NOACs is 12 hours, therefore, it is thought that discontinuation for 48 hours allows for safe surgery. Once haemostasis is deemed stable postoperatively, NOACs should be restarted as soon as possible.

However, with the exception of dabigatran, there is no specific antidote for these medications. Idarucizumab, a monoclonal antibody against dabigatran is now licensed for rapid reversal of bleeding associated with its use. In the emergency situation or when no antidote is available, expert opinion recommends the use of activated four-factor prothrombin complex concentrate, activated recombinant factor VII, the possible use of oral activated charcoal (patient presents within 2 hours of NOAC ingestion) and haemodialysis. It is important to acknowledge that the commonly measured laboratory assessments of haemostasis are either prolonged or unaffected by NOACs and that normal values may not exclude a clinically relevant concentration of

the drugs. Anti-Xa assays, diluted thrombin time (TT) tests, ecarin clotting times, and NOAC antidotes are currently being assessed in clinical trials to enable the development of evidenced-based guidelines for NOAC reversal (Gehrie and Tormey, 2015).

Heparin

Unfractionated heparin (UH) treatment is associated with ICH in only 0.1% of patients. Emergency reversal involves stopping the infusion and administering protamine. Monitoring APTT is mandatory as repeated doses of protamine may be indicated. LMWH inhibits factor Xa via antithrombin, but has a limited effect on thrombin. Protamine (1 mg per 1 mg of enoxaparin or 100 U of dalteparin) only partially reverses LMWH and any residual effect should be monitored using, an anti-factor Xa assay.

Antiplatelet agents

The association of antiplatelet agents with ICH is controversial and unconfirmed in recent literature (Sansing et al., 2009). In general, antiplatelet drugs should be discontinued when ICH is diagnosed. Interestingly, the PATCH study (Baharoglu et al., 2016) which was the first randomized trial of platelet transfusion for ICH associated with antiplatelet use, demonstrated a shift towards unfavourable outcome in the transfusion group. Although evidence is not conclusive, platelet transfusion is not recommended unless surgical intervention is planned (Frontera et al., 2016). DDAVP was shown in a small study to improve platelet function and may be considered for patients on aspirin, ADP receptor inhibitors or for COX-1 inhibitor associated ICH (Kapapa et al., 2014; Naidech et al., 2014; Frontera et al., 2016).

Venous thromboembolic disease in neurosurgery

Incidence

The development of a DVT of the lower or upper limbs is believed to be the source of up to 90% of pulmonary emboli. The term venous thromboembolism refers to both phenomena. It is the potential for embolization of the blood clot to the lung, associated with a mortality rate of 50–60%, which is of critical importance in relation to preventable death. In the neurosurgical population, the main risk factors for VTE include, neurological malignancy, traumatic brain injury, spinal cord injury, cerebrovascular disease, prolonged surgery, steroids, sepsis, and decreased mobility. Using only mechanical devices, the estimated risk of developing a DVT after a neurosurgical procedure is about 16%. When LMWH is added to the prophylactic regimen within 24 hours after surgery, the risk is reduced to 9%. The risk of a pulmonary embolism (PE) is generally acknowledged to be about 1.5–5%. Recent studies in neurosurgical interventions confirm a reduction in the number of symptomatic VTEs over bleeding episodes by the early use of LMWH (Rolston et al., 2014).

Prophylactic treatment

Craniotomy for brain tumours

Kimmell and Jahromi (2015) showed in their cohort of over 4000 patients undergoing a craniotomy procedure that the rate of VTE was higher than for other neurosurgical patients. Further analysis demonstrated that neuro-oncological surgery, medical comorbidities, age greater than 60 years, use of steroids, surgical time greater than four hours, and postoperative complications significantly increased the risk of VTE. In a systematic review by Salmaggi et al. (2013) it was concluded that all patients undergoing neuro-oncological surgery should have mechanical prophylaxis for VTE instituted preoperatively and continued until discharge, while patients considered to be at a low risk for major bleeding should have LMWH added 24 hours after surgery. However, in practice all patients after craniotomy for tumour, unless specifically instructed not to, should have LMWH DVT prophylaxis from post operative day 1.

Spinal surgery

The incidence of VTE in patients undergoing spinal surgery can vary according to the spinal level operated on, extent of the surgery, and the degree of perioperative mobility. Patients having thoracolumbar surgery with instrumentation and fusion appear to be at a higher risk of VTE. While some form of intraoperative mechanical prophylaxis is considered a minimum, postoperative chemoprophylaxis should be considered for patients undergoing complex spinal surgery of long duration, anterior-posterior approaches, and those with known thromboembolic risk factors such as spinal cord injury, malignancy, and hypercoagulable states. In view of the known and definable risks of neurological deterioration from epidural haematoma formation along with bleeding, transfusion and wound complications, individual risk–benefit analysis for chemoprophylaxis is required on all patients undergoing spinal surgery.

Traumatic brain injury

The incidence of DVT in TBI without prophylaxis can be as high as 54% (Foreman et al., 2014). Using mechanical prophylaxis, studies have shown a fall in rates to 30% for DVTs and 3% for PEs. Chemoprophylaxis in this setting is controversial because of concern over the expansion of the intracranial haemorrhage. Several studies have shown rates of around 3% progression in the setting of a stable intracranial injury (low risk TBI) leading to the generation of protocols (e.g. Parkland protocol) suggesting a stable repeat CT of the head within 24 hours from admission of a TBI can permit the safe administration of LMWH (Phelan, 2012). Where patients have multiple contusions, epidural, subdural, subarachnoid, or intraventricular blood, they are deemed a moderate risk TBI and LMWH is only instituted when a CT scan performed after 72 hours shows a stable lesion. Patients requiring a craniotomy or external ventricular drain for a high risk TBI pattern should be considered for insertion of an inferior vena cava (IVC) filter which has been shown to help reduce PEs but may increase DVT recurrence.

Low-grade glioma

Thomas Santarius, Lorenzo Bello, and Hugues Duffau

Introduction

The term 'low-grade glioma' generally means glioma of a grade lower than anaplastic according to the WHO Classification of Tumours of the Central Nervous System, last revised in 2016 (see Louis et al., 2016). In this chapter we are going to focus on the management of adult patients with supratentorial WHO grade 2 diffuse low-grade gliomas (DLGG), that is, astrocytomas and oligodendrogliomas. It is becoming increasingly clear that these histological diagnoses do not describe uniform entities, but rather a heterogeneous spectrum of neoplastic diseases with a diverse biological and clinical behaviour. At the same time, radiological and molecular markers are being identified, gradually improving the prognostic accuracy.

It was once generally believed that low-grade gliomas are static in terms of their biology, but now we know that these tumours, like most other neoplasias, undergo evolution into biologically more aggressive entities, eventually satisfying histological criteria for WHO grade 3 or 4. This is often referred to as malignant or anaplastic transformation (AT), a change from a non-malignant to a malignant entity. Although such change can be sudden and dramatic in some cases, especially from the clinical point of view, it is likely to be more incremental at the biological level in most patients. In other words, DLGGs rather than being a disease, constitute a period, a stage in the evolution of a disease.

Last decades have brought major technical and conceptual advancements in cognitive neurosciences, imaging, and genetics, leading to the emergence of seminal concepts of DLGG as a brain disease and individualized treatment. It is wrong to think of DLGG as a tumour mass within the brain. Instead, it should be thought of as a progressive, invasive, and chronic disease of the central nervous system. The effects of the disease on the brain and consequently on the patient are specific to the individual patient and have a dynamic dimension. Because of brain function is so fundamental to the definition of an individual, his/her role in family and wider society, even the most subtle impairment and alterations can have profound influence on patient's quality of life and social function. The management of patients with DLGG has therefore moved away from the classical, rigid order of therapeutic modalities (surgery followed by irradiation in the case of incomplete resection, followed by chemotherapy at recurrence) without any attempt to tailor the sequence of treatments to the individual patient. Here we present a modern view of the management of patients with long-term, multimodal, individualized, and dynamic planning with built-in flexibility to respond to the feedback provided by clinical, radiological, and histomolecular data with the aim to maximize the length and quality of life of each individual patient.

Incidence

Based on the data from Europe and the United States, the incidence of DLGG is approximately 1–1.5/100 000 patients/year (astrocytic low-grade glioma (LGG), 0.6–1.2/100 000 patients/year; oligodendroglial LGG, 0.3/100 000 patients/year), accounting for 10–15% of all primary brain tumours (Crocetti et al., 2012; Ostrom et al., 2014). At the time of diagnosis, patients with DLGG are typically between 30 to 45 years of age (Capelle et al., 2013). In the French study of 1295 DLGGs, 47 cases were incidental. The age at radiological diagnosis of the incidental DLGGs was found to be slightly lower as compared symptomatic DLGGs (median of 35.5 vs. 37.0 years; Pallud et al., 2010b). The incidence of GLGGs will likely increase with growing access to brain imaging worldwide.

DLGGs show predilection for eloquent areas, such as the insula or the supplementary motor area (Duffau and Capelle, 2004). This preferential location may be, at least partially, due to the fact that the threshold for triggering symptoms is lower in these areas of the brain (Pallud et al., 2010b). This is consistent with the observation that incidentally found DLGGs occur less likely in eloquent areas (Pallud et al., 2010b; Potts et al., 2012; Zhang et al., 2014).

Males constitute approximately 60% of patients in most DLGG series (McGirt et al., 2008; Schomas et al., 2009; Pallud et al., 2010a). This slight male preponderance was found to be inverted in the incidental DLGG cohort (58% females) analysed by Pallud et al. and later confirmed by Potts et al. (Pallud et al., 2010b; Potts et al., 2012). The reason for the gender distributions of symptomatic and incidental DLGGs is unclear. Based on the finding that headaches were listed as the most common reason for requesting an MRI, the authors hypothesized that the gender representation difference between symptomatic and asymptomatic cohorts (P <0.001) may be related to higher incidence of headaches in women (Pallud et al., 2010b) or women generally being more likely to seek medical attention than men (Potts et al., 2012).

Clinical presentation

More than 80% of patients will DLGGs present with seizures. Others present with focal deficits, altered mental state, or increased intracranial pressure (Pallud et al., 2010b; Pallud et al., 2014). Epileptic seizures are more frequently associated with cortically based tumours, particularly in frontal, temporal, and insular and central locations and with oligodendroglial tumours (Pallud et al., 2014).

Patients presenting with neurological deficit have always formed a minority, but they are getting even rarer. In a retrospective review of hospital records of 852 adult patients, Youland et al. compared clinical presentations of two historical cohorts, 1960–1989 and 1990–2011 (Youland et al., 2013). The authors found that in the earlier cohort more patients presented with multiple symptoms at diagnosis than in the more recent cohort (51% vs. 24%; P <0.0001)—see also **Table 6.1**.

The relative scarcity of neurological deficit as well the existence of time lag of months or even years before development of seizures in the presence of DLGGs may be somewhat surprising, especially as these tumours are frequently located within eloquent brain areas (Duffau and Capelle, 2004). This stands in clear contrast to the presentation of higher-grade gliomas, especially glioblastoma multiforme, and is due to several factors, including the lack, or only a minimum of cerebral oedema, and the slow-growing nature of DLGG. The latter allows relocation of invaded cerebral functional circuits, in other words remapping of brain function, a phenomenon known as brain plasticity (Duffau, 2005). Increasingly more DLGGs are diagnosed as a result of scanning for reasons other than suspected glioma. In the aforementioned 1960–1989 cohort of Youland et al. there were no incidental DLGGs, while there were 11 in 1990–2011 cohort (Youland et al., 2013).

Although 'gross neurological deficit' such as dysphasia and hemiparesis are rare at presentation of DLGGs, more subtle cognitive deficits are often observed when objective neuropsychological assessments are performed at the time of diagnosis. Disorders of executive functions, attention, concentration, working memory, or emotion are frequently detected (Klein et al., 2012; Duffau, 2013; van Loon et al., 2015; Racine et al., 2015). These deficits can be attributed to the tumour itself, to seizures, and to antiepileptic medications. A systematic assessment of higher mental functions and health-related quality of life is now recommended before oncological treatment. This serves several important purposes: (1) detection of subtle neuropsychological deficits; (2) tailoring of the therapeutic strategy for a given individual (e.g. choosing neoadjuvant chemotherapy rather than surgery first in cases of very diffuse DLGG with cognitive disturbances); (3) devising of surgical strategy according to the detected deficit and location of the tumour (i.e. selection the optimal neurological tests that should be administrated during awake surgery); (4) establishing of a pretreatment baseline that will allow detection of post-treatment deficit and facilitate planning of specific functional rehabilitation following surgery.

Radiological diagnosis

MRI is the main tool for diagnosing and assessing DLGGs. DLGGs are hypointense on T1 and hyperintense of T2. The extent of the tumour was shown to best correspond to FLAIR hyperintensity (Price, 2010). However, it is important to remember that DLGG is a diffuse neoplastic disease and that glioma cells have been shown to be present beyond the FLAIR signal abnormality as far as 2 cm (Pallud et al., 2010c).

Generally, the lack of enhancement results in a radiological diagnosis of 'low-grade glioma', while contrast uptake by the tumours raises suspicion of tumour being of grade 3 or 4. Although this is true for the majority, more than 30% of cases with no contrast enhancement will be reclassified as grade 3 or 4 and, conversely, some 15–30% of DLGGs enhance (Cavaliere et al., 2005). The likelihood of histological grade being higher than grade 2 in non-enhancing gliomas increases with age (Barker et al., 1997).

Among DLGGs, enhancement is more common in oligodendrogliomas (~20–50%), making the presence of enhancement a feature relatively less grade-specific in oligodendroglial tumours, whose anaplastic counterpart shows enhancement in 62–72% cases (White et al., 2005). Haemorrhage and calcifications are also more common in oligodendrogliomas. Approximately one-quarter of oligodendrogliomas show calcifications, which can be best observed on CT scans (Khalid et al., 2012). Calcifications are twice as common in anaplastic oligodendrogliomas, consistent with their progression from low to higher grade over time (Khalid et al., 2012).

Diffuse low-grade gliomas have characteristic shape, location, and spread along white matter tracts. The MRI appearance or DLGG is not uniform, but instead constitute a range from apparently well-circumscribed tumour at one end, to *gliomatosis cerebri* at the other end of the spectrum (**Fig. 6.1**). Making a diagnosis of DLGG on imaging is usually possible in the context of the clinical picture and by repeating the scan, typically in 3 months or earlier, depending on the degree of suspicion of pathology other than DLGGs and

Table 6.1 Presentation of patients with DLGGs in two historical cohorts, 1960–1989 and 1990–2011

Symptom	Overall N = 852 (%)	1960–1981 N = 281(%)	1990–2011 N = 571(%)	P value

the likelihood of harmful consequences of delayed diagnosis. The radiological differential diagnosis includes: encephalitis, cerebral ischaemia/infarction, and other intrinsic low-grade tumours (e.g. DNET, ganglioglioma) or gliomas of higher grades. However, in the context of good clinical history, the diagnosis of a glioma is rarely in doubt and a biopsy to differentiate this from another process (e.g. Rasmussen encephalitis) is rarely necessary. Needle biopsy is only performed if the alternative diagnosis is more likely and needs to be confirmed histologically (Fig. 6.2). An interval MRI scan, when appropriate, not only helps with differential diagnosis, but is important for patient management as the speed of growth is an established DLGG prognostic factor (see more details later on; see also Pallud et al., 2013). MR spectroscopy can also be useful in differentiating between neoplastic and non-neoplastic lesions (Oz et al., 2014).

Anaplastic transformation represents the principal lethal factor in these patients, as demonstrated by the parallel linearity of the survival and anaplastic curves in a series by Capelle et al. (Capelle et al., 2013). It is therefore important to monitor for this to occur. Positron emission tomography (PET) is not only useful in refining differential diagnosis, especially in the context of radiation-treated gliomas, but can be helpful in identifying potential anaplastic loci (Ewelt et al., 2011; la Fougère et al., 2011; Thon et al. 2015). However, for routine monitoring and detection of AT, perfusion MRI measuring the relative cerebral blood volume (rCBV) is more practical, especially if frequent (e.g. three-monthly) surveillance is required (Danchaivijitr et al., 2008; Hu et al., 2012).

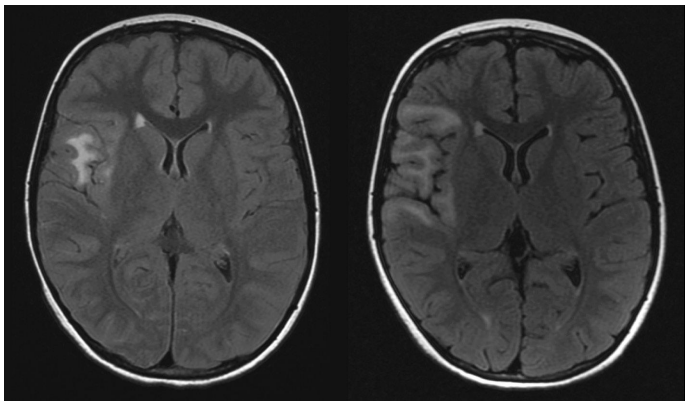

Fig. 6.2 The differential diagnosis of DLGG includes autoimmune encephalitis. This 14-year-old presented with progressive intractable seizures. The scans were taken one month apart.

Management after radiological diagnosis

Establishing radiological diagnosis of DLGG spells a beginning of a journey, whose course is determined by the cancer, the brain, and the choices the patient makes in collaboration with his/her treating team. Yet another level of complexity is added by the long OS and the constant evolution of our understanding of the nature of DLGGs and the effects of treatments on it. Nevertheless, at present, DLGGs remain incurable and over several years they relentlessly progress via serial anaplastic transformations towards the unequivocal endpoint, mortality. In the process the disease volume will increase, distorting and invading the surrounding brain, and will gradually interfere more and more with brain's normal function. The patient journey is complex and the treating team needs, together with the patient, devise a strategy that will maximize the patient's survival while preserving his or her quality of life (QoL). As applies for each patient, so each tumour is individual and both need individualized approach (i.e. personalized treatment).

In Table 6.2 are listed most important variables (prognostic factors) associated with outcome of patients with DLGGs (overall survival and time to anaplastic progression). Their individual and combined influence on the natural history of the disease and QoL need to be taken into. It is vital that patients understand as much as possible about these variables, including the uncertainties associated with each of them. Essentially, some variables are given (clinical, radiological, histological, and molecular prognostic factors) and others can be modified (volume of the tumour) or deployed (treatment: surgery, chemotherapy, and radiotherapy). These are

discussed in following five sections. In the last section we will describe the typical management paths used in our institutions.

Clinical prognostic parameters

Patient age has been a long-established prognostic factor in DLGGs (Bauman et al., 1999; Pignatti et al., 2002; Capelle et al., 2013; Jakola et al., 2013). Interestingly, age has also been associated with higher frequency of anaplasia in non-enhancing gliomas (Barker et al., 1997).

Age, presence of neurological deficits or absence of seizures at onset, and low performance status (KPS <70%) are associated with a poorer outcome (Leighton et al., 1997; Pignatti et al. 2002; Jakola et al., 2012; Capelle et al., 2013).

Radiological prognostic parameters

The negative association between tumour volume and OS has been seen in number of studies (Berger et al., 1994; Lote et al., 1997; Pignatti et al., 2002; Shaw et al., 2002; Chang et al., 2008).

Mass effect, focal deficits, and/or intracranial hypertension leading to a poorer functional status are significant factors on univariate analysis but not on multivariate analysis, probably because they are related to tumour volume. Larger tumour size limits therapeutic possibilities and increases the risk of treatment-related complications (Shaw et al., 2002; Smith et al., 2008). Similarly, extension to or location in eloquent areas is associated with shorter OS, presumably because of the functional limitations to the extent of resection and, possibly, because of earlier development of neurological dysfunction (Chang et al., 2008).

Speed of growth, expressed as velocity of diametric expansion (VDE), a measurement reflecting both the initial tumour volume and the increase in volume (Pallud et al., 2012), was found to be an independent prognostic factor for OS and malignant PFS, regardless of histopathological findings and molecular status (Pallud et al., 2013). One of the strengths of VDE as a predictor and a monitoring tool is its relative immunity to a sampling bias as it takes into account the tumour as a whole. In addition, the method is non-invasive, simple, reproducible, and relatively cheap.

PET, MR spectroscopy, and high cerebral blood volume measured by MRI (rCBV) can detect signs of malignant transformation and correlate with shorter OS (Bisdas et al., 2009; Caseiras et al., 2010), while the presence of lactates and lipids on MR spectroscopy is related to more aggressive behaviour (Guillevin et al., 2012). The choline-to-creatine ratio (Cho/Cr) known to be correlated with tumour cell proliferation (Herminghaus et al., 2002). Cho/Cr as well as NAA (N-acetylaspartate)/Cr ratio can help differentiating between low-grade and high-grade gliomas with sensitivity and specificity in an approximate range of 80–85% (Server et al., 2011; Zou et al., 2011; Collet et al., 2015) including differentiation between grade 2 and grade 3 (Collet et al., 2015). MR spectroscopy detected elevated 2-hydroxyglutarate (2HG) levels in gliomas with *IDH1* mutations compared with wild type in a study of 27 patients with gliomas ($P = 0.003$; see Pope et al., 2012).

Floeth et al. prospectively followed 21 patients with small non-enhancing T2-hyperintense incidental lesions with serial MRI scans and 18F-FET PET (Floeth et al., 2008). Two patients had lesions that demonstrated slow growth and negative 18F-FET PET studies. Subsequent tissue diagnosis revealed WHO grade 2 astrocytomas. A second group of patients had rapid growth with positive 18F-FET PET findings and were found to have high-grade gliomas. However, for routine monitoring and detection of anaplastic transformation, perfusion MRI measuring rCBV is more practical, especially if frequent (e.g. 3-monthly) surveillance is required (Danchaivijitr et al., 2008; Hu et al., 2012).

Functional MR, DTI tractography, and magnetoencephalography (MEG) can be helpful in preoperative planning, but discussion of their role in management of DLGGs is beyond the scope of this chapter (Ottenhausen et al., 2015).

Histological and molecular prognostic parameters

Based on histological examination, gliomas are graded according to the 2016 WHO Classification of Tumours of the Central Nervous System (Louis et al., 2016) into four grades; the higher the grade, the worse the prognosis (Table 6.3). Grade 1 astrocytomas, such as pilocytic astrocytomas and giant cell astrocytomas, for example, constitute an entirely different group of diseases and will not be considered here. Although grade 2 diffuse supratentorial gliomas (astrocytoma and oligodendroglioma; Fig. 6.3) are the subject of this chapter, these cannot be discussed without reference to grade 3 and grade 4 gliomas, not least because grades 2–4 are a continuum rather than discrete categories and, perhaps even more importantly, grade 2 tumours invariably progress to higher grades. Therefore, a grade 2 glioma is a stage of a disease rather than disease itself.

Although overall survival broadly correlates with each histological diagnosis (Table 6.3) there is extensive evidence that tumours from individual patients who share the same histological diagnosis do not necessarily share the same biology and their outcomes may vary widely (Gravendeel et al., 2009; Gorovets et al., 2012). There is a number of reasons for this, but perhaps the two most important being the possibility of erroneous grading and the inherent dynamism of the disease.

The two main sources of diagnostic error are sampling and interobserver variability. The latter is related to the descriptive and ambiguous nature of some of the classification criteria, especially criteria for discriminating between grade 2 and 3 tumours (Louis et al., 2007). For example, the criterion for grade 3 designation of astrocytomas ('brisk mitotic activity') does not clearly specify any mitotic cut-off and is, therefore, subjective and often based on the pathologist's individual experience and bias. In a large study investigating the rate of diagnosis disagreement after expert neuropathology review, approximately 40% of case reviews had some type of disagreement with the original diagnosis, of which approximately 9% were serious with immediate effect on treatment (Bruner et al., 1997). Similarly, the criteria for the mixed oligoastrocytoma category ('recognition of neoplastic glial cells with convincing astrocytic oligodendroglial phenotypes') present in the 2007 edition of the Classification was felt to be highly subjective and this diagnostic category was practically eliminated from the 2016 revision (see more later in this chapter; also see Louis et al., 2016).

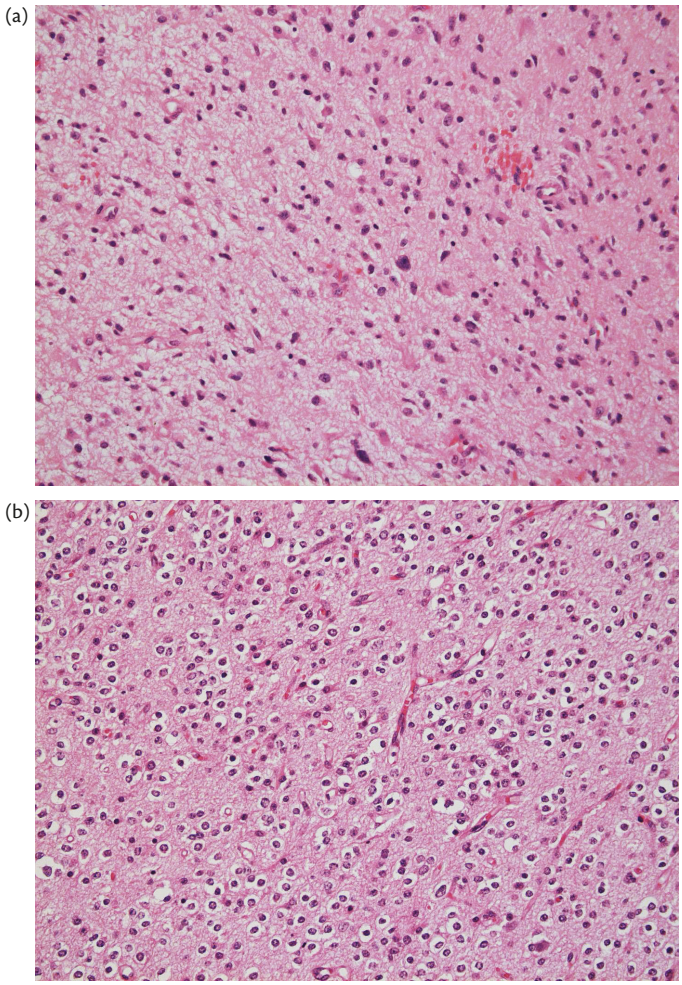

Fig. 6.3 Histological appearance of diffuse low-grade gliomas: astrocytoma (A) and oligodendroglioma (B) (haematoxylin and eosin staining, 20× magnification).

(A) Aastrocytomas are hypercellular area as compared to the normal white matter. There is nuclear pleomorphism and small microcysts. There are no vascular proliferation and no necrosis. (B) Oligodendrogliomas are composed of monomorphic cells with uniform round nuclei and perinuclear halos ('fried egg' or 'honeycomb' appearance). The perinuclear halo is artefact due to fixation, and is not present in frozen sections. Another typical feature seen on this slide is the arborizing thin capillaries often described as 'chicken wire pattern'.

Histological grade intratumoural heterogeneity and consequent sampling error is another important source of possible misdiagnosis. Kunz et al. have found anaplastic foci to be between 0.6 and 8.7 ml in volume and covering 4–44% of the entire visible tumour volume (Kunz et al., 2011) Inadequate sampling (especially with needle biopsy and subtotal resections), failure to process, and histologically examine the entire specimen, could lead to overlooking anaplastic foci and so result in an erroneous diagnosis, usually undergrading of the disease. Sampling accuracy can be improved with the use of PET-directed guidance, both in the case of needle biopsy and resection (Kunz et al., 2011; Thon et al., 2015). The addition of 5-ALA may also help with intraoperative identification of the hotspot(s) demonstrated on preoperative PET (Ewelt et al., 2011). These facts need to be taken into account when interpreting old studies in which diagnosis was established based on needle biopsy alone.

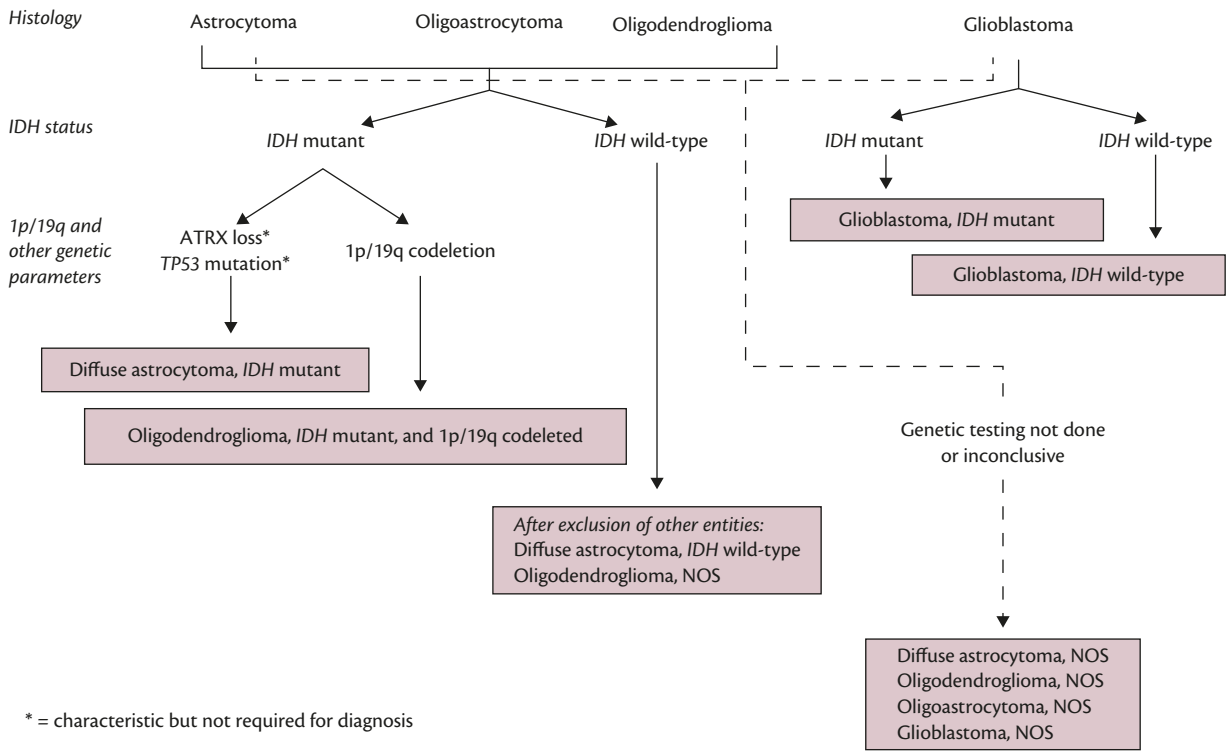

Fig. 6.4 A simplified algorithm for classification of the diffuse gliomas based on histological and genetic features.
Data from Louis, D.N. et al., *WHO classification of tumours of the central nervous system*, IARC Press. 2016.

The limitations of histological diagnosis are a major driver for searching for more accurate, objective, and clinically relevant markers for stratifying patients with DLGGs. As cancer is essentially a genetic disease (Vogelstein and Kinzler, 2004), undoubtedly it will be molecular biology that will deliver many of such markers. Indeed, a number of glioma-relevant molecular markers have been discovered and seem to be superior to histology in predicting outcome (Gorovets et al., 2012). These include the presence of mutations or *IDH1* or *IDH2, ATRX*, and *TERT* genes, and the loss of 1p/19q chromosomal arms and have been incorporated, for the first time, in the latest WHO classification (Louis et al., 2016). In fact, if the tumour bears the molecular characteristics of an oligodendroglioma (IDH-mutant and 1p/19q-codeleted) it is diagnosed as oligodendroglioma, even if histologically it was to look like an astrocytoma. Similarly, if the tumour was to look like an oligodendroglioma under the microscope, but was found to have mutated IDH, ATRX, and TP53, but intact 1p/19q it will be diagnosed as diffuse astrocytoma (see also **Fig. 6.4**). This will leave the rather vague category of oligoastrocytoma reserved for cases where cell population with demonstrated oligodendroglial and astrocytic molecular features, respectively, are demonstrated or where histologically (phenotypically) both oligodendroglial and astrocytic tumour cells are present. The latter applies only to situations where molecular diagnostic tests are not available.

An inactivating mutation of a gene coding for isocitrate dehydrogenase 1 or 2 (IDH-1 and 2) occurs in approximately 75% of grade 2 and 3 diffuse gliomas and 80% of secondary glioblastomas, which themselves constitute only a minority of glioblastomas (~10%). IDH mutations are very rare (<5%) in secondary glioblastomas. These facts are consistent with the notion that IDH mutations are early events in the evolution of gliomas. There appear to be a separate, mutually exclusive with IDH-mutated DLGGs, lineages of development of DLGGs, characterized by ATRX and p53 or TERT mutations (Eckel-Passow et al., 2015). These lineages are associated with an astrocytic phenotype. 1p19q codeletion is associated with oligodendroglial phenotype.

Recently, two major molecular studies by the Cancer Genome Atlas (TCGA) group (Cancer Genome Atlas Research Network et al., 2015) and the Mayo Clinic-University of California San Francisco (Mayo-UCSF; Eckel-Passow et al., 2015) collaborative were published. In the TCGA study, diffuse grade 2 and 3 tumours displaying IDH mutation and 1p/19q codeletion (1p/19q-del) had the best prognosis, followed by those with IDH mutation and no 1p/19q-del. IDH wild-type tumours had the same survival as glioblastomas (Cancer Genome Atlas Research Network et al., 2015). In the Mayo-UCSF study, diffuse grade 2 and 3 tumours were classified into five glioma molecular groups using three alterations: mutations in the TERT promoter and in IDH, and 1p/19q codeletion (Eckel-Passow et al., 2015). *IDH mutation only* tumours were found to be the most common (45%) and bear intermediate prognosis. They account for half of all patients who have gliomas with an oligodendroglial component and two-thirds of those who have grade II or III astrocytomas. These tumours almost always acquire mutations in TP53 and ATRX. *Triple-positive* (IDH- and TERT-mutated, 1p/19q-del) tumours were the second most common (29%) and were found to have good prognosis. They have few additional acquired alterations and are strongly associated with the oligodendroglial histological type. IDH- and TERT-mutated without 1p/19q-del have similar prognosis, but are rare (5%). Triple negative tumours occur with similar frequency (7%) and have poor prognosis. The

associated mutations occur in *EGFR, PTEN*, and *NF1* genes. The worst prognosis is associated with TERT-only mutation (wild-type IDH, no 1p/19q-del). These tumours made up 10% of the grade 2 and 3 cohort. Similarly to the triple negative group, they had numerous other gene mutations, including *EGFR, EGFRvIII, PTEN, NF1, RB1*, and *PIK3CA* or *PIK3R1*.

The classification of tumours is an evolving process. The discovery of molecular markers and better understanding of the biology of gliomas will undoubtedly accelerate and further change the way gliomas are classified today.

Surgery

The value of surgery in the management of DLGGs had been controversial. Over the last two decades, however, it has become increasingly clear that surgical resection can be a major positive factor influencing the natural history of patients with DLGG. Both, improved data collection and refined surgical techniques based on better understanding of the brain and tumour/brain interaction facilitated these developments.

The classical low-grade glioma literature suffers from several shortcomings related to data collection, including lack of stringent reporting of histological diagnosis, length, and quality of follow-up and measurement of the extent of resection, which was largely based on the surgeon's intraoperative impression (Sanai and Berger, 2008). If postoperative imaging was used at all, it was not used in a systematic manner and lacked uniformity (Sanai and Berger, 2008). Due to the invasive nature of DLGG, the extent of residual tumour was underestimated in numerous studies, resulting in erroneous conclusions about the benefit of surgery. Today, FLAIR MRI is the gold standard for objective calculation of postoperative residual volume.

In all recent series with objective postoperative evaluation of the extent of resection (EOR) based on volumetric assessment of FLAIR MRI (reviewed later on), the degree of resection predicted a significant improvement in OS. When no signal abnormality was visible on postoperative MRI (complete resection), patients had a significantly longer OS compared with patients having any residual abnormality. Moreover, even with incomplete resection patients with greater degree of resection had a significantly longer OS. This is due to the fact that surgery delayed 'histological upgrading', because the volume of residual tumour serves as a predictor of AT (Berger et al., 1994). The likely underlying mechanism of this effect is removal of all or many of anaplastic foci, which could result in immediate histological upgrading and the case being excluded from the 'low-grade cohort' or true biological downgrading of the tumour. In fact, such downgrading is not a binary event, but rather graded reduction of the anaplastic potential of the residual tumour, which is reflected by continuous character of the inverse relationship between OS and the residual tumour volume.

In 156 DLGGs, Claus et al. (2005) reported that patients who underwent incomplete resection had 4.9 times the risk of death compared with those who underwent total resection.

Yeh et al. (2005) demonstrated that EOR and postoperative KPS showed independent prognostic significance for OS using multivariate analysis of 93 consecutive DLGGs.

Comparing two historical cohorts one of 100 DLGG resections without (1985–1996) and one of 122 resections with functional mapping (1996–2003), Duffau et al. (2005) found that 20.6% of patients with more than 10 cc of residue died, while only 8% of patients with less than 10 cc of residue died and no patients with complete resection died ($P = 0.02$).

In the series by Smith et al. (2008) with 216 DLGGs, after adjusting for the effects of age, KPS, tumour location, and tumour subtype, EOR remained a significant predictor of malignant PFS ($P = 0.005$) and OS ($P = 0.001$), with an 8-year OS of 98% of patients who underwent complete resection. Moreover, the survival was significantly better with at least 90% EOR compared with less than 90% EOR, whereas EOR of at least 80% also remained a significant predictor of OS.

McGirt et al. (2008) observed that gross total resection (complete resection of the preoperative FLAIR signal abnormality) versus subtotal resection was independently associated with increased OS ($P = 0.017$). In 191 consecutive DLGGs, the same team also showed that gross total resection was an independent factor associated with anaplastic transformation ($P = 0.05$; see Chaichana et al., 2010).

In 130 DLGGs studied by Ahmadi et al. (2009), using multivariate analysis the authors identified more than 90% resection to be associated with prolonged OS.

In a study of 314 DLGG patients with 13.6-year follow-up, Schomas et al. (2009) identified by multivariate analysis that less than subtotal resection was an adverse prognostic factor for OS. The same team has also recently confirmed that gross total resection and subtotal resection were factors associated with improved OS in a series with 852 DLGGs (Youland et al., 2013).

Based on a review of 190 cases of DLGGs, Ius et al. (2012) demonstrated that patients with an EOR equal to or more than 90% had an estimated 5-year OS of 93%, those with EOR between 70% and 89% had a 5-year OS of 84%, and those with EOR less than 70% had a 5-year OS of 41% ($P = 0.001$).

Jakola et al. (2012) investigated survival in population-based parallel cohorts of DLGGs from two hospitals with different surgical strategies. Treatment at a centre that favoured early surgical resection was associated with better OS (median survival was not reached) than treatment at a centre that favoured biopsy and watchful waiting (median survival, 5.9 years).

Finally, the French Glioma Network (FGN) published the largest surgical series of DLGG ever reported (1097 patients), showing that EOR and postsurgical residual volume were independent prognostic factors significantly associated with longer OS (Capelle et al., 2013). The same group has also found surgical resection being an independent prognostic factor associated with increased malignant PFS ($P = 0.001$) and OS ($P = 0.016$), based on a series of 1509 DLGGs (Pallud et al., 2014), In this series, the OS was almost 15 years, that is, about double of the OS reported in classical studies in which no attempt was made to perform extensive resection (Karim et al., 2002; Pignatti et al., 2002; van den Bent et al., 2005; De Witt Hamer et al., 2012) or in series with only a biopsy (Jakola et al., 2012).

The modern literature has thus provided ample evidence about the oncological benefit of radical resection of DLGGs. This oncological benefit has to be, however, balanced against the risk of functional deficit that may arise from radical surgery (onco-functional balance). The advances in the understanding of the brain, tumour, brain-tumour interaction as well as popularization of awake surgeries and direct electrical brain stimulation (DEBS) techniques led to improvement of surgical techniques and consequent reduction of permanent neurological deficit to below 5% (Keles et al., 2004; Duffau et al., 2008; McGirt et al., 2008; Smith et al., 2008; Capelle

et al., 2013), thus gaining oncological advantage while controlling the functional risks. Some of the factors that have driven improvements in surgical outcomes, both technical and conceptual, will be discussed next.

A great deal of progress has been made in understanding of brain function, moving from the concept of 'cortical areas' with specific functions to the concept of functional networks, also known as the hodotopical model (hodos—pathway, topos—place; see Duffau, 2015). As gyri and sulci are readily recognizable at surgery, surgeons have traditionally focused on recognizing and preserving cortex known to be associated with certain function, such as precentral gyrus housing neurons of the corticospinal tract. White matter, on the other hand appears amorphous and was, therefore, largely ignored with the consequences of either very conservative degree of resection or uncontrolled risk of neurological deficit or both.

Another important concept is that of brain plasticity, that is, the ability of brain functions to relocate from one anatomical location to another ('brain rewiring'). Brain plasticity is the underlying reason why neurological deficits are rare in patients with DLGG, even if these tumours are frequently located within eloquent areas (Duffau and Capelle, 2004). The slow-growing nature of these tumours allows functional remapping of the brain to take place, thus allowing broad surgical resection of brain regions traditionally deemed to be inoperable (Desmurget et al., 2007; Duffau, 2014). For example, extensive removal of diffuse tumour invading the classical 'Broca's area' in the left hemisphere has been carried out without causing permanent neurological deficit. (Benzagmout et al., 2007; Lubrano et al., 2010). In addition, resection of the pars opercularis and/or pars triangularis of the left inferior frontal gyrus is possible without risking aphasia, for two reasons. First, in a networking model of the human brain based on a probabilistic map of critical regions built from 771 stimulation sites, it has recently been demonstrated that Broca's area is not the speech output region (Tate et al., 2014; Tate et al., 2015). Second, tissue loss in this area can be compensated for by recruitment of adjacent regions, primarily the ventral premotor cortex (the crucial epicentre for speech articulation), and the pars orbitalis of the inferior frontal gyrus, the dorsolateral prefrontal cortex, or the insula as well as by remote areas, such as the contralateral homologous region (Benzagmout et al., 2007; Duffau, 2012a).

Even if some DLGGs may appear as 'well-circumscribed', they all infiltrate brain along the white matter tracts and, as such, tumour and tissues are intermingled. Aiming primarily 'to remove tumour' will either carry out an uncontrolled risk of neurological deficit or will result in lower than possible degree of resection. Instead, it is helpful to think of DLGG surgery as surgery on the brain rather than tumour surgery. The limit of resection should not be the 'tumour boundary' but rather brain functional boundary. Therefore, although image navigation is useful, it is the identification of critical brain 'hodos' and 'topos' through the combination DEBS and suitable neurophysiological and clinical feedback tools (Coello et al., 2013; Bello et al., 2014). It is therefore not surprising that the use of intraoperative DEBS has been found to be associated with greater degree of resection (gross total resection of 75% vs. 58%) and lower rate of permanent neurological deficit than in surgeries without DEBS (3.4% vs. 8.2%; see De Witt Hamer et al., 2012). Awake surgery is another important tool in the armamentarium for surgery for DLGGs and is absolutely essential for gaining functional feedback in cases infiltrating or adjacent to regions of the brain involved in speech. A prospective study of 105 patients conducted by the European Low Grade Glioma Network has found awake surgery to be well-tolerated and safe (Beez et al., 2013). Resection probability maps, a quality assessment tool of resective glioma surgery, was developed by De Witt Hamer et al. (2013) The technical details of surgery for DLGG are beyond the scope of this chapter and are covered elsewhere in this textbook.

The concept of functional boundaries being the limit of resection enables, in some cases, performing a supratotal resection (i.e. resection extending beyond the MRI signal abnormalities). A recent series reported that a supratotal resection performed in patients with a DLGG within non-eloquent brain regions avoided AT at a mean follow-up of 35.7 months and maximum follow-up of 135 months (Yordanova et al., 2011). This series was compared with a control group having only complete resection for a DLGG. AT was observed in seven patients in the control group but not in any of the patients who underwent supratotal resection ($P = 0.037$). Furthermore, adjuvant treatment was administrated to ten patients in the control group versus only one patient with supracomplete resection ($P = 0.043$).

In addition to the oncological benefit, surgical resection can often result in symptomatic improvement (Teixidor et al., 2007; Duffau et al., 2009). This is especially true for patients suffering from epilepsy, the most common and often debilitating symptom of patients with DLGGs. Gross total resection was found to be predictive of seizure freedom in two institutional studies (Englot et al., 2011; You et al., 2012). In a large series (N = 1509) by the FGN not only total, but also subtotal resections were found to be predictive of postoperative seizure control (Pallud et al., 2014).

Reoperation should be considered not only at recurrence, but right at the outset as a part of a long-term, multimodal treatment plan for a patient with DLGG. In the FGN series using multivariate analysis, subsequent surgical resection was an independent prognostic factor significantly associated with longer OS (Capelle et al., 2013). As with primary surgery the degree of resection influences OS (Ramakrishna et al., 2015). Reoperation should be considered in all recurrent tumours, including those located in eloquent areas as greater degree of resection can be achieved. In the series by Martino et al., total or subtotal resection was achieved in 73.7% of patients during the reoperation, despite involvement of functional areas (Martino et al., 2009). In this series, the median time between surgeries was 4.1 years. As the rate of anaplastic transformation found at reoperation is high (42–58%; see Schmidt et al., 2003; Martino et al., 2009; Ramakrishna et al., 2015) and because transformed tumours had longer time to second operation (49 compared to 22.5 months; Schmidt et al., 2003), it was proposed to overindicate early reintervention rather than perform late surgery after AT had already occurred (Martino et al., 2010).

Such a multistage surgical approach—beginning with initial function-guided resection, followed by a period of several years, and then a second surgery with optimization of EOR while preserving QoL—is possible, thanks to brain plasticity (Duffau, 2005; Duffau, 2014). Cerebral remapping can be induced by the first surgery itself, the postsurgical functional rehabilitation, and the slow-growing nature of DLGG (Duffau, 2011). Regular neurocognitive assessments and serial functional neuroimaging can provide helpful data for predicting EOR of a second or even third or fourth surgery. (Duffau, 2013; Duffau, 2014). Thus, the optimal onco-functional balance of

multiple surgeries can be found for each patient only if the relationship between the growth of DLGG and brain adaptation are taken into account (Duffau, 2012c).

However, a significant oncological benefit of surgery was demonstrated only when the resections were at least subtotal. Therefore, when the glioma is very diffuse, especially with wide invasion of the cortico-subcortical structures that cannot be removed due to limitations of cerebral plastic potential (Duffau and Taillandier, 2015) and/or with bihemispheric infiltration, one can predict that surgical removal will be only partial (Duffau, 2011; De Witt Hamer et al., 2013). In these cases, there is no indication to perform (re-) operations except in patients with intractable epilepsy because even partial resection may result in a relief of seizures. This is particularly true for tumours located within the insula or mesiotemporal structures. Rarely, planned subtotal resection maybe indicated for existing or anticipated radiation treatment-induced focal symptomatic mass effect or raised intracranial pressure. In cases with intractable epilepsy, chemotherapy (ChT) and/or radiation therapy (RT) should also be considered.

Although the vast majority of GLGGs present with seizures, increasingly more DLGGs are discovered when cranial imaging is ordered for reasons other than suspected glioma, the most common reasons being headaches and trauma (see also the section on incidence; Pallud et al., 2010b; Potts et al., 2012; Zhang et al., 2014). Incidental compared to symptomatic DLGGs are less likely to be located in eloquent areas of the brain, have lower preoperative volume, greater likelihood of total resection and longer OS (Pallud et al., 2010b; Potts et al., 2012; Zhang et al., 2014). Incidental discovery was found to be associated with a significant survival benefit ($P = 0.04$) (Pallud et al., 2010b). As EOR is a major predictor of OS, PFS, and AT, and because of gross total and supratotal resections are more likely achievable in incidental DLGGs, early and radical surgical resection has been proposed (Duffau, 2012b) and arguments are now being put forward for screening for DLGGs (Mandonnet et al., 2014).

Chemotherapy

The usefulness of chemotherapy for patients progressing after surgery and RT is well established (Soffietti et al., 2010). PCV (procarbazine, lomustine (also known as CCNU), vincristine) and temozolomide (TMZ) yield similar objective response rates on MRI (45–62%) and duration of response (10–24 months). However, the toxicity profile favours TMZ because of its better tolerability (especially reduced myelotoxicity) and resulting QoL (Soffietti et al., 1998; van den Bent et al., 1998; Quinn et al., 2003; van den Bent et al., 2003; van den Bent et al., 2012; Fisher et al., 2015). ChT may also result in improvement of QoL, especially for patients responding radiologically and some patients with stable disease, thanks to reduction of seizures and neurological deficits. (Quinn et al., 2003; Koekkoek et al., 2015).

ChT as initial treatment after surgery has also been investigated in DLGG patients with incomplete resection, persisting seizures, or rapid progression on follow-up MRIs (Hoang-Xuan et al., 2004). In most cases, a response was observed by objectively calculating the growth rate on repeated MRIs with at least minor, or even partial, shrinkage of the tumour (Ricard et al., 2007). The reduction in volume can occur with a latency of as much as 24–30 months and may persist once ChT has been terminated, even though this is not the case for the majority of patients. Most patients with seizures have clinical benefit, even in the absence of a radiological change (Koekkoek et al., 2015). Patients with oligodendroglial tumours are more likely to respond, but those with mixed or astrocytic tumours also may respond (Koekkoek et al., 2015). Although the vast majority of DLGGs exhibit some response to TMZ treatment, the response rate is significantly higher and the duration of response is longer and resulted in longer PFS and OS for patients with 1p/19q loss than for those with 1p/19q intact (Kaloshi et al., 2007; Kesari et al., 2009). Although patients with methylated MGMT promoter had a longer OS when treated with TMZ, protracted low doses of TMZ when compared with standard TMZ regimen have resulted in prolonged OS and PFS even in patients with unmethylated MGMT promoters (Kesari et al., 2009). However, this was associated with increase in TMZ-related toxicity.

Johnson et al. (2014) have described occurrence of multiple mutations in DLGG patients treated with TMZ. Six out of their ten patients treated with TMZ recurred as high-grade gliomas. However, the study cohort (N = 23) is not representative of DLGGs as a whole as only one case was an oligodendroglioma with all samples having either *ATRX* or p53 or both genes mutated and nearly three-quarters of the tumours recurred as high-grade gliomas. At present it is unclear whether this TMZ-induced hypermutation genotype found in this study is a phenomenon occurring in DLGGs across the board and it is even less clear whether the hypermutation genotype influences outcome in DLGGs. As such these findings should be regarded only as a laboratory finding (van den Bent, 2014).

Radiotherapy

Two phase III randomized trials have demonstrated no advantage for high versus low radiation doses and reported increased toxicity in higher doses (Karim et al., 1996; Shaw et al., 2002). Regarding the timing of radiotherapy (RT), the European Organization for Research and Treatment of Cancer (EORTC) 22845 phase III randomized trial has shown that early RT had no impact on OS, despite an increase in PFS (Karim et al., 2002; van den Bent et al., 2005). Although RT may be beneficial for seizure control, patients who had neuropsychological follow-up at a mean of 12 years and were free of tumour progression maintained their cognitive status if not irradiated, whereas patients who received RT experienced worsening of their attentional and executive functioning as well as their information-processing speed (Douw et al., 2009). It is nonetheless important to acknowledge some limitations in this study: the lack of baseline testing, the inherent selection bias of patients who received radiotherapy having more aggressive disease, and the use of out-dated techniques such as whole brain radiotherapy.

Results from RTOG 9802 trial (18–39-year-olds with less than total resection or biopsy or 40-year-olds and older with any extent of resection) presented at the 2014 meeting of the American Society of Clinical Oncology showed improved OS when upfront RT and PCV were given compared RT alone (13.3 vs. 7.8 years, $P = 0.03$; see Mehta et al., 2014). The upfront RT and PCV also conferred advantage over RT alone in PFS (10.4 vs. 4.0 years, $P = 0.002$). This study is frequently misinterpreted as demonstrating benefit of early use of radio- and chemotherapy. Instead, it demonstrates benefit of early use of chemotherapy. Because of its potentially delayed neurotoxicity and the equivalent results in terms of OS whatever the timing of treatment (early or late), RT is being increasingly reserved to high-risk patients with unresectable tumours or tumours that cannot be

reoperated and in cases of progression after ChT, but not as a first therapeutic option (Youland et al., 2013).

Multimodal and multistaged treatments strategies used at our institutions

In this section we present a brief summary of our current approach to the treatment of patients with DLGGs (Fig. 6.5). It is a constantly evolving process depending on our understanding of the condition, which in turn, is determined by published data and, inadvertently, by our personal experience.

In the first instance, a proper assessment of patient and the disease has to be carried out. This includes calculation of the tumour volume and its growth (at least two scans with at least two-month interval are needed) and extensive neuropsychological assessment. The imaging and clinical information is used to discuss the specific aims and risks of surgery as well as to select specific tools for intraoperative mapping that will help minimize the risks of permanent neurological deficit and maximize the extent of resection (Coello et al., 2013).

As alluded to before, the treatment plan should be developed together with the patient. He or she should be appropriately informed about the chronic and incurable nature of the disease and that multiple therapeutic interventions will be required in the coming years, the type and timing of which will depend on the evolution of each individual disease. It is important that immediate, medium-, and long-term benefits and risks of available interventions are discussed and, considering the relatively long OS, the possibility of new therapies also taken into account.

Early and maximal surgical resection is the first therapeutic option to consider in DLGG, as recommended by the European guidelines published in 2010 (Soffietti et al., 2010). The role of needle biopsy is limited to patients who do not want or who are not able to undergo resection for medical reasons. Biopsy can be mainly considered for diffuse lesions, such as gliomatosis, when a subtotal resection is not a priori possible.

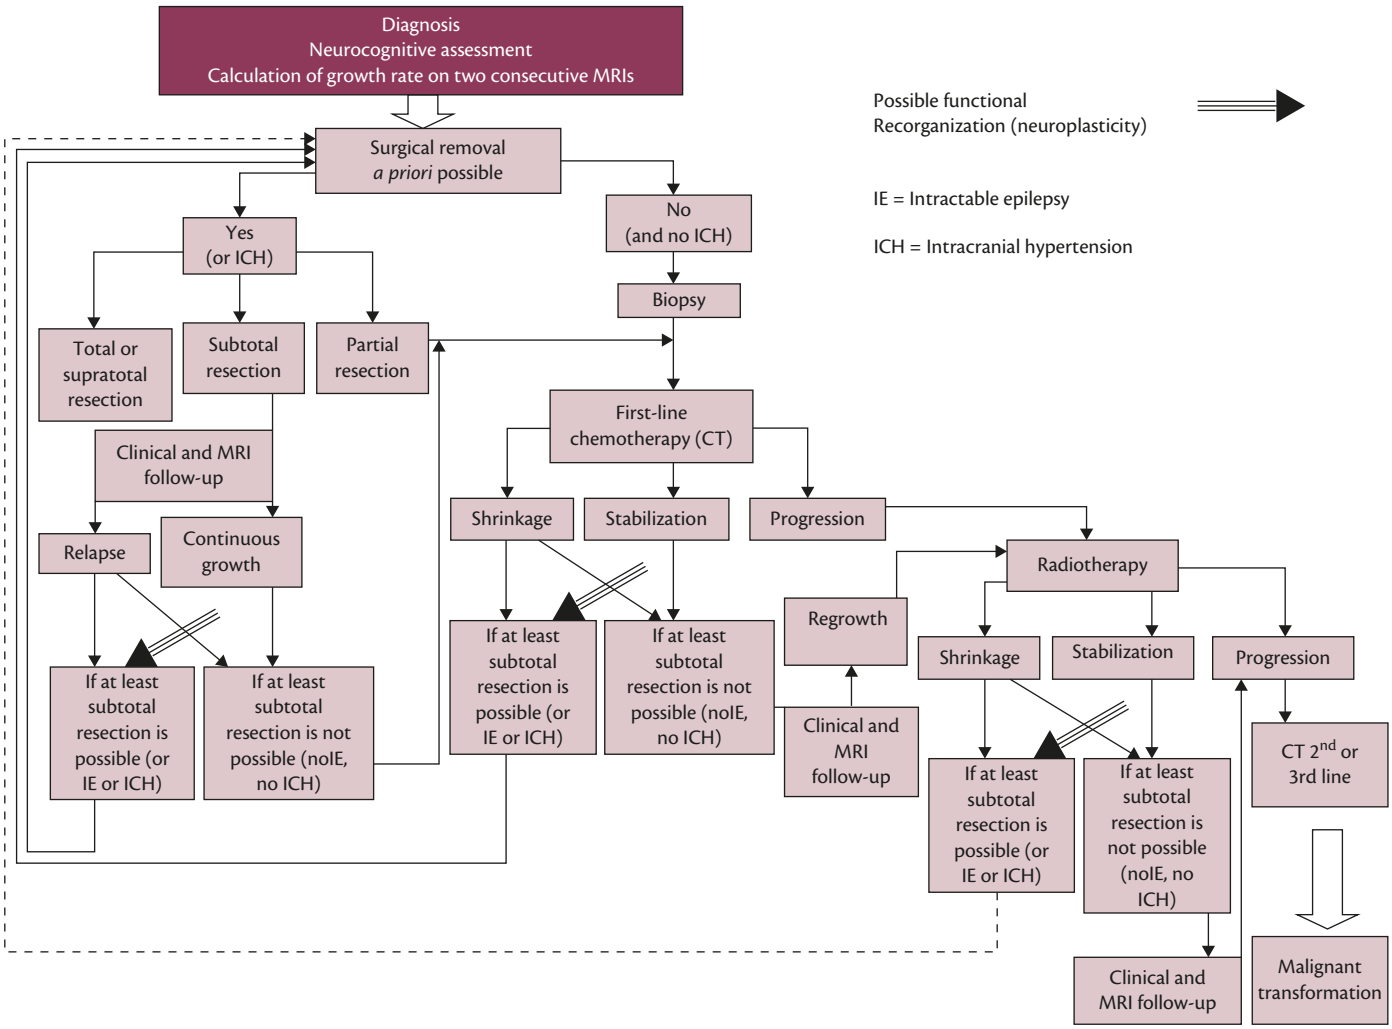

Fig. 6.5 Schematic depiction of the treatment algorithm used in our institutions.

Once histological diagnosis has been established, certain clinical parameters need to be taken into account to decide whether adjuvant therapy should be instituted. The following clinical characteristics would make recommendation of adjuvant treatment more likely: aged more than 40, partial resection/residual more than 10 ml, astrocytoma histology, triple negative, or TERT mutation status, rapid growth, difficult to control seizures. The threshold for radiotherapy will probably be lower in the case of astrocytoma, TERT, and triple negative tumours, considering their poorer OS and the poor response to ChT. However, the significance of the molecular markers ought to be considered with a degree of caution, especially as they await wider validation.

High-grade gliomas and molecular biology of neurosurgical oncology

Stephen J. Price, Harry Bulstrode, and Richard Mair

The molecular basis of neurosurgical oncology

Normal human cells develop into cancer cells through a stepwise accumulation of genomic and epigenomic alterations. These alterations, in the context of a permissive tissue microenvironment, cooperate to drive deregulated cell growth, proliferation, and survival, leading to tumour development. Recent conceptual developments frame tumours not as balls of cells proliferating uncontrollably, but rather as complex tissues in their own right: tumour initiation, maintenance, and progression then represent complex emergent products of deregulated mechanisms of tissue maintenance and renewal.

Fundamentals of cancer genomics

Somatic mutation

Over the past decade it has become technically feasible to understand the cancer genomic landscape. This has largely been enabled by the development of, and refinements made to, next-generation sequencing (reviewed in Goodwin et al., 2016). Tumours contain an average of 33–66 mutations that affect protein production, but this figure varies depending upon the cancer aetiology and the age of the patient at cancer onset (Vogelstein et al., 2013). Brain tumours contain relatively few mutations when compared to tumours arising in proliferating tissues in response to mutagens. For example, glioblastomas (GBM) average 35 non-synonymous mutations (i.e. mutations that lead to amino acid sequence change) per tumour, compared to an average 135 mutations in melanomas arising in response to UV radiation and average 163 mutations in small cell lung cancers resulting from cigarette smoke exposure (Meyerson et al., 2010). Mutations that confer selective growth advantage and are encountered repeatedly across examples of a given tumour type are termed 'driver' mutations. Driver mutations can be subdivided into *oncogenes*, whose mutational product drives tumour generation (e.g. KRAS), and *tumour suppressor genes*, by whose loss-of-function tumours progress (e.g. NF2). A typical GBM cell will have 2–5 driver mutations. Oncogenes and tumour suppressors exhibit markedly distinct patterns of mutation in gliomas (Vogelstein et al., 2013). Oncogenes typically exhibit missense point mutations at key locations: these single base substitutions in the DNA code introduce a specific functional change in the amino acid sequence, resulting in initiation of oncogene activity. Specific mutations at specific locations are necessary to achieve this effect, but mutation of a single allele is sufficient to drive cancer formation. Alternatively, chromosomal rearrangements can result in the expression of fusion proteins with oncogenic activity. By contrast, tumour suppressors are subject to inactivation by any mutation resulting in the incidence of a stop codon within the reading frame, including insertions, deletions, and even single base substitutions occurring throughout the coding sequence. Typically, loss of both tumour suppressor alleles is necessary for cancer development, either by somatic mutation of both alleles, or else somatic mutation of a single allele in the context of a germline mutation in the other—for example, in phakomatoses such as neurofibromatosis and von-Hippel Lindau disease.

Although individual tumour cell clones typically demonstrate just a handful of driver mutations, genetic instability means that a wide range of additional driver mutations exist at low frequency in subclones of a few cells within the tumour bulk. Therefore, targeted treatments directed at specific mutations often demonstrate a dramatic initial response, followed by treatment failure as a pre-existing resistant subclone grows up to replace the lost cells. Tumours also possess many mutations that do not offer a growth advantage. These 'passenger' mutations represent an accidental payload, which varies between and within tumours, and can be used to map tumour evolution.

Chromosomal alteration

Chromosomal changes in cancer cells are common with aneuploidy consistently observed in cancers from a variety of origins. Copy number variation is prevalent in cancer cells with amplification of gene expression, through simply the increased number of gene copies per cell; for example, epidermal growth factor receptor (EGFR), occurring alongside deletions of genomic regions, where tumour suppressor genes are lost (e.g. phosphatase and tensin homolog (PTEN), resulting in a decrease or absence of their expression (Cancer Genome Atlas Research, 2008)). A non-balanced translocation affecting chromosome arms 1p and 19q with subsequent loss of one of the derivative chromosomes is the molecular classifier for oligodendroglioma and of predictive significance (Cairncross et al., 1998). This is described in more detail later.

Chromosomes can also undergo fusion events whereby breakage of DNA and subsequent mal-reconstitution lead to the generation of an oncogenic target, for example, C11orf95-RELA in supratentorial ependymoma (Parker et al., 2014). These rearrangements can be interchromosomal, intrachromosomal, or intragenic, and lead to aligning disparate regions of the genome erroneously.

Capabilities of a cancer

Mutagenesis has downstream effects on 12 intracellular signalling pathways, which enable cancer cells to develop a neoplastic phenotype. This occurs through the development of eight 'hallmark' capabilities, famously described by Hanahan and Weinberg (Hanahan and Weinberg, 2011) and relate back to the three fundamental cellular processes of cell fate, cell survival, and genome maintenance.

Sustained signalling

Cells respond to their external environment through the development of signalling pathways. Cancer subverts these pathways through several mechanisms such as the upregulation of receptor proteins, autocrine proliferative signalling, constitutive receptor activation (i.e. activation even if no ligand is present, e.g. EGFRvIII amplification in GBM) and disruption of intracellular negative feedback loops (PTEN loss).

Evading growth suppressors

Normal cell cycle regulatory proteins are commonly mutated in cancer. Uncontrolled flux through the cell cycle occurs following mutation of retinoblastoma (Rb) via the loss of intracellular transduction of extracellular inhibitory signals and through mutation of TP53, which detects intracellular stress and induces apoptosis accordingly.

Evading contact inhibition

Cell contact inhibition is often bypassed in cancer. Mutation of NF2 affects the production of merlin (schwannomin), a cytoskeletal protein that limits mitogenic signalling through intracellular tyrosine kinase binding. Thus loss of this inhibition results in cellular proliferation under conditions in which it would usually be suppressed (Okada et al., 2005). Over half of meningiomas contain NF2 tumour suppressor gene mutations. Through clustering of this and other somatic mutations in meningioma, the mutation of NF2 and deletion of chromosome 22 correlated with a hemispheric origin of the meningioma (Arnold et al., 2013).

Genomic instability, mutation, and avoiding cell death

TP53 induces apoptosis following DNA strand break and chromosomal injury (e.g. following cell stress or during cell division). Loss of p53 protein thus enables the cell to evade programmed cell death and continue to proliferate. Concomitantly cells with mutations in TP53 thus have an ongoing increased rate of mutation due to the loss of this checkpoint. Mismatch repair gene mutation, occurring following temozolomide treatment in LGG, has also been shown to lead to the development of a hypermutated phenotype (Turcan et al., 2012). Interestingly, the loss of apoptosis within cells does not always lead to continued cell proliferation. Cells often become non-viable and although unable to undergo apoptosis, they undergo necrosis. This is potentially protumourigenic as it induces a pro-inflammatory microenvironment that stimulates cytokine secretion that induces angiogenesis and promotes tumour cell invasion and proliferation (Grivennikov et al., 2010).

Enabling replicative immortality

Normal cells can undertake only a limited number of cell divisions: the loss of genetic material at the ends of chromosomes inherent to the division process results in replicative senescence after ~50 divisions, the Hayflick limit. Various mutations associated with elongation and maintenance of telomeric DNA exist within neuro-oncology. Two common mutations to affect this process that are commonly mutated within glioma are ATRX and TERT. These are both described later as molecular biomarkers.

Inducing angiogenesis

Angiogenesis is a key factor in the instigation, sustenance, and progression of a variety of neoplastic processes both local to and distant to the primary tumour, it has been shown to be an independent predictor of poor prognosis in GBM (Jain et al., 2007). GBM has been shown to display the highest degree of vascular proliferation and endothelial cell hyperplasia of any solid tumour (Folkman, 1972).

Gliomas need to develop a blood supply to promote tumour growth. The initial phase involves vascular co-option where the tumour takes over normal brain vessels. The next phase involves angiogenesis where new vessels start sprouting. vascular endothelial growth factor (VEGF) is a key driver of tumour angiogenesis, and the VEGF receptor inhibitor bevacizumab has a potent but short-lived effect on tumour growth although it may also promote tumour invasion.

Deregulating cellular energetics

The development of abnormal cellular metabolism plays a fundamental role in tumour development as it fuels the energy requirements of upregulated cellular proliferation as well as generating the biosynthetic precursors required for rapid cell turnover (Vander Heiden et al., 2009). Isocitrate dehydrogenase is an intracellular enzyme that catalyses the oxidative decarboxylation of isocitrate forming a-ketoglutarate and CO_2. It has three isoforms: IDH1, which is cytosolic as well as IDH2 and 3 which are located within the mitochondria. Mutation of either IDH1 or IDH2 alters the enzymatic function, through altered substrate specificity, and thus leads to the erroneous production of 2-hydroxyglutaric acid (Dang et al., 2009). This 'oncometabolite' affects dioxygenase activity within the cell. Ten-eleven translocation (TET) enzyme (amongst others) are inhibited resulting in the hypermethylated phenotype identified in low-grade glioma (glioma CpG island methylated phenotype or G-CIMP) and leads to tumour formation (Turcan et al., 2012). Finally, cancer cell to stromal cell metabolic symbiosis has been demonstrated whereby lactate generating stromal cells 'feed' lactate utilizing cancer cells in an analogous fashion to the glial and neuronal relationship within the central nervous system (Feron, 2009).

Tumour-promoting inflammation

As discussed earlier, genomic instability, in isolation is unlikely to be sufficient for tumour maintenance. A supportive microenvironment is also required to drive tumour progression. The complex interplay between a tumour and the immune system results in the expression of both suppressive cytokines as well as chemokines (Qian and Pollard, 2010). Studies within GBM have suggested a correlation between GBM

subtype and immune characteristics. The correlation between immune cell infiltration and differing underlying mutational landscapes alongside the ability of prominent cytokines (e.g. TGF-b) to regulate proliferation, migration, and tumorigenicity in mesenchymal GBM further defines the role of the immune microenvironment in GBM.

Epigenomics

Epigenomics refers to DNA modifications that result in gene expression changes that do not alter the base pair sequence. For example, methylation of the MGMT promoter is an epigenomic modification resulting in reduced expression of this DNA repair gene, thereby conferring increased sensitivity of GBM to alkylating chemotherapy. In practice, tumourigenesis involves a process of genomic and epigenomic evolution converging on traits which confer selective advantage and hence malignancy, for example unconstrained cell division. Genomic mutations can also drive epigenomic progression: unbiased genome-sequencing based approaches have repeatedly and unexpectedly identified examples of driver mutations in genes concerned with cellular regulation of gene expression including histone proteins responsible for DNA packaging in paediatric GBM (H3K27M and H3G34R/V mutations) (Wu et al., 2012), and IDH mutations driving production of the oncometabolite 2-hydroxyglutarate which inhibits DNA methylation turnover in diffuse glioma (Dang et al., 2009).

Glioma stem cells

Stem cells are defined by their ability to self-renew: the ability to divide indefinitely giving rise to more cells of the same type, multipotency: the capacity to differentiate into multiple lineages, for example, glia and neurons and their ability to generate tumours *in vivo*.

GBM and medulloblastoma are two prototypical examples of tumours with a stem cell fraction that can be isolated and transplanted into mice to form tumours with high efficiency, while the bulk of the tumour cell population does not have this property. Cancer stem cells and bulk tumour progeny share the same mutations, so it follows that these mutations are necessary but not sufficient to specify stem cell identity, with gene expression and genome configuration (epigenomics) as well as microenvironment also playing key roles. In practice, the cancer stem cells found in GBM consistently demonstrate gene expression patterns associated with neural stem and progenitor populations in the embryonic brain. This is perhaps to be expected given that these cell programmes have evolved to support rapid proliferation in the specific central nervous system (CNS) niche, and given that the cell-of-origin for these stem cells is likely to be a CNS progenitor, or a cell derived from one. Seminal experiments demonstrated that surface markers of neural stem cells including CD133 and CD15/SSEA-1 also select for brain tumour stem cells (Singh et al., 2004). These brain tumour stem cells may be selectively resistant to radiotherapy and chemotherapy (Bao et al., 2006).

Stem cells in medulloblastomas

Medulloblastoma provides an excellent example of how co-option of neural stem cell pathways may drive brain tumour stem cell proliferation. Distinct medulloblastoma subgroups demonstrate gene mutations in either the sonic hedgehog pathway, or the Wnt/B-catenin pathway. These pathways demonstrate a degree of functional redundancy, converging to drive tumour stem cell self-renewal proliferation and medulloblastoma histology. Key differences in biology and prognosis are reflected in the incorporation of molecular subtyping in the World Health Organization (WHO) 2016 CNS classification (Louis et al., 2016). Medulloblastoma, WNT-activated (typically exhibiting CTNNB1 mutations) and medulloblastoma, Shh-activated (typically PTCH1, SMO, SUFU mutations), are recognized alongside Group 3 and Group 4 medulloblastoma, less well characterized, and conferring generally poorer prognosis. Medulloblastoma classification typifies a new generation of molecular tumour classification systems, which promise to capture the association of mutation and gene expression profiles, grounded in mechanistic understanding. While the classification described here is based on gene expression, identification of concurrent genomic mutation within subgroups further delineates prognostic groups (e.g. TP53 mutation within the SHH group predicts a poorer prognosis). Likewise, in meningioma, SMO mutation resulting in activation of the Sonic Hedgehog pathway has been associated with tumours arising from the anterior skull base. Mutations within meningioma have also been correlated to histological subtype. For other tumours, including GBM, expression-based classification systems exist. The Cancer Genome Atlas classification (summarized in **Table 7.1**) is perhaps the best-known molecular classification system of glioblastoma to date, but is by no means definitive (Verhaak et al., 2010). The proneural group showed improved survival, but interestingly showed no survival advantage with chemoradiotherapy vs. radiotherapy alone. Further work is underway to understand the significance of this classification for individual patients. Analysis of trials of antiangiogenic drugs suggest that this proneural group may gain benefit from antiangiogenic therapy (Sandmann et al., 2015).

Table 7.1 Cancer Genome Atlas classification of GBM subtypes

Subtype	Characteristic mutations	Expression signature
Proneural	*TP53, PDGFRA, PI3K, IDH1*	*OLIG2, NKX2-2*
Neural	*TP53, EGFR*	*MBP, SYT1*
Classical	*EGFR, Chr10, PDGFRA*	*EGFR, AKT2*
Mesenchymal	*NFkB, NF1*	*CD44, YKL40*

High-grade gliomas

The term high-grade glioma (HGG) encompasses several histological entities that are considered by the WHO Classification as WHO Grade III and IV tumours. They have traditionally been considered as having similar behaviour and had been treated in a similar manner. Recent advances in our understanding of tumour biology, however, have led to the identification of molecular markers that are now central to the classification of these tumours. This has led to us thinking of these tumours as molecularly distinct subtypes that will behave differently and should be managed in a particular way.

Classification of high-grade gliomas

High-grade gliomas arise from supporting glial cells in the brain. The predominant cell type determines the pathological classification.

Tumours are graded on appearances seen on light microscopy, according to the WHO grading system (Grade I to IV). HGGs comprise of WHO grade III (anaplastic astrocytoma and anaplastic oligoastrocytoma) and IV tumours (glioblastoma, glioblastoma with oligodendrocyte component, and gliosarcoma). The 2016 version of the WHO grading system removed the mixed gliomas (i.e. oligoastrocytomas)—these are now classified according to their molecular classification.

Histologically, grade III tumours are diffusely infiltrating gliomas with focal or dispersed anaplasia and a marked proliferative potential with increased cellularity, distinct nuclear atypia, and high mitotic activity. Grade IV tumours show cellular polymorphism, nuclear atypia, brisk mitotic activity, vascular thrombosis, microvascular proliferation, and necrosis. Examples are shown in **Figure 7.1**.

Tumours are graded on the most malignant part of the tumour. For that reason, adequate sampling to determine the proper grade is essential—especially in biopsy procedures.

Epidemiology

High-grade gliomas are the commonest primary intrinsic brain tumour accounting for 85% of all newly diagnosed primary malignant brain tumours. The incidence of these tumours is often reported as approximately 5/100 000 person-years in Europe and North America. Recent data on glioblastomas from the UK Tumour Registries found a similar overall national age standardized incidence of 4.64/100 000/year, with an average of over 2100 cases per year (Brodbelt et al., 2015). These figures are likely to underestimate the true numbers as a fifth are not admitted to hospital (Pobereskin and Chadduck, 2000).

Of all high-grade gliomas, glioblastomas account for 60–70%, anaplastic astrocytomas for 10–15%, anaplastic oligodendrogliomas for about 10%, while anaplastic ependymoma and anaplastic ganglioglioma make up the rest.

There has been a recent increase in incidence of HGGs in the Western world, particularly in the elderly population. This probably reflects the easy availability of improved diagnostic imaging (Wen and Kesari, 2008). Incidence of glioblastomas increases with age, with a peak between 65 and 75 years of age (Brodbelt et al., 2015). Men have an incidence 1.66 that of women (Brodbelt et al., 2015).

Aetiology of high-grade gliomas

In most cases, no causative factors can be attributed. However, exposure to ionizing radiation, such as from treatment of previous cancer is an established risk factor (Walter et al., 1998). Many other factors have been studied including head injury, foods with N-nitrose compounds, electromagnetic fields, smoking, and most recently usage of mobile phones, none of these have been shown to

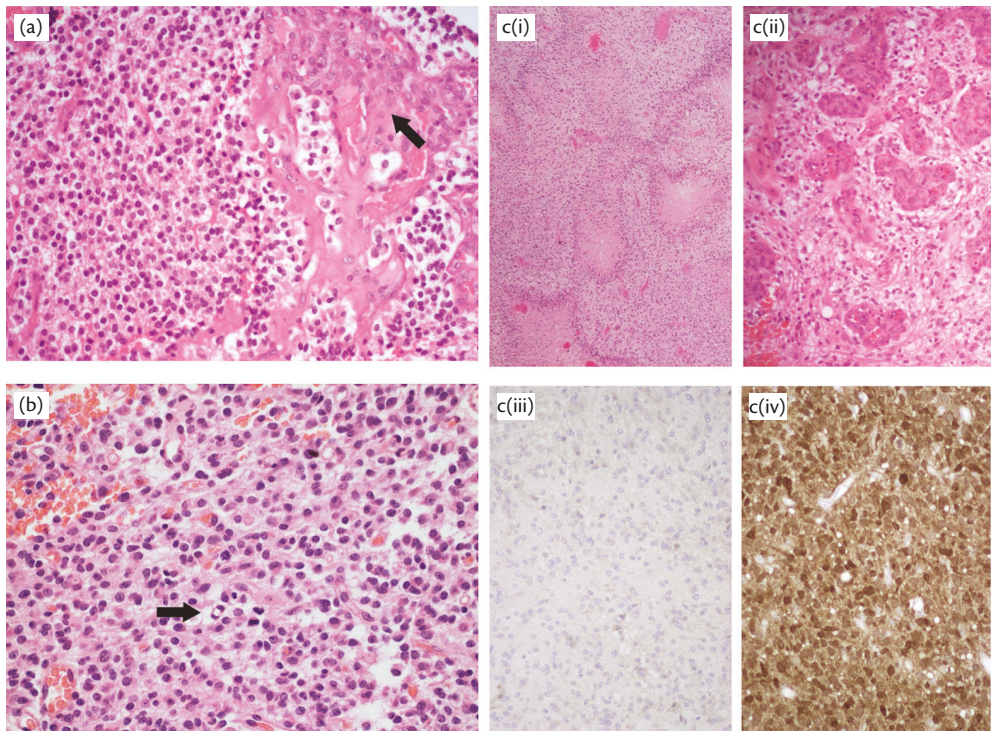

Fig. 7.1 (A) Anaplastic oligodendroglioma (grade III): round nuclei with perinuclear haloes indicate oligodendroglial lineage; microvascular proliferation (arrow), necrosis, and brisk mitotic activity are high-grade features. This histological diagnosis is strongly associated with IDH mutation and 1p/19q codeletion. (B) Anaplastic astrocytoma (grade III): high cellularity, nuclear pleomorphism, and the presence of mitotic figures (arrow) are high-grade features. Necrosis and microvascular proliferation, present in glioblastoma grade IV, are absent. (C) Glioblastoma (Grade IV) (i) A hypercellular band of tumour cells highlights the borders of the necrotic tumour in what is known as palisading (or pseudopalisading) necrosis. This is a classic histological feature of glioblastoma. (ii) Microvascular proliferation, forming these glomeruloid structures, is another classic histological feature of glioblastoma. Immunostaining for the IDH1 R132H mutation distinguishes IDH wild-type (iii) and IDH mutant (iv) tumours.

be a risk factor for the development of HGG (Inskip et al., 2001; Kleinerman et al., 2005; Holick et al., 2007).

There does appear to be some genetic risk to developing gliomas. The risk of an individual with a family member with a glioblastoma developing a GBM appears to be double that of people without a family history (Schwartzbaum et al., 2006). Approximately 5% of patients with HGG have a family history of gliomas (Bondy et al., 1994). Some of these are familial and associated with genetic syndromes such as neurofibromatosis types 1 and 2, Li-Fraumeni syndrome, and Turcot's syndrome. Studies have also shown links between DNA repair genes and tumour aggressiveness (Bhowmick et al., 2004; Okcu et al., 2004; Simon et al., 2006). Mutations of the telomere shelterin gene complex, in particular POT1, have been recently associated with these familial glioma syndromes (Bainbridge et al., 2015). At present there are no clear guidelines on screening for familial gliomas.

Role of cytomegalovirus in glioblastoma aetiology

There has been much interest in the possibility that viral infections are involved in the multistep development of gliomas. When one study found cytomegalovirus (CMV) gene products in 100% of glioblastoma samples but failed to identify it in normal tissues (Cobbs et al., 2002), there was great interest that this could be an important cause of gliomas. But other studies failed to replicate these results (Dey et al., 2015). A randomized, double-blind trial of valganciclovir, an anti-CMV therapy used in addition to chemoradiotherapy (the VIGAS Study), failed to show any survival benefit (Stragliotto et al., 2013). A subsequent letter to the *New England Journal of Medicine* by the same group, however, created much publicity (Stragliotto et al., 2013). They reported that in a retrospective analysis of a subset of their patients treated with valganciclovir both as part of the trial and on compassionate grounds had an improved survival compared to contemporary controls. This study has several flaws, and currently the consensus statement concluded that current literature supports an oncomodulatory role for CMV in malignant gliomas, but future studies are needed to focus on determining the role of CMV as a glioma-initiating event (Dziurzynski et al., 2012).

Atopic diseases may be protective

One unusual finding is that atopic diseases (e.g. asthma, eczema, or allergies) are 'protective' factors for developing gliomas. Patients with gliomas have fewer atopic symptoms compared to control subjects. As atopy may be a marker of immune dysfunction it may indicate a role for immunologic factors in glioma causation.

Pathology and pathogenesis of high-grade glioma

Molecular biology of high-grade gliomas

The introduction of the World Health Organization (WHO) Classification of Tumours of the Central Nervous System has resulted in broad changes for the categorization of high-grade glioma (Louis et al., 2016). The definition of molecular subgroups has grossly divided glial-origin tumours into isocitrate dehydrogenase (IDH) wild-type, IDH mutated, and IDH not specified (i.e. where IDH mutation has not been sought; see Louis et al., 2016). Within this classification (and with the inclusion of 1p 19q chromosomal codeletion for oligodendroglioma) diffuse glioma, oligodendroglioma, anaplastic astrocytoma, anaplastic oligodendroglioma, and glioblastoma have all now been defined.

Mutations and intratumoural heterogeneity in glioblastomas

Mutations that do occur tend to converge upon three intracellular signalling pathways: Specifically, PI3K, TP53 and Rb (Cancer Genome Atlas Research, 2008). Typical 'hits' include activating mutations of the growth signalling receptors *EGFR, PDGFR*, and *MET*, and their downstream targets *PI3K, AKT, MTOR*, and *RAS*. Equally tumour suppressors responsible for regulating these cascades are subject to loss-of-function mutations in GBM—these include *PTEN, NF-1, RB1*, and *TP53*. These pathways are summarized in **Figure 7.2**.

Despite this convergence, inter and intratumoural heterogeneity is seen in GBM and has been proposed as a major source of treatment failure and disease relapse. Gene expression-based classification systems exist for GBM, but have so far proved less reliable (Verhaak et al., 2010) and widespread coexistence of different groups within single tumours have been identified (Sottoriva et al., 2013).

Development and progression of high-grade gliomas

Glioblastomas develop either as primary tumours or arise from pre-existing low-grade gliomas. These primary and secondary GBMs constitute separate and distinct disease entities. They affect different epidemiological groups and carry different prognoses.

Primary gliomas usually are of *de novo* manifestation involving older patients with a shorter clinical history. On the other hand, secondary gliomas are usual part of a malignant progression from low grade to high grade involving younger patients with a variable interval between one to ten years.

Spread and progression in high-grade gliomas

Tumour invasion

Local white matter invasion is a key pathological hallmark of gliomas, and a major cause of treatment failure. This extent of invasion varies between individuals. Histological studies looking at the extremes of invasion show that between 20% and 27% of GBM have limited invasion defined as less than 1 cm spread (Scherer, 1940; Burger et al., 1988) while about 20% have diffuse invasion defined as greater than 3 cm spread (Burger et al., 1988).

Invading cells show changes in gene expression with upregulation of genes that promote migration and reduced expression of proapoptotic genes (Hoelzinger et al., 2005). The invasion process itself has three stages, firstly there is expression of cell adhesion molecules allowing glioma cells to attach to components of the extracellular matrix (especially tenascin-C), secondly there is production of proteases (e.g. metalloproteinases) which degrade the matrix removing the barriers to cell movement. In gliomas the production of metalloproteinases (MMP)—especially the secreted MMP-2, MMP-9 and the tissue bound MT1-MMP appear critical to invasion (Lampert et al., 1998; Beliveau et al., 1999). The secreted MMPs are regulated by their tissue inhibitors TIMP-1 and TIMP-2 which are down regulated in gliomas (Beliveau et al., 1999) Finally the cells migrate into the region of the matrix degraded by protease

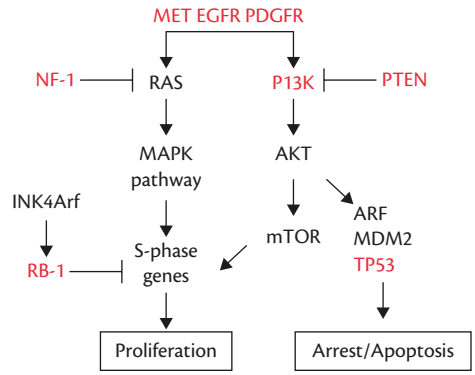

Fig. 7.2 Metabolic pathways that are involved in gliomagenesis. Commonly mutated components of these pathways are highlighted in red in the figure.

activity. This is promoted by the increased secretion of the chemokine CXCL12 (Zhang et al., 2005) that binds to the CXCR4 receptor that is upregulated in invasive glioma cells.

Recently glioblastomas have been shown to contain a small population of cells capable of self-renewal and tumour formation. The cells have been shown to be representative of the parent tumour at the molecular genetic level. They are highly motile *in vitro* and show extensive host invasion *in vivo*. Preliminary gene expression analysis shows that they express several markers associated with invasion and migration including membrane–bound proteins such as MT1-MMP, NG2, and B1-integrin, and soluble factors including plasminogen, MMP2, and MMP9.

Glioma dissemination and metastasis

As mentioned in the previous section, high-grade gliomas mostly progress by invasion of white matter tracts. Scherer described other mechanisms of tumour growth (Scherer, 1938) including subpial growth along the pial surface and subependymal growth along the ventricular surface. This can lead to the occasional 'drop metastasis' into the spine.

Metastasis of HGG is very rare but has been described. It is mostly related to spread along ventriculoperitoneal shunts into the peritoneal cavity or into the scalp, especially where the bone flap is missing. There have been cases of developing HGG metastases in patients who have been transplanted organs from HGG patients, suggesting that suppression of the immune system is required for these cells to grow.

The 'hypoxic switch' in glioma progression

The invasive cells that are growing into white matter tracts have different biology and behaviour to central tumour cells. These cells are more motile, but do not divide (Giese et al., 1996). As their number increases, they challenge for the available metabolites. In the rapidly dividing areas of high-grade gliomas this competition will lead to the development of hypoxia. This 'hypoxic switch' leads to three major behavioural changes within these tumours (Bjerkvig et al., 2009), hypoxia promotes cancer stem cell division, it promotes angiogenesis due to production of factors such as VEGF, and finally it promotes invasion by up regulating invasive factors.

As the degree of malignancy increases this hypoxia will lead to eventual necrosis and microvascular proliferation—both histological features of glioblastomas.

Hypoxia is central for the dichotomized behaviour of glioma stem cells where they either 'go or grow' (Giese et al., 1996). In hypoxic conditions the tendency is to migrate and invade, while at higher oxygen tensions proliferation is favoured: neither phenotype is clinically desirable.

Molecular biomarkers in high-grade gliomas

Several molecular biomarkers of tumourigenesis can be identified. A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biological or pathogenic processes or pharmaceutical response to a therapeutic intervention. These biomarkers can be diagnostic, prognostic, or predictive of response to therapy. In high-grade gliomas, a number of these have been identified, and are now being used to better classify these tumours.

Isocitrate dehydrogenase (IDH) mutations

Isocitrate dehydrogenase (IDH) gene encodes a cytosolic enzyme that converts isocitrate to α-ketoglutarate. Mutation of this gene causes a tenfold increase in the production of 2-hydroxyglutarate instead of α-ketoglutarate (Dang et al., 2009). Mutation of IDH-1 gene was found in 5.6–12% of GBM patients and seems to confer a better progression-free survival and median survival, (3.7 years vs. 1.1 years) (Parsons et al., 2008; Weller et al., 2009) suggesting that IDH mutations are prognostic rather than just predictive (van den Bent et al., 2010). Most mutations are a point mutation involving arginine 132—the R132H mutation. This allows an immunohistochemistry test on paraffin embedded tissue and has been shown to have 88–99% concordance with DNA sequencing (Zou et al., 2015). An example of IDH R132H mutation with immunohistochemistry is shown in Figure 7.1C. The other mutations can involve either other point mutations of IDH-1 or mutations of the mitochondrial IDH-2.

What is becoming clear is that low-grade gliomas without mutation have a very poor prognosis (Eckel-Passow et al., 2015). It suggests that the division between high- and low-grade gliomas should now be based on IDH mutation status rather than histology (Brandner and von Deimling, 2015).

Deletion of chromosome 1p/19q

In the WHO 2016 classification loss of heterogeneity of 1p19q in IDH mutated tumours is diagnostic of oligodendroglioma or anaplastic oligodendroglioma. This mutation has an improved survival with chemotherapy and was originally thought to be predictive of chemosensitivity. Results from a trial of radiotherapy versus chemoradiotherapy showed the radiotherapy only arm with 1p19q loss did better than the chemoradiotherapy arm without loss of 1p19q suggesting again the prognostic nature of these molecular markers (van den Bent et al., 2006). Long-term follow-up of two similar studies, however, have now clearly showed a survival advantage for 1p19q deleted tumours treated with radiotherapy and chemotherapy suggesting that this should be part of our standard care for these tumours (van den Bent et al., 2013, Cairncross et al., 2013).

Epigenetic methylation of O-6-methylguanine-DNA methyltransferase (MGMT)

The MGMT gene encodes O-6-methylguanine-DNA methyltransferase enzyme—a DNA repair enzyme that removes alkyl groups from the O-6 position of guanine, an important site of DNA alkylation. MGMT methylation status has been used to prognosticate response to alkylating chemotherapeutic agents like temozolomide. In the methylated form, it is non-functional (i.e. the enzyme is not produced thus limiting DNA repair). MGMT methylation occurs in up to 45% of cases of GBM (Hegi et al., 2005; Stupp et al., 2005), and is associated with improvements in median survival which is significantly longer after radiotherapy with temozolomide than radiotherapy alone (Hegi et al., 2005; Weller et al., 2009). In comparison, the difference in survival in the unmethylated group was insignificant, but there was a survival tail in the cohort treated with chemoradiotherapy (Stupp et al., 2005). As the methylated group with radiotherapy alone has better survival than either unmethylated groups, it suggests MGMT methylation functions as a prognostic marker rather than a predictive marker.

Assessment of MGMT methylation status is not without its technical problems. Multiple sites for mutation have been identified making this marker difficult to assess. In addition, the results are semiquantitative with no clear cut off to define positive or negative status, resulting in no clear clinical standard test for interpretation of results.

TERT promoter mutations

Mutations of TERT, a gene that encodes for telomerase has been found to be present in some brain tumours. Interestingly mutations have been found in both GBM and low-grade gliomas. This suggests maintenance of the telomere may be important for the formation of gliomas (Killela et al., 2013; Vinagre et al., 2014).

Histone H3 mutations

Mutations of histone H3 family 3A (H3F3A) have been identified in paediatric brain stem and midline glioblastomas (Wu et al., 2014). These are point mutations between glycine-to-arginine/valine alteration at codon 34 (G34R/V) within H3F3A. In adults they occur in 3.4% of all glioblastomas (Yoshimoto et al., 2017). These tend to be midline tumours in younger adults.

Controversy: Should we classify high-grade gliomas by histology or molecular markers?

It is now very clear that tumour diagnoses based on histological criteria encompass several different subclasses of tumour and that molecular markers will be essential in our subclassifications of HGG. The current question is how much should these molecular markers play in our classification of these tumours?

Studies combining three markers—namely IDH mutations, 1p19q codeletions and TERT mutations have been able to identify five molecular subclasses of gliomas (Eckel-Passow et al., 2015; summarized in **Table 7.2**). In WHO Grade II/III tumours, most have either mutations of all markers (triple positive), TERT and IDH, or IDH alone. These mutations have a favourable prognosis. Around 17% of tumours however have either mutations of TERT alone or no abnormalities, and these have a similar outcome to glioblastomas. The recent International Society of Neuropathology Consensus of Haarlem (Louis et al., 2014) has highlighted the importance of including these molecular markers in diagnosis.

The latest WHO 2016 Classification System has now incorporated molecular diagnostics to provide a layered diagnosis. This layered diagnosis ensures the classification can be used in resource-limited countries where molecular diagnostics are not available. The integrated diagnosis allows incorporation of molecular information and tissue-based diagnosis to provide a specific *identity*. Where molecular diagnostics are not available tumours are classified as not otherwise specified (NOS). These layers are:

Layer 1: Integrated diagnosis (incorporating all tissue-based information)
Layer 2: Histological classification
Layer 3: WHO grade (reflecting natural history)
Layer 4: Molecular information

Table 7.2 Molecular subclassification of gliomas based on three molecular markers

	Triple-positive	TERT and IDH	IDH alone	Triple-negative	TERT only
Grouping alterations	IDH-1, 1p/19q and TERT mutations	TERT and IDH mutations	IDH mutation	-	TERT mutation
Common acquired mutations	CIC, FUBP1, NOTCH1, and PIK3CA, or PIK3R1	TP53 and ATRX	TP53 and ATRX	EGFR, PTEN, and NF1	EGFR, EGFRvIII, PTEN, NF1, RB1, and PIK3CA, or PIK3R1
Average age	44 years	46 years	37 years	50 years	59 years
TGCA subtype	Proneural	Mesenchymal, neural, proneural	Proneural	Classical, mesenchymal, neural, and proneural	Classical and mesenchymal
Common histology	Oligodendroglioma	Astrocytoma–WHO Grade II or III	Astrocytoma–WHO Grade II or III	67% GBM	90% GBM 10% Grade II or III

Source data from Eckel-Passow, J., Lachance, D., Molinaro, A., et al., Glioma groups based on 1p/19q, IDH, and TERT Promoter Mutations in Tumors, *N Engl J Med* 2015; 372: 2499–508. DOI:10.1056/NEJMoa1407279.

Table 7.3 Examples of the layered diagnosis in the WHO 2016 Classification

	Glioblastoma	Anaplastic astrocytoma	Anaplastic oligodendroglioma
LAYER 1: Integrated diagnosis	Glioblastoma—IDH wild-type	Anaplastic astrocytoma—IDH mutated, 1p19q non-codeleted	Anaplastic oligodendroglioma—IDH mutated, 1p19q codeleted
LAYER 2: Histological Diagnosis	Glioblastoma	Anaplastic astrocytoma	Anaplastic oligodendroglioma
LAYER 3: Grading	IV	III	III
LAYER 4: Molecular information	IDH wild-type TERT mutated MGMT methylated	IDH mutated 1p19q non-codeleted	IDH mutated 1p19q codeleted
DIAGNOSIS WITHOUT MOLECULAR INFORMATION	Glioblastoma NOS	Anaplastic astrocytoma NOS	Anaplastic oligodendroglioma NOS

An example is shown in Table 7.3.

Clinical presentation

Many patients with HGG present with signs and symptoms of raised intracranial pressure from mass effect, oedema, or haemorrhage. These frequently manifest as headaches, nausea, and vomiting, reduced visual acuity, diplopia, drowsiness, and confusion. Other presentations include focal neurological deficits, symptoms which are dependent on the location of the tumour such as aphasia, limb weakness, altered sensation and neurocognitive defects including disinhibition and personality changes (Tucha et al., 2000). Approximately 50% of grade III and 25% of Grade IV tumours presented with seizures compared to 80% of low-grade gliomas.

Imaging high-grade gliomas

The initial imaging modality is usually a contrast-enhanced computed tomography (CT) scan, however, magnetic resonance imaging (MRI) is more sensitive and is now the imaging modality of choice for all patients with brain tumours.

HGG typically appears as an irregular, ill-defined mass with associated vasogenic oedema on both CT and MRI. Enhancement typically is around the rim of the mass with a central area of non-enhancing tissue. Enhancement *per se*, cannot be taken as a diagnostic feature as between 30% and 50% of anaplastic tumours fail to enhance on CT (Chamberlain et al., 1988), and 16% fail to enhance on MRI (Al Okaili et al., 2007). In addition, 20% of low-grade gliomas (typically oligodendrogliomas) enhance on CT (Chamberlain et al., 1988) and 35% enhance on MRI (Al Okaili et al., 2007).

The location of these tumours is mostly in the supratentorial component. The frontal lobe is the most common site (24.9%), followed by temporal lobe (21.8%), parietal lobe (16.7%), occipital lobe (4.8%), cerebellum (0.5%), brain stem (0.4%), or was not specified/other (30.9%) (Brodbelt et al., 2015).

One of the major problems with using imaging for treatment planning is that anatomical imaging is unable to identify tumour margins. Both post-mortem and biopsy studies have shown that the tumour extends beyond the margin on CT (Lilja et al., 1981; Selker et al., 1982; Burger et al., 1983; Kelly et al., 1987), contrast-enhanced T_1-weighted MRI (Lunsford et al., 1986; Kelly et al., 1987; Price et al., 2006), and T_2-weighted MRI (Lunsford et al., 1986; Kelly et al., 1987; Johnson et al., 1989; Watanabe et al., 1992; Price et al., 2006). These techniques cannot determine the margin or the invasiveness of these tumours. Advanced imaging methods have been developed for assessment of these tumours. These are being used in clinical practice and are summarized elsewhere (Price, 2007).

Postoperative MRI is the only method of objectively assessing the extent of resection. Studies have shown it identifies more cases of incomplete resection compared to the judgement of the surgeon (Albert et al., 1994). Imaging within 72 hours avoids the postoperative changes that occur later.

Advanced MRI for HGG

Some advanced MR methods are now in routine practice to assess tumours and provide information on tumour physiology and pathology and are summarized next and elsewhere (Price et al., 2007; see Fig. 7.3).

Diffusion imaging is a method sensitive to diffusion of protons within an image. Areas where there are trapped protons, such as in areas of ischaemic cytotoxic oedema, epidermoid cysts or abscesses appear bright on diffusion-weighted imaging (DWI). As DWI has a component of T2-weighted signal DWI cannot be used as a quantitative measure. The apparent diffusion coefficient (ADC) is used as a quantitative measure that relates to how far protons can diffuse. In areas of free diffusion (e.g. CSF spaces) the ADC is large. Where there is restricted diffusion the ADC is low. In HGG due to increased water from oedema the ADC is larger than normal brain, but as the cellularity increases the ADC reduces. As a result, lower-grade gliomas have a lower ADC than high-grade gliomas (Sugahara et al., 1999).

Diffusion tensor imaging is an extension of DWI imaging that is sensitive to directional diffusion of water molecules. It is used to assess disruption of white matter tracts and the location of tracts close to the tumour.

Perfusion MRI assesses blood flow. Higher grade tumours tend to have higher perfusion and there is some evidence that perfusion may be able to identify anaplastic foci within low-grade gliomas (Danchaivijitr et al., 2008).

MRI Spectroscopy can identify tumour metabolites in a volume of interest. High-grade gliomas have a spectral pattern with reduced N-acetylaspartate (a marker of white matter integrity), increased total choline (a marker of membrane turnover) and signals for lipids and lactate (due to necrosis).

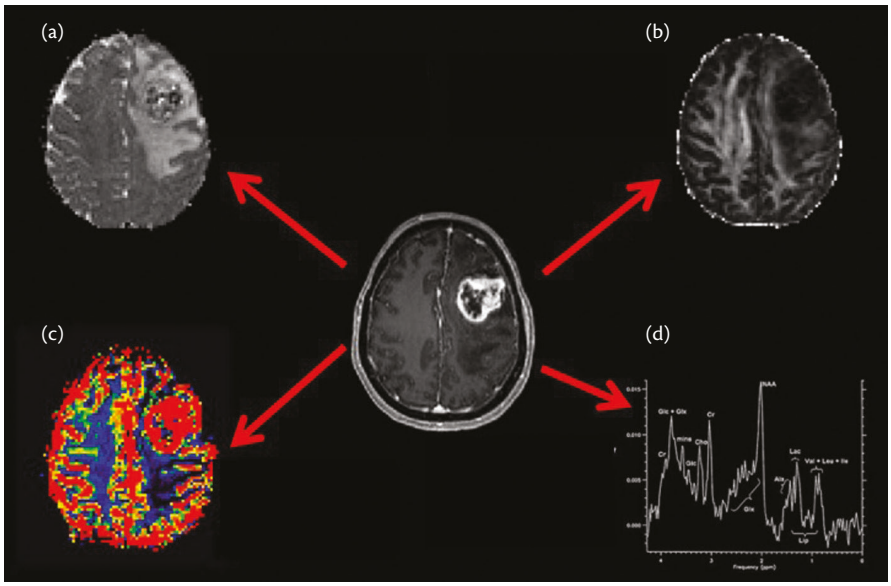

Fig. 7.3 Advanced imaging of the tumour. This contrast enhancing glioblastoma can be evaluated using other imaging techniques. (A) Shows an apparent diffusion coefficient (ADC) image from diffusion-weighted MRI. Decreased ADC can be due to increased tumour cellularity. There is a general reduction in ADC within the tumour due to the increased tumour cellularity. (B) Shows a fractional anisotropy (FA) image from diffusion tensor MRI (DTI)—this shows disruption of white matter tracts and can be used to tract white matter tracts and see how they relate to the tumour. (C) Is perfusion imaging and shows a map of relative cerebral blood volume (rCBV)—a measure of vascularity and angiogenesis. (D) MR proton spectroscopy can be used to look for metabolic profile of high-grade glioma. In this case the spectra shown is of normal brain.

Positron-emission tomography (PET) imaging of HGG

On PET imaging high-grade gliomas tend to be hypermetabolic compared to normal cortex. In FDG PET the tumour may be difficult to differentiate from functioning cortex. In addition, increased FDG uptake is not specific to tumour and can be seen in inflammatory regions. Amino acid PET using either [11C]-methionine (MET PET) or [18F]-ethyl tyrosine (FET PET) is more specific for tumour and appears to better delineate the tumour extent (Pirotte et al., 2006).

Studies that have used PET to direct image-guided biopsies have shown that it improves diagnostic yield from biopsies (Levivier et al., 1995) and can help identify the region for surgical resection (Pirotte et al., 2009)

Management of high-grade gliomas

HGGs are best managed with a multidisciplinary team (MDT) approach. Options for management span the spectrum from conservative treatment to surgery and adjuvant therapy. The main thrust of management is diagnosis and prolongation of progression-free survival.

Dexamethasone is vitally important in controlling cerebral oedema associated with tumours. The response to steroids can be extremely rapid. Failure to improve with steroids suggests radical surgical resection may cause a worsening neurological deficit (Stummer et al., 2011a). The role of steroids, their complications and dosing in neuro-oncology has been reviewed elsewhere (Ryan et al., 2012).

Conservative management is a valid option in patients with a poor prognosis as identified by age and poor performance status—especially for tumours that are considered unresectable. In this situation good palliative and supportive care is important.

Changes in behaviour and personality are very common in patients with brain tumours—often due to the location of the tumour and the effect of treatment. Support of psychosocial function is important and a neuropsychologist should be involved. Major depression in patients with HGG is much more common than in the normal population and impacts on quality of life.

Surgery for HGG

The aims of surgery are to obtain a representative tissue sample of the tumour for histological and molecular marker assessment, to safely remove tumour with the aim of improving pressure symptoms, improving efficacy of adjuvant therapy, delaying deterioration, and improving survival and finally there is the potential of delivering surgically delivered treatments.

Image-guided tumour biopsy

Biopsies are minimally invasive, well tolerated, and suitable for lesions at any site or of any size but are usually only considered when the risks of resection outweigh the benefits. Biopsy is best utilized in cases where the initial diagnosis may influence subsequent management. It has pitfalls, however, in the form of sampling error especially in small or heterogeneous samples as well as complications due to haemorrhage. Image-guidance is now normally used to reduce the risk of non-diagnostic biopsies.

Sampling error is a problem when biopsying HGGs; when the diagnoses are compared between series of patients undergoing biopsy with those undergoing resection, there are discrepancies. In patients undergoing resection, 82% had glioblastomas and 18% had anaplastic astrocytomas, whereas in patients undergoing biopsy 49% had glioblastomas and 51% had anaplastic astrocytomas

(Glantz et al., 1991). In patients who underwent an initial biopsy before a subsequent resection the diagnosis changes in 39–49% of cases (Jackson et al., 2001; McGirt et al., 2003).

Tumour resection

Debulking surgery is beneficial in reducing the tumour load and thus the side effects of raised intracranial pressure and providing a more representative histological sample. The aim of surgery for glioblastomas is to remove as much of the tumour as possible without damaging the surrounding normal brain. Estimates suggest that 50% of patients are suitable for radical resection (Schucht et al., 2012). Whether it provides an improvement in survival has been controversial. The Cochrane review of the literature has highlighted the lack of quality studies in this area (Hart et al., 2000). Retrospective studies have suggested that gross total resection as defined by postoperative MRI findings of more than 98% tumour resection, has shown better quality of life and progression-free survival (Lacroix et al., 2001). The median survival, according to one study, improved from 8 months for subtotal resection to 13 months after gross total resection (McGirt et al., 2009b). This was reconfirmed by a study involving an RPA analysis that showed the survival benefit was greatest in patients with more severe baseline disease based on age, performance status, neurology, and mental status (Pichlmeier et al., 2008). When combined with chemotherapy and radiotherapy, complete resection of contrast enhancement is associated with a prolonged survival (Stummer et al., 2012). This improvement was not seen where any residual enhancing tumour remained. The results of three major randomized controlled studies also confirm improvement in survival with radical resection (Stummer et al., 2011b).

The difficulty with these cohort studies is that there is an inherent resectability bias. Patients with good prognostic features (i.e. those that are young, with good performance status, with smaller tumours in non-eloquent areas) are more likely to have a gross total resection than older patients with poorer performance status and larger tumours in eloquent regions (Stummer et al., 2008). In addition, most surgeons would now consider it unethical to randomize their patients into partial resection.

The difficulty in performing gross total resections (i.e. complete resection of the contrast enhancing component of the tumour on early postoperative imaging; see Vogelbaum et al., 2012) of these tumours is identifying the limits of resection within these tumours. As there is a poor margin between tumour and normal brain most studies suggest that a gross total resection is performed in less than 30% of patients (Wood et al., 1988; Vecht et al., 1990; Albert et al., 1994; Barker et al., 1996; Kowalczuk et al., 1997). A variety of tools have been developed to improve this resection rate.

Image-guidance is essential for planning craniotomies, but unpredictable brain shift limits its use in identifying the tumour limits.

Intraoperative ultrasound is a useful method, but user dependent. Assessment of the tumour border with biopsies, preresection shows a high specificity and sensitivity of 95%, but this deteriorates during resection (sensitivity 87% and specificity 42%) (Rygh et al., 2008).

Intraoperative MRI provides the most accurate method, but is very expensive and does add time to tumour resections. Cohort studies suggest that maximal resection using intraoperative MRI improves survival (Mehdorn et al., 2011).

5-aminolevulinic acid fluorescence guidance (5-ALA) provides a method that can be used in all neurosurgical centres and helps identify tumour (Fig. 7.4). 5-ALA is a new surgical adjuvant used to identify glioma tissue under blue (400 nm) light. 5-ALA is taken up and is converted in the normal haem biosynthesis pathway. In tumours there is a deficiency of the ferrochelatase enzyme that leads to the accumulation of the fluorophore protoporphyrin IX that fluoresces under blue light. The use of 5-ALA enables more complete resections of contrast enhancing tumour, leading to improved progression-free survival in patients with malignant glioma. Stummer et al. showed a 29% increase in complete resections rates in the 5-ALA group as opposed to the white light group. The 5-ALA group also had a higher 6-month progression-free survival than the white light group (41% vs. 21.1%) (Stummer et al., 2006).

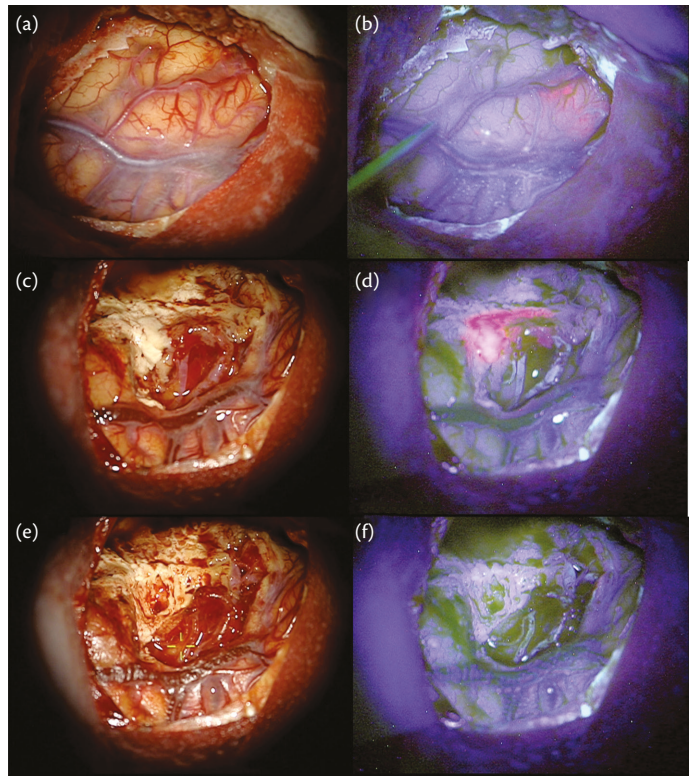

Fig. 7.4 Resection cavity and 5-ALA. Precorticotomy view of the cerebral cortex under white light (A) and 5-ALA fluorescence (B). This shows fluorescent tumour visible in the posterior part of the tumour. The next row shows intraoperative view under white light (C) and 5-ALA (D). The fluorescent area appears normal under white light. At the end of resection there is complete resection of fluorescent tumour (E—white light, f—5-ALA), providing a suitable endpoint to the resection.

The key issue for the surgical neuro-oncologist is to maximize the extent of resection but avoid causing neurological deterioration. It is clear that causing motor and language deficits not only impacts quality of life but also is associated with worse survival (McGirt et al., 2009a). Intraoperative mapping of function using cortical and subcortical mapping (De Witt Hamer et al., 2012) can half the incidence of postoperative neurological deficits.

Radiotherapy for HGG

Radiotherapy has been the mainstay of adjuvant therapy for high-grade gliomas. Multiple studies from the 1970s showed a survival benefit (Walker et al., 1978). Attempts to improve on the initial benefits by increasing the dosage of radiation have failed. Unfortunately,

the therapeutic window for radiotherapy to the brain is narrow and there is an increasing incidence of radiation necrosis with increasing radiation dose. Part of the reason for this is the inability of conventional imaging to identify infiltrating tumour. As a result, radiotherapy planning outlines the obvious tumour as the gross tumour volume (GTV). A 2.5 cm margin is then applied to form the clinical target volume (CTV). A 0.5 cm margin is added to account for set up errors and patient movement to form the planning target volume (PTV). In other words, a 3 cm margin is applied around the tumour that will contain normal brain. To reduce the risk of radiation necrosis the dose is therefore limited.

There are two radiotherapy regimes normally used in HGG. Radical radiotherapy gives a 60 Gray dose over 30 daily fractions while short course or palliative radiotherapy gives 30 Gray over two weeks in 6 fractions. There is less planning required for palliative radiotherapy so patients can start treatment very quickly and it is well tolerated. It is useful where patients are acutely deteriorating.

Chemotherapy for HGG

Procarbazine, lomustine, and vincristine (PCV) was the standard adjuvant chemotherapeutic regime in use before the advent of temozolomide. This nitrosourea-based chemotherapy provided a small survival benefit; a 5% increase in 2-year survival rates (Stewart, 2002). The treatment involves a 10-day oral course of procarbazine, a single oral dose of CCNU (lomustine), and a single intravenous infusion of vincristine given in six weekly cycles.

The introduction of temozolomide has provided some improvement in survival. It is given orally over five days every 28-day cycle. Leucopenia and thrombocytopenia are commonly associated side effects of this treatment. The combination of radical radiotherapy and daily, concomitant temozolomide followed by six cycles of adjuvant temozolomide has significantly altered the prognosis of GBM. Stupp et al. in a multicentre trial showed that at a median follow-up of 28 months, the median survival was 14.6 months in the radiotherapy plus temozolomide group as compared to 12.1 months with radiotherapy alone. The 2-year survival rate was 26.5% versus 10.4% (Stupp et al., 2005) while a 5-year review of the same population has revealed 9.8% survival at 5 years in the temozolomide group compared to 1.9% in the radiotherapy group (Stupp et al., 2009). This represents a significant advance over previous survival statistics in high-grade glioma. The MGMT status was found to be the single most important predictive factor for a favourable outcome.

It is now well recognized that MR appearances immediately after chemoradiotherapy can show apparent progression of disease, 22% of patients in the study reported by Stupp et al. (2009) did not receive adjuvant chemotherapy phase due to presumed tumour progression. Subsequent imaging shows that this either stabilizes or improves. This *pseudo progression* is more commonly seen in patients with methylated MGMT and is thought to represent a good prognostic sign of response to therapy.

Local chemotherapy

Another adjuvant to surgery has been local therapy with BCNU loaded wafers. These wafers provide a method of local delivery of high concentration chemotherapeutic agent bypassing the blood-brain barrier. A placebo-controlled study in patients at progression showed a significant improvement in median survival (31 weeks vs. 23 weeks) and six-month survival (44% dead at 6 months vs. 64%) compared to placebo (Brem et al., 1995). A further study in newly diagnosed HGG also showed a survival advantage

The use of these agents remains controversial though, as questions have been raised about their efficacy as well as side effects including CNS and wound infection rates as high as 28% (Engelhard, 2000; McGovern et al., 2003). However, there is substantial evidence for the use of BCNU wafers in adjuvant treatment. A retrospective review on BCNU wafer implantation in combination with temozolomide and radiotherapy in newly diagnosed GBM revealed a median survival of 20.7 months with a 2-year median survival of 36% (McGirt et al., 2009b). It is clear that more extensive resection (>90%) is required to obtain benefit (Stummer et al., 2012).

Targeted molecular therapies

Targeted molecular therapies are an exciting new therapeutic option, presently at various stages of research and development. These are drugs that target the oncogenic pathways in gliomas either by interacting with receptors or affecting a downstream target. Clinical trials of drugs blocking the EGFR, platelet-derived growth factor receptor (PDGFR), phosphatidylinositol 3-kinase (PI3K), and related pathways and the SRC-related pathways have so far been disappointing. It is clear that monotherapy will have little effect and trials combining these are now underway as summarized by Wick et al. (2011). The reason for this poor response is thought to be the fact that multiple receptor tyrosine kinases are activated in the development of a glioma, so blocking one receptor has little effect on the overall pathway (Stommel et al., 2007). Combinations of targeted therapies are likely to be the way forward.

Antiangiogenic therapies

One targeted therapy of particular interest blocks the vascular endothelial growth factor pathway involved in tumour angiogenesis. A small, non-randomized phase 2 study of bevacizumab at recurrence showed a high response rate (PFS at 6 months 46%; OS at 6 months 77%) (Vredenburgh et al., 2007). This trial paved the way for an FDA approval. But the non-randomized nature of the study and non-standard endpoints has made the European Medicines Agency (EMEA) reject its use in Europe. One of the problems with studies using antiangiogenic agents is the marked decrease in enhancement due to closure of the blood-brain barrier. This so called *pseudoresponse* does not predict the response to these agents, and subsequent progression can occur with no apparent contrast enhancement (Norden et al., 2008).

Two large, phase III studies—the European AVAGlio study (Chinot et al., 2014) and the North American RTOG 0825 study (Gilbert et al., 2014) have both failed to show any survival advantage from adding bevacizumab to standard treatment. The studies found differing findings on quality of life—RTOG 0825 found patients deteriorated on bevacizumab treatment whereas the AVAGlio study showed stable quality of life until tumour progression (Taphoorn et al., 2015).

Immunotherapy

The brain is often considered an immune-privileged organ due to its lack of lymphatics, a blood-brain barrier blocking the passage of cytokines and cells into the brain, low baseline expression of major histocompatibility complex proteins (MHC) and high levels of immunoregulatory cells that decrease baseline function.

These assumptions have been refuted in recent years. Nevertheless, brain tumours further evade and suppress the immune response by their very low expression of MHC proteins, reduction of monocyte phagocytic function and antigen presentation, reduced T-cell activation, and expressing markers that promote immune cell apoptosis. Overcoming these mechanisms would allow specific identification and destruction of tumour cells without injuring normal brain. Immunotherapy would seem an ideal treatment to deal with invasive cells that are distributed within normal brain. Immunotherapy is an exciting method of targeting individual tumour cells without injuring normal tissue and is independent of whether the cell is in cycle (as is the problem with cytotoxic therapies).

Three methods for overcoming tumour-induced immunosuppression have been suggested.

Cytokine therapy—this is based on activating the immune system by these potent immunoregulators. The difficulty has been delivery across the blood-brain barrier and attempts have been made with injection and infusion of cytokines or gene therapy to promote cytokine expression. Certain early phase studies have shown that this is safe but with variable efficacy and these methods might provide a useful adjunct to other therapies.

Passive immunotherapies—including serotherapy—whereby monoclonal antibodies are directed to tumour-specific antigens to deliver toxins or radioactive substances to selectively kill cells. Targets such as tenascin or the mutated EGFR-Viii form that is found in gliomas have been used, but results of early phase studies have been disappointing. Adoptive immunotherapy attempts have largely aimed to augment the tumour response by using IL-2 to stimulate harvested lymphocytes to produce lymphokine-activated killing cells. The results of early studies have shown a small benefit, but are limited by toxicity from IL-2 induced cerebral oedema.

Active immunotherapies—these methods have involved priming the immune response by vaccination against tumour-specific antigens. The difficulty with such methods is the poor antigen presentation ability within the brain. Interest has recently focused on dendritic cells which, when stimulated by an antigen, can activate T-lymphocytes to proliferate and destroy these cells. Approaches have involved taking autologous dendritic cells from either blood or bone marrow, stimulating them with antigens, and then delivering them back to the patient as a subdermal injection. The antigens used have either been common ones found within tumour or individualized from the patient's tumour. Early phase studies have shown promise and minimal toxicity, thus allowing some of these methods to enter phase III studies (Hdeib and Sloan, 2015).

Dietary therapy

The role of diet in managing neurological disease is well established. Ketogenic diets to control medically refractory epilepsy have been used for many years. As gliomas preferentially metabolize glucose and do not metabolize ketone bodies well, inducing a state of ketosis using high fat, low carbohydrate diets. Preclinical studies have shown the antitumor, proapoptotic, and antiangiogenic effects of interrupting these glycolytic pathways in cancer cell lines including gliomas. It is clear that ketogenic diets will not be tolerable for most patients, so a modified Atkin's diet has been suggested. Studies of varying quality have so far failed to show clear efficacy.

Tumour treating fields

Tumour treating fields are a novel device for treating brain tumours. Preclinical studies showed that using a low intensity and intermediate frequency electrical field can disrupt mitosis without causing heating or depolarizing neurons. A recently reported phase III study shows there is a significant survival advantage when used during the adjuvant phase of chemotherapy (Stupp et al., 2015). There is now a move that this should be considered as standard of care (Mehta et al., 2017), although the costs may prohibit routine use at present.

Managing HGG in older people

With an increasingly aged population, gliomas in older people are becoming more of a common problem. The elderly tend to have a more aggressive phenotype and, often due to frailty and other comorbidities, respond poorly to treatments. They tend to be excluded from clinical trials. As a result, patients over the age of 60 are less likely to receive the most radical treatment (Brodbelt et al., 2015).

Radical surgery for these tumours appears to be a useful treatment with improved outcome (Ewelt et al., 2011). Two large studies have shown that in elderly patients who have MGMT methylated glioblastomas there is better survival with temozolomide alone than with radiotherapy (Malmström et al., 2012; Wick et al., 2012).

Treatment at tumour progression

Despite the best management, virtually all patients with HGG will develop recurrence of tumour at some point. Salvage therapies may be considered at this point depending on the patient's clinical condition.

Surgery: Reoperation is associated with higher morbidity and mortality than for the original operation. It is, however, an option in patients with a long progression-free survival who have tumour that is maximally resectable. Insertion of carmustine wafers at this stage has been shown to improve survival (Brem et al., 1995).

Radiotherapy: There has been some suggestion that the toxicity of re-irradiation has been overestimated. Re-irradiation is an increasingly used option with precise fractionated radiotherapy being the most optimal technique. There has also been some suggestion that for accurate, focal radiotherapy to a recurrent tumour, radiosurgery may be considered. On average, time to secondary progression is in the range of several months.

Cytotoxic chemotherapy: Conventional chemotherapy regimens also improve time to secondary progression, but the efficacy is only modest and treatment related toxicities like myelosuppression occur very frequently (Niyazi et al., 2011). Recent phase III trials have failed to show that temozolomide has a survival advantage over PCV regimes (Brada et al., 2010). Recent data suggests that MGMT methylation is a prognostic biomarker for dose-intense temozolomide rechallenge (Weller et al., 2015).

At present there is little data to support routine use of targeted therapies. These should therefore be considered only as part of a clinical trial.

Prognosis

Despite many advances in management, a diagnosis of HGG still carries a dismal prognosis. The median survival without any treatment is less than 6 months, but with treatment, this increases up to 18 months. Poor survival is associated with increasing age, poor initial neurology, poor general condition as evidenced by Karnofsky Performance score (KPS) and absence of MGMT methylation. Patients who undergo surgery and chemoradiotherapy have shown better long-term benefits. Why certain group of patients survive longer than others is still unknown. Death is usually due to cerebral oedema and raised intracranial pressure.

Intracranial metastases

Andrew Brodbelt and Rasheed Zakaria

Introduction

See **Box 8.1** for the principles of the management of patients with metastases.

Epidemiology

Intracranial metastases are among the most common intracranial tumours. Western population-based studies describe annual age adjusted incidence rates of 7–14 per 100 000 (Fox et al., 2011) compared to 4.6 for glioblastoma and 7.6 for meningioma (Ostrom et al., 2014; Brodbelt et al., 2015). Autopsy studies suggest a brain metastasis may be found in up to 24% of patients with a solid organ cancer, although only 6% of patients will develop symptomatic intracranial metastases in the course of their disease (Posner and Chernik, 1978). The incidence is increasing, due, in part, to improved survival from better systemic cancer treatments and more sensitive detection methods (Fox et al., 2011). The effects of age and gender on brain metastasis incidence are dependent on the primary cancer. Female patients with lung and breast cancers are more likely to develop brain metastasis than their male counterparts but the reverse is true for melanoma, renal and colorectal cancer (Davis et al., 2012). While younger patients (<40 years) with breast and lung cancer are approximately twice as likely to develop brain metastasis as those over 70 years, the increased prevalence of cancer in older patients means that overall more metastases are still seen in older patients. Clinicians should not therefore consider any patients with suspicious symptoms to be 'too young' to develop brain metastases.

Approximately one-third of patients present with a solitary lesion, one-third oligometastatic (2–3 lesions), and a third polymetastatic (>4 lesions; see Norden et al., 2005). Metastasis rates vary with tumour type, with up to 20% of lung cancer patients developing brain disease, compared to less than 1% of thyroid, prostate, stomach, or ovarian cancer patients (National Cancer Institute, 2015). Some 30–60% of patients with brain metastases will have lung cancer (Fox et al., 2011) and of those non-small cell lung cancer (NSCLC) is the most prevalent (Delattre et al., 1988). Other common tumour primary sites include breast, melanoma, renal and colorectal cancers (Delattre et al., 1988). The median time between diagnosis of the primary cancer to presentation of brain metastasis is approximately 12 months but ranges from 3 (NSCLC) to 46 months (ovarian carcinoma) (Nussbaum et al., 1996; Kolomainen et al., 2002). Certain genetic subtypes can also favour brain spread, for example in breast cancer, both triple negative (oestrogen receptor, progesterone receptor, and HER2 receptor negative) and HER receptor positive subtypes are associated with a higher risk of brain metastasis (Pestalozzi et al., 2006).

A brain tumour in a patient with a known cancer does not always mean a brain metastasis. In one small series, 4 out of 21 patients with previous systemic malignancy were misdiagnosed as having brain metastases and received WBRT when they actually had a new primary malignant brain tumour (Maluf et al., 2002). Suspicion of a second malignancy should be aroused when there is a lack of active systemic disease (particularly in lung cancer), a long disease-free interval, a primary tumour type that rarely metastasizes to the brain (e.g. prostate carcinoma), or prior exposure to cranial radiation. One-third of patients with a new brain metastasis will have no history of systemic cancer. In these cases, the primary will usually be found within 2 months (synchronous presentation) but 5–10% will not. Patients with cancer of unknown primary do badly and may not always benefit from traditional chemo and radiotherapy strategies (Norden et al., 2005; NICE, 2010).

Pathology

In contrast to primary brain tumours, brain metastases arise from the haematogenous spread of cancer cells and are therefore found in areas of high relative cerebral perfusion. Eighty percent of metastases are seen in the cerebral hemispheres, 15% in the cerebellum, and 5% in the brainstem (Delattre et al., 1988). In the cerebrum, the metastatic cells preferentially adhere at the narrow vascular branch points found in the watershed zone at the grey white interface (Louis et al., 2007). The capillaries around brain metastases have an abnormal microstructure and leaky gap junctions which, coupled with the local release of cytokines, make them permeable to large molecules and water then follows by osmosis. This intense vasogenic oedema contains few tumour cells, and is reduced with steroids or metastectomy.

The metastatic cascade, describing cancer cell movement from primary site to the brain, is a complex and inefficient process

Box 8.1 Principles of the management of patients with metastases

Treatment is not curative. The aim is extension of quality life.
The patient's performance score is crucial to outcome.
Increasing age is associated with worsening outcomes.
Minimum staging includes an MRI brain with either CT or CT PET of chest/abdomen/pelvis.
The whole patient and their cancer load must be considered, not just the brain metastasis
If the treatment is not working, consider malignant meningitis.
In patients with a history of cancer, a new brain lesion can still be a different cancer or an abscess.

(Fig. 8.1). Each stage is a potential drug or therapeutic target. For example, detection of early metastases with labelled iron particles attached to the cell adhesion molecule VCAM-1, before they are seen on conventional contrast-enhanced magnetic resonance imaging (MRI), offers future treatment development opportunities (Serres et al., 2012).

The macroscopic appearance of metastases may be firm or rubbery, with necrotic areas in the core. They are usually yellow or tan in colour, although melanoma metastases are often black due to melanin. Blood products may be present, altering the colour. Haemorrhage is most commonly reported in renal, melanoma, choriocarcinoma, thyroid, and hepatocellular metastases. The tumour frequently appears well demarcated and compresses the adjacent glial tissue forming a pseudocapsule (Fig. 8.2).

Despite an apparent macroscopic plane, there is increasing evidence of local invasion in brain metastases with implications for both treatment and prognosis (Fig. 8.2). More infiltration is associated with poorer survival (Siam et al., 2015). Diffusion MRI changes at the tumour-brain interface are predictive of local recurrence, and could be used to aid treatment planning, including increased resection margins, or stereotactic radiosurgery (SRS) treatment field (Zakaria et al., 2014).

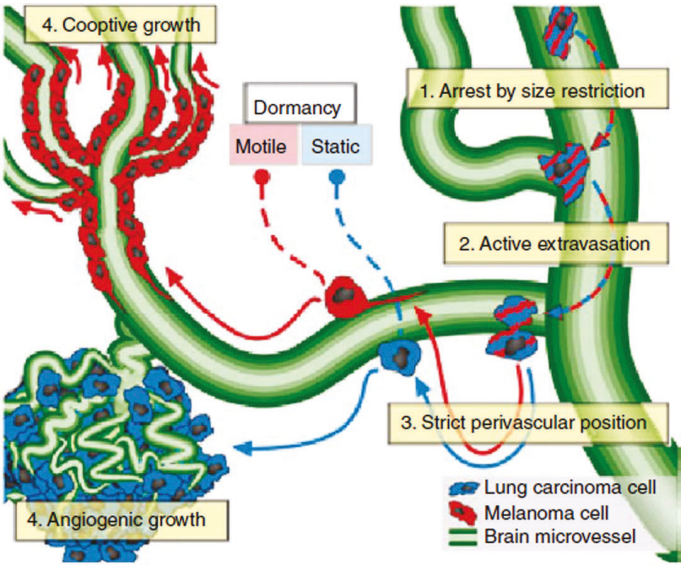

Fig. 8.1 The metastatic cascade: a solid organ cancer cell transitions from a static 'epithelial' to a more mobile 'mesenchymal' cell phenotype, driven by growth factors including TGF-β, IGF, and EGF, detaches from its neighbours, and invades the local extracellular matrix requiring cadherin breakage, and proteolytic enzymes, such as matrix metalloproteinases. Intravasation (entering the bloodstream) is facilitated by the formation of invadopodia, actin rich protrusions of the plasma membrane that guide the cell through its microenvironment, coupled with tissue plasminogen activator release. 1. Once in the circulation, the cells must survive intense sheer forces and immune attack, which involves a strengthened cytoskeleton. The cells attach to the endothelium at branch points and narrowings. 2. Crossing the blood–brain barrier requires integrin and cell adhesion molecule mediation. 3. Metastatic cancer cells remain adjacent to the blood vessels. 4. Brain invasion is tumour specific, with melanoma cells growing along blood vessels (co-optive growth) whereas lung cancer cells generate new blood vessels (neoangiogenesis).

Symptoms and signs

Patients with metastases present with symptoms and signs of raised intracranial pressure, CSF pathway obstruction, neurological mass effect, and in the untreated situation, coning and death. Irritation of the cortex may lead to focal or generalized seizure presentation in 15–20% of patients, but more so (50%) in those with melanoma (Taillibert and Delattre, 2005). Solitary or oligometastatic disease presents with headache (80%), focal neurological deficit (30–40%), and visual disturbance (6%) while polymetastatic disease may present as an encephalopathic or acute confusional state (Gaspar et al., 1997). Any of these features in a patient with known cancer should lead to suspicion of intracranial metastases, although one series found 40% of patients with lung cancer and brain metastases were asymptomatic (Ohana et al., 2014).

Investigations

The first step is to take a history and perform a clinical examination. This should include an enquiry for indicators of cancer (weight loss, change in bowel habit, smoking), any previous cancer history, other medical problems, and breast or rectal examinations. The performance score should be calculated and recorded. The World Health Organization (WHO), European Organisation for the Research and Treatment of Cancer (EORTC), and Karnofsky performance scores are all used, but the main determinate of outcome relates to the need of the patient for any help with daily activities. This is indicated by a score of 2 or over (WHO, EORTC), or less than 70 (Karnofsky).

Initial radiological investigations include a CT scan of the head, which is often enough to suggest the diagnosis. MRI is essential for diagnosis and treatment planning (Fig. 8.3). MRI detects smaller tumours than CT, although the exact size depends on slice thickness. Double and triple contrast dosing improves detection rates, but risks nephrotoxicity and increases false positives.

Questions the imaging should help answer include whether this is a brain metastasis; that is, can infection, high-grade glioma, lymphoma, and other lesions including multiple sclerosis or toxoplasmosis be excluded? How many and what size/volume are the metastases? Where is the primary cancer and how extensive is the extracranial disease? How safe is surgery?

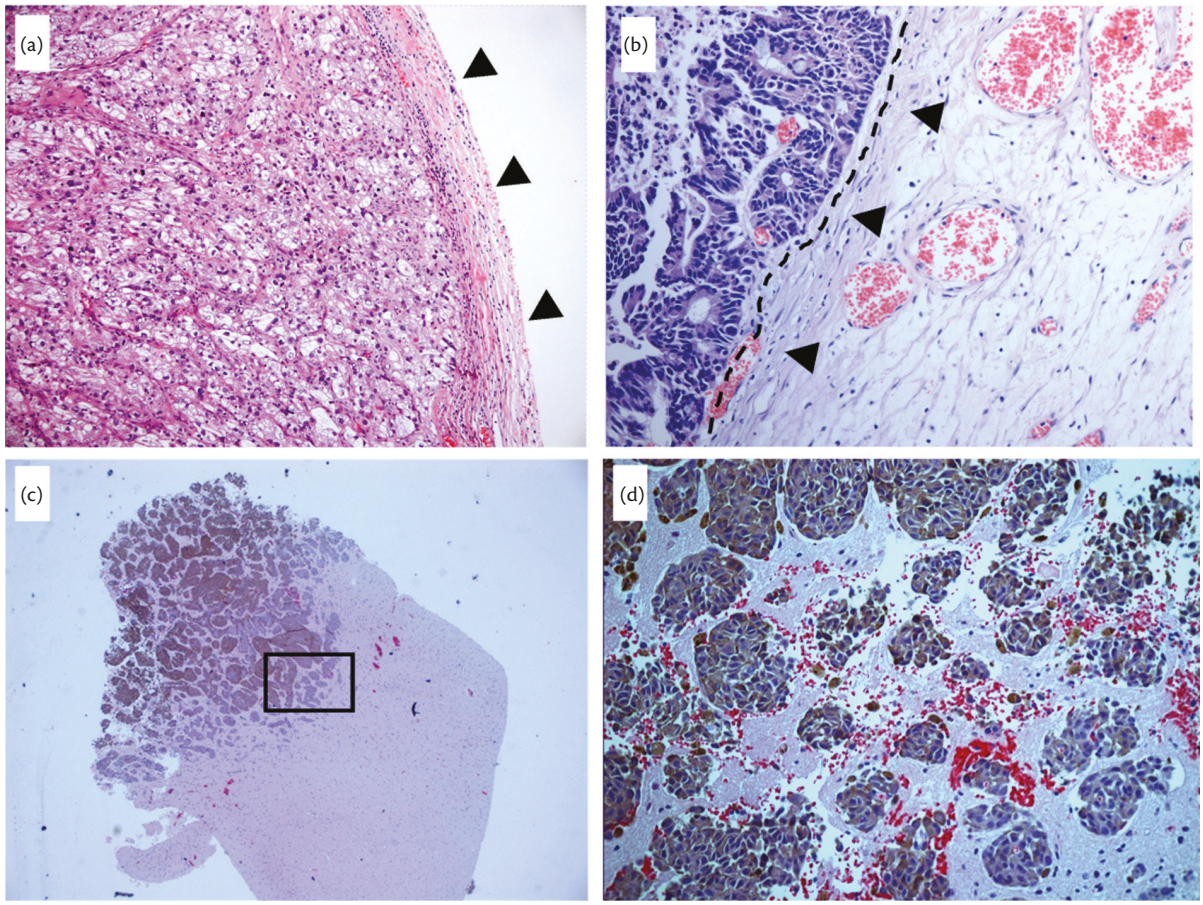

Fig. 8.2 (A) and (B) Brain metastases may appear to have a definite plane with the surrounding brain. Renal (A, ×100) and lung adenocarcinoma (B, ×200) metastases demonstrate the pseudocapsule of compressed white matter (arrowheads) with a clear boundary between brain and tumour (dashed line). (C) and (D) A diffusely invasive edge is found in up to a third of metastases (Neves et al., 2001; Berghoff et al., 2013). C (×50), D (×200) melanoma metastasis showing microscopic islands of tumour in the surrounding brain parenchyma.

Multimodal MRI has been used to aid in differentiating metastases from other imaging abnormalities. Metastases may show lower peritumoral perfusion and higher diffusion than infiltrating gliomas, while the MR spectroscopic signature can help differentiate meningioma or lymphoma. In practice, the best guide remains the presence of surrounding vasogenic oedema and the appearance of the lesion on standard T1, T2, and gadolinium-enhanced T1 weighted MRI sequences. Diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) MRI maps are rapid to obtain and can show an abscess by restricted water movement, although restricted diffusion can also occur in mucinous metastases (Fig. 8.4; see also Ebisu et al., 1996). Cranial [18F] FDG-PET appears to be a sensitive way of detecting brain metastases in patients with known or suspected solid organ cancers, and may distinguish brain metastases from lymphoma but not high-grade glioma. Poor spatial resolution mandates a clinical assessment and MRI to complete the evaluation.

Quality of life after treatment impacts on survival, and advanced techniques such as functional MRI and tractography are being increasingly used in metastasis surgery (Fig. 8.5).

Staging aids in treatment decisions, and a full blood count, urea, and electrolytes, clotting profile, and liver function tests can all help assess systemic cancer effects. Specific tumour staging requires whole-body positron emission tomography (PET) CT or contrast CT of the chest, abdomen, and pelvis. In patients with synchronous or unknown primaries, tumour markers may be considered which include human chorionic gonadotrophin (ßHCG) for germ cell tumours, alpha fetoprotein (αFP) for hepatocellular carcinoma, carcinoembryonic antigen for gastrointestinal, lung, and breast cancers, and CA125 for ovarian tumours. Further radiological assessments include a skeletal survey, mammography, ultrasound, and MRI where indicated. Rapid, appropriate staging within 2–7 days aids efficient decision-making and avoids clinically relevant tumour progression which might reduce treatment options.

Treatment

Oral or intravenous corticosteroid therapy (dexamethasone) can dramatically reduce the symptoms caused by a tumour's vasogenic oedema. The initial dexamethasone dose is 16 mg per day in two or four divided doses but should be tapered as fast as tolerated. The side effects of dexamethasone include, but are not limited to, peptic ulceration, insomnia, myopathy, weight gain, psychosis, skin thinning, Cushing's syndrome, adrenal suppression, and increased risk

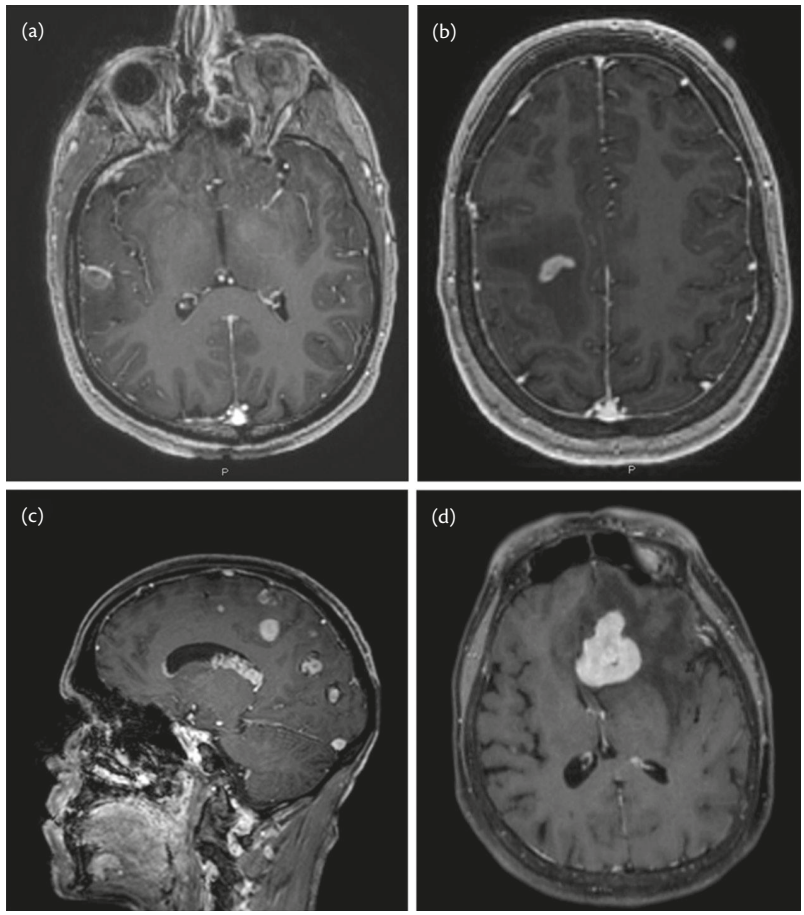

Fig. 8.3 Differential diagnoses of an enhancing mass on T1 + gadolinium MRI. (A) A 55-year-old, with negative staging and no history of primary cancer, was found on resection to have a high-grade glioma. (B) A 22-year-old with a short history of left-sided numbness and weakness, and normal whole-body CT, had an inflammatory picture on LP, and a diagnosis of a multiple sclerosis plaque was made. (C) A 42-year-old HIV positive male with a history of melanoma required a biopsy to prove toxoplasmosis. (D) A 70-year-old smoker presented with confusion and a hilar mass on chest CT which could not be sampled by the thoracic surgeons. Biopsy revealed lymphoma.

of infection. These effects support routine, synchronous gastric protection with a proton pump inhibitor and the use of as low a dose of dexamethasone for as short a time as possible.

Individual treatment options can be divided into focal (Surgery, SRS, interstitial laser therapy, and focused ultrasound treatment) and whole brain or body techniques (whole-brain radiotherapy (WBRT), chemotherapy and targeted or immune therapies). The aim of the final treatment plan, using therapy options individually or in combination, is to improve local control, extend life, and prevent further neurological complications.

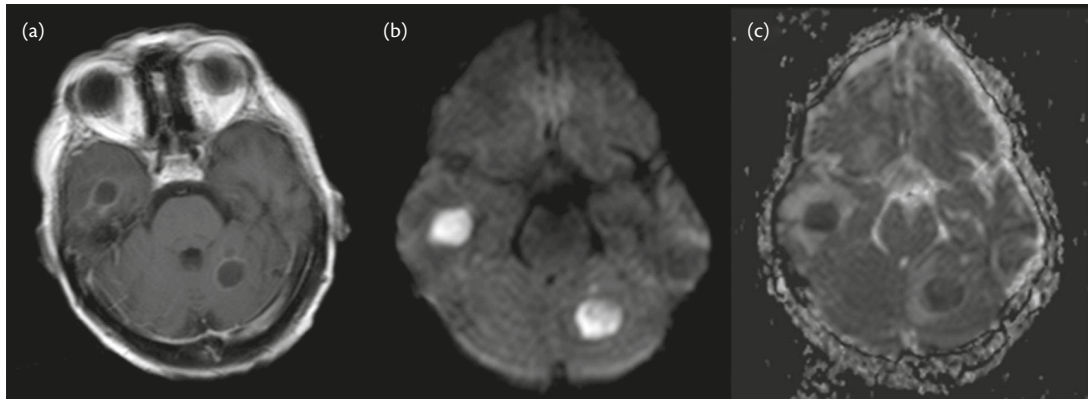

Fig. 8.4 A 53-year-old male with a history of head and neck cancer, presented with low grade fever and confusion. A T1-weighted MRI scan with gadolinium (A) indicated multiple enhancing lesions. Diffusion-weighted MRI (B) and apparent diffusion coefficient map (C) showed restricted diffusion. Aspiration demonstrated pus (*Streptococcus)* and investigation found endocarditis. After prolonged IV antibiotic therapy there was complete resolution.

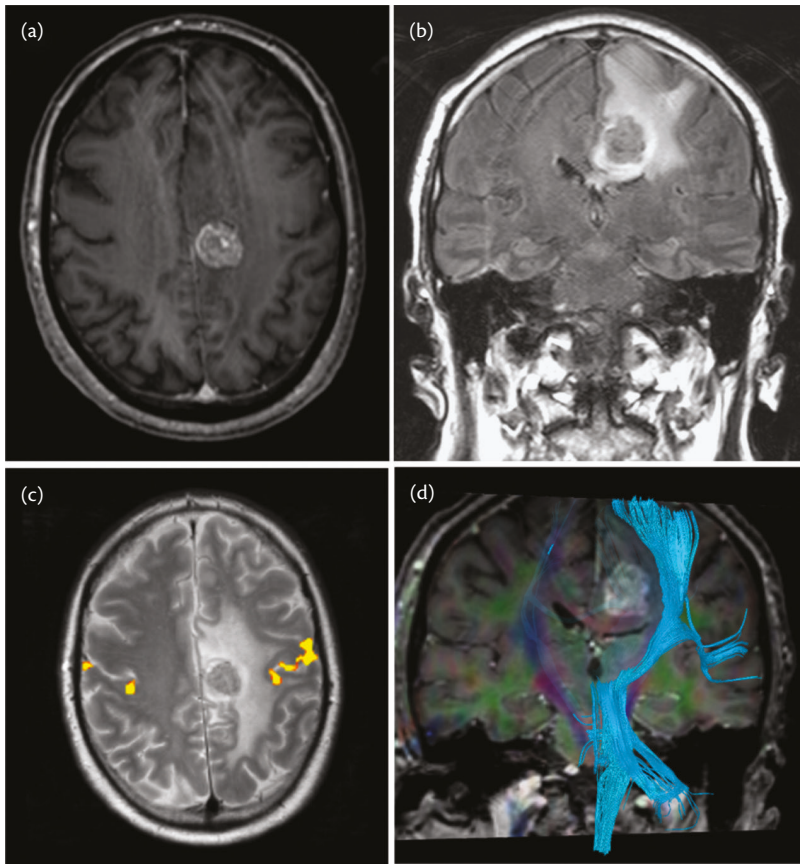

Fig. 8.5 A 58-year-old man presented with right sided hemiparesis, which improved with steroids, and a suspected brain metastasis. (A) Postcontrast T1-weighted MRI demonstrated an enhancing mass. (B) Sagittal FLAIR confirmed a cingulate location with oedema. The patient was a heavy smoker and CT staging identified a small hilar mass. Hilar biopsy and bronchial washings were unsuccessful. (C) Functional MRI using a finger tapping paradigm localized the primary motor cortex. (D). Seeded tractography with diffusion tensor imaging (DTI) showed the corticospinal tracts displaced laterally. An interhemispheric resection removed an adenocarcinoma, with no increase in neurological morbidity and following treatment he survived almost a year with good performance status before succumbing to the primary tumour.

Surgery for intracranial metastases provides diagnostic tissue, relieves mass effect, and is considered for solitary or oligometastatic disease. Meta-analysis of randomized controlled trials has shown surgery improves survival and functional status compared to WBRT alone (Hart et al., 2005). The disadvantages, even with modern microneurosurgical techniques that include awake surgery, integrated multimodal MRI studies, and image guidance (Fig. 8.4), remain the risk to life, infection, and neurological disability. Surgical techniques originally used in cancer resections in other organ systems, including *en bloc* and supramarginal methods are being used in brain metastectomies to reduce local recurrence rates and leptomeningeal spread (Yoo et al., 2009; Patel et al., 2010). Surgery remains the method of choice for large tumours with mass effect, cystic, or radioresistant tumours, if diagnostic tissue is required, and when SRS is not available.

Stereotactic radiosurgery describes a form of ionizing radiation therapy that focuses high-powered energy on a small target in a single or a few fractions. The advantages of SRS include that it can be done as a day case, can use a thermoplastic mask rather than a frame, avoids any surgical procedure, can target multiple lesions in deep or eloquent cortex, and has results comparable to surgical series. Limitations exist and not all tumours are suitable, as lesions need to be typically 4 cm (or less) or 20 cc, those abutting the optic nerves or brainstem risk local radionecrosis while cystic and radioresistant tumour (commonly renal and melanoma) lesions respond less well. Tumours can swell after treatment leading to extended steroid treatment and concomitant side effects which make SRS less suitable for certain post fossa metastases. No tissue is taken for diagnosis. There are no certain efficacy or safety differences between the different platforms available (gamma knife, cyberknife, and linear accelerator). Radiation necrosis rates increase with increasing tumour volume irradiated and hypofractionated regimes for lesions larger than 20 cc may be used.

WBRT improves survival and tumour control in the brain, but current concerns relate to cognitive harm. Ninety percent of patients with brain metastases have impaired neurocognitive function at diagnosis and up to two-thirds will show further decline within 2–6 months of WBRT (Pinkham et al., 2015). Omitting whole-brain radiotherapy after local therapy increases the time until cognitive decline and improves verbal memory but it is argued that progression and the associated salvage treatments outweigh any benefit that has been gained. Recent evidence suggests WBRT does not improve survival in all patients and notably in those older patients with NSCLC, and poor performance score, simple steroid treatment and good palliative care may be more appropriate (Mulvenna et al., 2016). New fractionated radiotherapy strategies may reduce

cognitive harm by hippocampal sparing, using reduced whole brain fields while boosting the tumour bed, or by using neuroprotective agents such as memantine (Brown et al., 2013).

Recent developments have challenged the view that systemic drug therapy is not effective in treating brain metastases. Areas under investigation include identifying antimetastasis effects among agents that cross the blood–brain barrier (BBB), developing agents that act systemically to prevent brain metastases occurring and facilitating traditional chemotherapy agents to cross the blood–brain barrier. In melanoma pretreatment with the immunotherapy agent ipilimumab improved the effects of surgery (Jones et al., 2015) and in the half of patients with a B-Raf Proto-oncogene (BRAF) mutation, inhibiting the pathway can extend overall survival (> 7 months) for patients with untreated brain metastases (Goyal et al., 2015). A new UK study (CAMBT1) of a tyrosine kinase inhibitor for patients undergoing resection of lung or breast metastases is testing whether low-dose, targeted radiotherapy to the metastasis preoperatively improves drug penetration.

Novel treatments include interstitial laser thermal therapy which passes a laser through a burr hole to heat up tumours, controlled by almost real-time MR thermography (Hawasli et al., 2013). MR-guided focused ultrasound (MRgFUS) uses ultrasound, controlled with MR thermography, to target deep seated lesions. Initially used for fibroids, MRgFUS is starting to be used for cranial lesions (Coluccia et al., 2014). Carmustine wafers (Gliadel) implanted in the cavity following surgery have been reported to reduce local recurrence (Abel et al., 2013) but are rarely used.

As treatment for brain metastases is unlikely to lead to a cure, patients and their families will require ongoing supportive and symptomatic care whatever management plan is agreed. Specific problems include cognitive decline, poor mobility, thromboembolism, pain, reduced self-care, anxiety, depression, and epilepsy (Taillibert and Delattre, 2005). Early involvement of palliative care teams is essential to maximize a patient's quality of life.

Treatment selection

Regular multidisciplinary team (MDT or tumour board) meetings have been developed to optimize the efficient review of a patient's planned management. Experienced neuroradiological review, discussion between oncologists, neurosurgeons, pathologists, specialist nurses, and palliative care teams ensures modern treatment practices are followed and improves recruitment into clinical trials. The final treatment choice remains the responsibility of the treating clinician and the patient.

There are a number of possible treatment combinations. Traditionally surgery was followed by WBRT. WBRT is used following local treatments to reduce the local recurrence rates, and control disease elsewhere in the brain, but concerns remain regarding the associated cognitive decline. In a randomized controlled trial comparing surgery plus WBRT (n = 49) to surgery alone (n = 46), the addition of WBRT improved intracranial control from 30% to 82% (Patchell et al., 1998). However overall survival and quality of life (in the form of time spent in good performance status) were only secondary measures and neither showed improvement. These results have been used to justify omitting WBRT after surgery. However, local recurrence in this study was associated with increased neurological death, which was more common in the surgery only group. A large European trial (Kocher et al., 2011) randomized patients who had undergone surgery to observation or WBRT. WBRT reduced the frequency of recurrence in the resection bed from 60% to less than 30% but with only a modest increase in progression-free survival and no change in overall survival. Quality of life data from this trial found that WBRT caused poorer physical functioning and fatigue at 8 weeks, worsening global health status at 9 months, and deteriorating cognitive functioning.

If SRS is used, it can be followed by WBRT. A large trial (Kocher et al., 2011) randomized patients who had received SRS for between one and three brain metastases to observation or WBRT. There was no difference in overall survival from adding WBRT but intracranial progression causing death was reduced from 44% to 28% and fewer salvage therapies were required. A meta-analysis concluded that adding WBRT to SRS improves local control but not overall survival, but then recommended omitting WBRT due to the deleterious cognitive effects (Tsao et al., 2012).

Surgery followed by SRS is one way of improved local control with less cognitive side effects. A randomized controlled trial suggested SRS to the surgical cavity gave comparable survival rates to surgery followed by WBRT but with improved cognitive outcomes (Brown et al., 2017) and this paradigm is gaining popularity. Advanced MRI (e.g. DWI) prediction of microscopic infiltration and tumour residual could be used in the future to try to improve SRS planning and treatment selection.

Although WBRT remains the standard of care for patients with polymetastatic brain disease, improved planning algorithms have allowed the use of SRS for these patients. A prospective observational study of 1194 patients with up to ten metastases (total volume <15 ml) and a performance score of 70 or over treated with SRS alone, showed no difference between those patients with 2–4 and those with 5–10 metastases with respect to overall survival, complications, and local recurrence (Yamamoto et al., 2014). There is no randomized controlled trial comparing SRS with WBRT for polymetastatic disease. SRS delivers a lower dose to normal brain tissue, is deliverable as a day case, and appears to provide promising outcomes in this patient group.

Principles in treatment selection are vital (**Box 8.2**). In solitary or oligometastatic disease, a patient who can still look after themselves (KPS >70, WHO ≤2), and a systemic disease load allowing at least a 3–6-month prognosis, should be considered for aggressive treatment. Surgery where appropriate or SRS provides local control, may improve neurological function, and will extend life. The addition of WBRT reduces local and distal recurrence and hence neurological deterioration and death. SRS to the cavity following surgery aids local control. Avoiding WBRT reduces the risk of cognitive decline but necessitates continued surveillance and further salvage treatments. In polymetastatic disease, WBRT remains the treatment of choice, but SRS is becoming more important. As personalized systemic chemotherapy and immunotherapy develops, new alternatives to surgery or radiation and novel combination treatments are likely. A close discussion between the patient, neurosurgeon, and treating oncologist is required to balance the risks and benefits of the therapies available (see **Box 8.2**).

Malignant meningitis

Five percent of brain metastasis patients will develop malignant meningitis (carcinomatous meningitis, leptomeningeal metastasis), and may present with cranial neuropathies, unexplained hydrocephalus,

Box 8.2 Principles of treatment decision-making

Treatment is not curative; the aim is extension of quality life.
The psychological and supportive care of the patient is as important as the treatment of the metastasis.
If a patient is unable to look after themselves, they are unlikely to benefit from treatment.
WBRT is the standard of care to improve intracranial control following surgery but the risks of associated neurocognitive decline should be considered.
Local treatments (surgery and SRS) increase quality life expectancy and improve local control.
Local treatments given alone have less cognitive side effects than WBRT, but require continued monitoring to control distal neurological disease.
Systemic cancer treatments are evolving. A discussion with an oncologist may offer alternatives to radiation treatments and surgery.

or confusion (Le Rhun et al., 2013). Perineural spread of tumour cells along the subarachnoid spaces may be detected on contrast-enhanced T1 and FLAIR MRI or at lumbar puncture (LP). Repeated large volume LPs, processed immediately can reveal the diagnosis in 80% (Le Rhun et al., 2013). Open biopsy for larger deposits is problematic, and surgical CSF diversion risks tumour seeding into the abdomen, although both may have a role. Craniospinal radiation and intrathecal chemotherapy via a CSF reservoir are the mainstays of treatment, although outcomes remain poor (6 weeks untreated).

Prognosis

Multiple prognostic scoring systems exist (Table 8.1). These systems emphasize the importance of the patient's performance score

Table 8.1 The prognosis of patients with brain metastases may be estimated by scoring systems of increasing complexity. The Recursive Partitioning Analysis (RPA) paper statistically examined a series of patients treated with radiotherapy and described a three-class system, with no benefit found from treating patients with a poor performance score. The graded prognostic assessment (GPA) included patients from various trials treated with different strategies, and split each feature and included the number of metastases, while the diagnosis-specific GPA included different primary cancer types. The one factor that is common to every scoring system and disease is the Karnofsky performance score.

Scoring system	Category	Factors				Outcomes (median overall survival)						
RPA	Class I	Age <65, KPS ≥ 70, Controlled primary tumour, no extracranial metastases				7.1 months						
	Class II	All patients not in Class I or III				4.2 months						
	Class III	KPS <70				2.3 months						
GPA	0 points	Age >60	KPS <70	>3 mets	Extracranial metastases	GPA 0–1		2.6 months				
	0.5 points	Age 50–59	KPS 70–80	2–3 mets		GPS 1.5–2.5		3.8 months				
	1 point	Age <50	KPS 90–100	1 met	No extracranial metastases	GPA 3		6.9 months				
						GPA 3.5–4.0		11.0 months

RPA, recursive partitioning analysis; GPA, graded prognostic assessment; DS, disease specific; KPS, Karnofsky performance score; ECM, extracranial metastases; NSCLC, non-small cell lung cancer; SCLC, small cell lung cancer; GI, gastrointestinal; RCC, renal cell cancer.

Data from Gaspar et al., Recursive partitioning analysis (RPA) of prognostic factors in three Radiation Therapy Oncology Group (RTOG) brain metastases trials, *International Journal of Radiation Oncology, Biology, Physics*, Volume 37, pp. 745–51, 1997; Sperduto PW, Berkey B, Gaspar LE, Mehta M, Curran WJ, A new prognostic index and comparison to three other indices for patients with brain metastases: An analysis of 1960 patients in the RTOG database, *International Journal of Radiation Oncology, Biology, Physics*, Volume 70, pp. 510–14, 2008; Sperduto PW, Chao ST, Sneed P, et al., Diagnosis-specific prognostic factors, indices and treatment outcomes for patients with newly diagnosed brain metastases: a multi-institutional analysis of 4259 patients, *International Journal of Radiation Oncology, Biology, Physics*, Volume 77, Issue 3, pp. 655–61, 2010.

in treatment decisions. The only exception for the poor performance score patient is when surgery improves functioning by reducing mass effect or treating hydrocephalus. More recent scoring systems incorporate tumour subtypes, biochemical parameters, and imaging data (Sperduto et al., 2010). Currently, screening of asymptomatic patients does not appear to improve survival.

Landmark papers

Patchell and colleagues ran two landmark studies in the 1990s which defined the modern treatment of intracranial metastases. They asked two questions:

Should we take out intracranial metastases?

In the first study they randomized 48 patients with a solitary brain metastasis to tumour removal or biopsy followed by WBRT (Patchell et al., 1990). Recurrence at the site of the original metastasis was less frequent in the surgical group than in the radiation group (5 of 25 [20%] vs. 12 of 23 [52%]; P <0.02). Survival was significantly longer in the surgical group (median, 40 weeks vs. 15 weeks; P <0.01), and the patients treated with surgery remained functionally independent longer (median, 38 weeks vs. 8 weeks; P <0.005).

If we completely take out a metastasis, should we give radiotherapy postoperatively?

Ninety-five patients were randomized to WBRT or no further treatment after resection of their tumour. Patients underwent a postoperative brain MRI to confirm complete resection (Patchell et al., 1998). Patients treated with radiation were less likely to show recurrence in the brain or die of neurological causes.

Controversies: SRS or neurosurgery?

Debate continues on whether SRS or surgery provides better local treatment but there has never been a direct, controlled trial comparing surgery and SRS. A retrospective case series found no difference between SRS or surgery, when both were followed by WBRT (Schöggl et al., 2000). In a separate study, SRS alone was compared to surgery and WBRT, and showed no difference at 6 months (Muacevic et al., 2008). In UK clinical practice, SRS is reserved for treating 1–3 smaller tumours (with an upper limit of 20 cc or 30 mm diameter), where there is little oedema or mass effect and the patient is expected to survive 6 months. SRS is undoubtedly quicker and less invasive than neurosurgery alone, but some tumour types are known to be relatively radioresistant (e.g. melanoma, renal cell carcinoma). In patients fit enough for anaesthesia, neurosurgery has the advantage of removing mass effect and relieving oedema, thus potentially improving CSF flow and neurological deficits, particularly in the posterior fossa or with larger, non-eloquent supratentorial lesions. Crucially, surgery also provides tissue for diagnosis in those without a known primary cancer. For patients with cystic metastases, a combined approach with surgical cyst drainage and SRS has proved effective (Franzin et al., 2008). In the future, hybrid approaches with combinations of surgery for the larger tumour plus SRS, interstitial laser thermal therapy, or MRgFUS., for smaller inaccessible lesions could become standard unless significant improvements in chemotherapy and immunotherapy occur.

Conclusions

Intracranial metastases are becoming more common, the management of these patients can be challenging and crosses multiple subspecialties. Treatments are developing, although surgery, SRS, and WBRT remain the core options. The patient's performance score is central to outcome, and care must be taken to maximize quality of life. Progress in the management of cancer is beginning to lead to better outcomes for this patient group.

Primary central nervous system lymphoma

Boon Leong Quah, Thangaraj Munusamy, and Colin Watts

Introduction

Primary central nervous system lymphoma (PCNSL) is a rare form of non-Hodgkin's lymphoma (NHL) confined to the central nervous system, which continues to be a challenging malignancy to treat. The reason behind this lies in the fact that its systemic counterpart carries a more favourable prognosis with a cure rate of approximately 70%, whereas the prognosis of PCNSL remains poor in the immunocompetent and even poorer in HIV-associated PCNSL. Fortunately, the median overall survival has nearly doubled since the 1970s reflecting a better understanding, and more effective management of this disease. In this chapter, we will explore the many reasons behind this increased survival as well as current management options from a neurosurgical perspective.

Epidemiology

Primary central nervous system lymphoma (PCNSL) is a rare tumour affecting approximately 0.48 in 100 000, comprising approximately 2–3% of primary central nervous system (CNS) tumours, they are aggressive and high grade. PCNSLs are non-Hodgkin's lymphomas, and account for approximately 2% of all cases of NHL. The vast majority of PCNSL's are the diffuse large B-cell type (DLBCL). In the immunocompetent, the peak incidence occurs in the 60-year and above age group whereas the median age of presentation is 37 years in HIV-associated PCNSL (Norden et al., 2011). HIV-associated PCNSL is almost always associated with Epstein–Barr virus (EBV), which is in contrast to only 20% of systemic AIDS-related lymphomas (Wang et al., 2014). The male to female ratio is 1.2–1.7:1 in immunocompetent patients, in contrast to a male predominance for the immunocompromised group (**Table 9.1**).

Epidemiological data has also shown an increase in the frequency of PCNSL cases in immunocompetent patients from the 1990s onwards, especially in those above 65 years old. Conversely, the frequency of cases has dropped in HIV-associated PCNSL, not surprisingly due to the widespread availability and access to highly effective antiretroviral treatment.

Clinical presentation

PCNSL is defined by involvement of the brain, leptomeninges, cranial nerves, spinal cord, cerebrospinal fluid (CSF) or eyes, without evidence of systemic disease. Patients usually present with neurological symptoms that reflect the neuroanatomical location of the lesion(s). The majority of patients have constitutional, cognitive, neuropsychiatric, or motor symptoms, 20% present with seizures. Leptomeningeal disease occurs in 15–20% of patients and may present with multiple cranial nerve palsies. Approximately 20–30% of patients have ocular involvement at the time of diagnosis, often affecting both eyes causing non-specific symptoms such as pain, redness, photophobia, blurred vision, and reduced visual acuity. HIV-associated PCNSL is an AIDS-defining illness associated with low CD4 counts and Epstein–Barr virus (EBV) infection, and is more likely to present with encephalopathy and a history of other concurrent infections. Temporal progression of disease is variable among patients. Some exhibit chronic symptoms that precede diagnosis by years, while for others disease progression is rapid and aggressive.

Diagnosis

Radiological

The common sites affected by PCNSL are the periventricular region, basal ganglia, corpus callosum, and deep white matter. The frontal lobe is the most frequently affected, followed in order by the parietal, temporal, and occipital lobes. MR imaging characteristically shows an avid, homogenously contrast-enhancing lesion (**Table 9.1**).

However, 10% of immunocompetent patients will harbour non-enhancing lesions, particularly seen at recurrence. Multiplicity is seen in approximately 70% of AIDS patients, in which heterogenous ring-enhancing lesions are more commonly seen. PCNSL is characteristically seen tracking along Virchow-Robinson perivascular spaces. Calcification, haemorrhage, and necrosis are rarely present but are more commonly seen following treatment. MR spectroscopy (MRS) commonly demonstrates much higher choline to creatine ratio compared to gliomas. Also, large lipid peaks on single-voxel proton MRS are characteristic (Yamasaki et al., 2015).

Table 9.1 Comparison between immunocompetent and immunocompromised patients with PCNSL

PCNSL		Immunocompetent	Immunocompromised
	Age (years)	60s (median 56)	30s (median 35)
	Time to diagnosis	3 months	2 months
Symptoms		Neurological deficits (extent dictated by location of tumour) Seizures and cranial nerve palsies less common	Neurological deficits (extent dictated by location of tumour) Commonly presents with seizures, encephalopathy, and cranial nerve palsies
Location in CNS	Adults	Solitary (70%), supratentorial (85%), periventricular (60%), corpus callosum (12%)	Multiple (50%), supratentorial
	Paediatrics	Solitary Parietal and frontal lobes, cerebellum, pituitary stalk, hypothalamus Leptomeningeal spread commoner (18%)	
Differential diagnosis		High-grade gliomas Multiple sclerosis Metastasis Neurosarcoidosis	Toxoplasmosis Abscess Progressive multifocal leukoencephalopathy
Radiological features	CT	Hyperdense to grey matter Enhances homogenously with contrast	Heterogenous, ring enhancing
	MRI	Hypointense on T1WI, hyperintense on T2WI, homogenously enhancing	Heterogenous, ring enhancing (also commonly seen in paediatric population)
Subtyping		Ranges from low grade to high grade 95% DLBCL Association with EBV: rare	Almost always EBV-positive Mostly high-grade, DLBCL, immunoblastic type (features similar in both AIDS and transplant patients)

Abbreviations: AIDS, acquired immunodeficiency disease; BCL-6, B-cell lymphoma 6 protein; CNS, central nervous system; CT, computed tomography; DLBCL, diffuse large B-cell lymphoma; DWI/ADC, diffusion-weighted imaging/apparent diffusion coefficient map; EBV, Epstein–Barr virus; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy; PCNSL, primary central nervous system lymphoma; T1WI, T1-weighted imaging; T2WI: T2-weighted imaging.

PCNSL lesions are hypermetabolic when imaged by positron emission tomography (PET) and single-photon emission computed tomography (SPECT). This is useful in differentiating it from the hypometabolic toxoplasmosis lesions in patients with AIDS. Figures 9.1 and 9.2 give radiological examples of cases of PCNSL and other differential diagnoses.

Eye examination (slit lamp, vitrectomy)

All patients suspected of having PCNSL must undergo a complete ophthalmic examination and CSF analysis, if no contraindication exists. Approximately 25% of patients with PCNSL develop ocular involvement, and conversely, up to 90% of patients with primary intraocular lymphoma (PIOL) go on to develop PCNSL (Gündüz et al., 2003). Abnormalities consistent with PCNSL on the slit-lamp examination would prompt a biopsy with either a fine-needle aspiration to obtain a vitreous sample or a diagnostic vitrectomy in the eye where vision or disease is worse. Vitrectomy can also improve vision by removing the cellular debris that is responsible for the blurred vision and floaters. This procedure is less invasive than a brain biopsy and could potentially clinch the diagnosis in about 25% of patients without having to subject them to the hazards of a stereotactic brain biopsy.

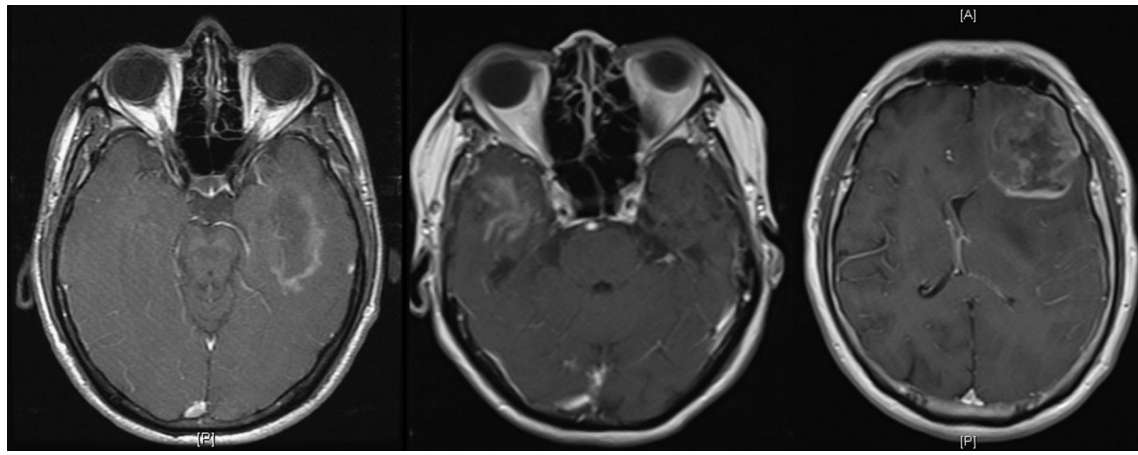

Fig. 9.1 Similarity of contrast-enhanced MR imaging of PCNSL to other pathologies. Left: Left temporal tumefactive multiple sclerosis. Middle: Right temporal DLBCL type PCNSL. Right: Left frontal glioblastoma WHO Grade IV.

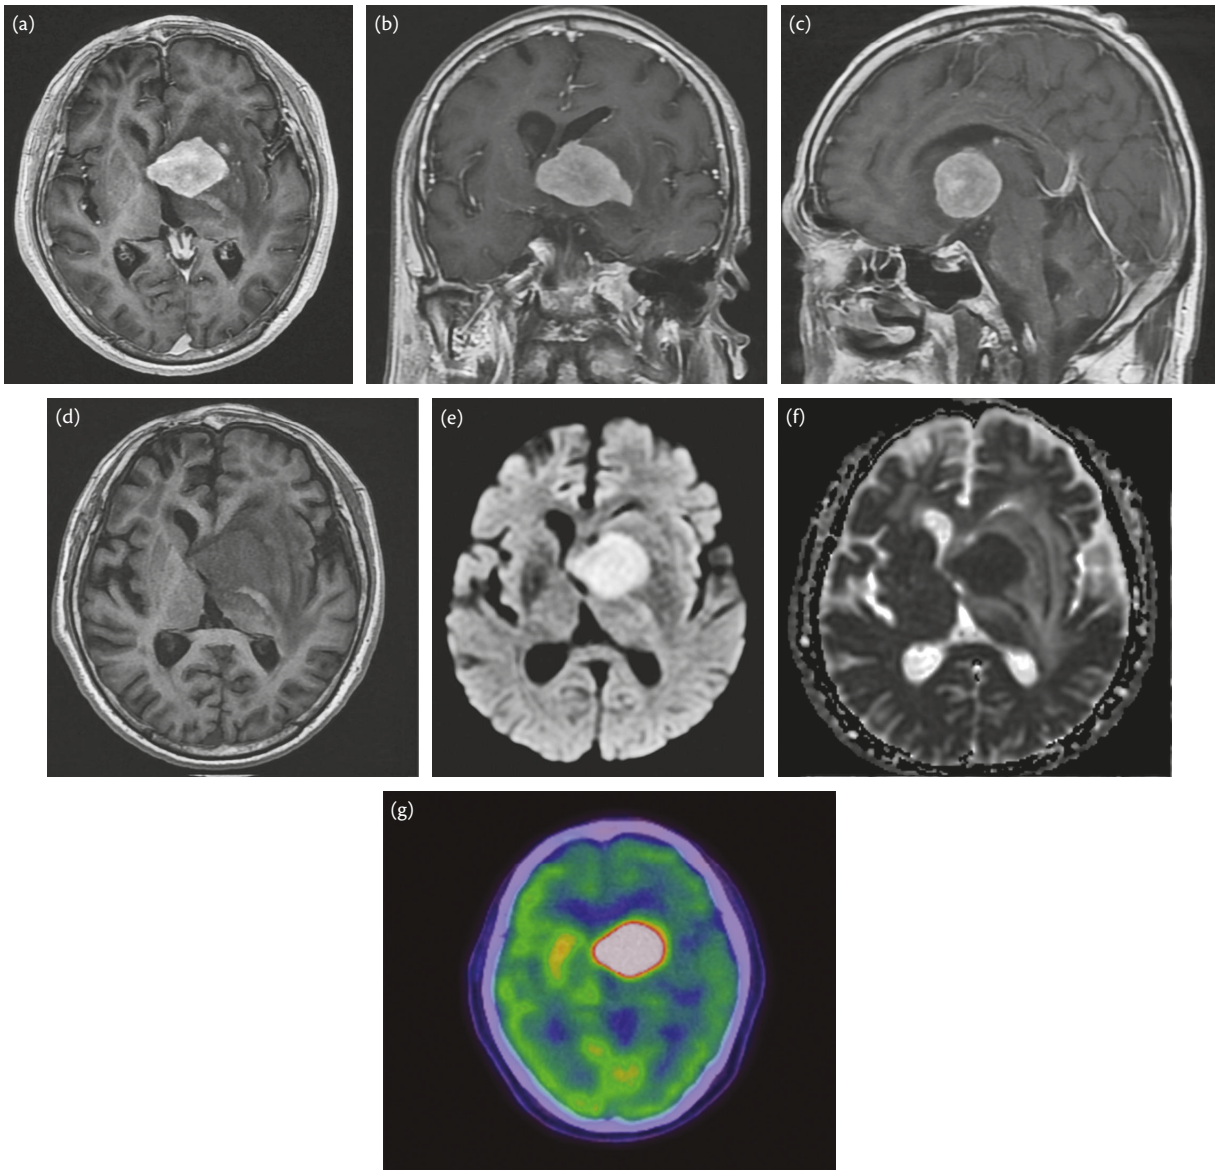

Fig. 9.2 MR images of a patient with PCNSL involving left basal ganglia and the internal capsule.
(A) Homogenous and avidly enhancing axial (B) and (C) coronal and sagittal T1-weighted images with gadolinium. (D) Non-contrasted axial T1-weighted image demonstrating a hypointense lesion. (E) and (F) Restricted diffusion on DWI and ADC images. (G) PET scan revealing a hypermetabolic PCNSL lesion.

CSF examination (cytology, flow cytometry, PCR)

Multimodal CSF analysis utilizing cytology, flow cytometry, and polymerase chain reaction (PCR) investigations are important additional investigative tools that complement each other, and aid in the diagnosis of PCNSL in the presence of suspicious radiological findings. Positive CSF cytology nearly always represents leptomeningeal involvement but has limited sensitivity in specimens with low cellularity. CSF flow cytometry on the other hand, does not suffer from this limitation and has demonstrated good sensitivity and specificity in the detection of PNCSL (Craig et al., 2011). Demonstration of monoclonality of lymphocytes in the CSF by PCR can establish the diagnosis, and this technique can also be used in vitrectomy specimens to diagnose PIOL. CSF examination is particularly useful and important in the setting of AIDS associated PCNSL by demonstrating EBV DNA and obviating the need for a stereotactic brain biopsy.

Histopathology

It cannot be overemphasized that the gold standard for diagnosis of PCNSL is a positive tissue biopsy and histology. The WHO 2016 revision of the 2007 Classification of CNS Malignancies has expanded and clarified the tumour entities included, aligning them with the 2008 WHO Classification of Haematopoietic and Lymphoid Tissues (Louis et al., 2016). Diffuse large B-cell lymphoma of the CNS or primary CNS lymphoma (PCNSL) is strictly defined as a large B-cell lymphoma confined to the CNS at presentation. PCNSL is a distinct mature B-cell lymphoma that corresponds to late germinal-centre exit B cells with blocked terminal B-cell differentiation. They show

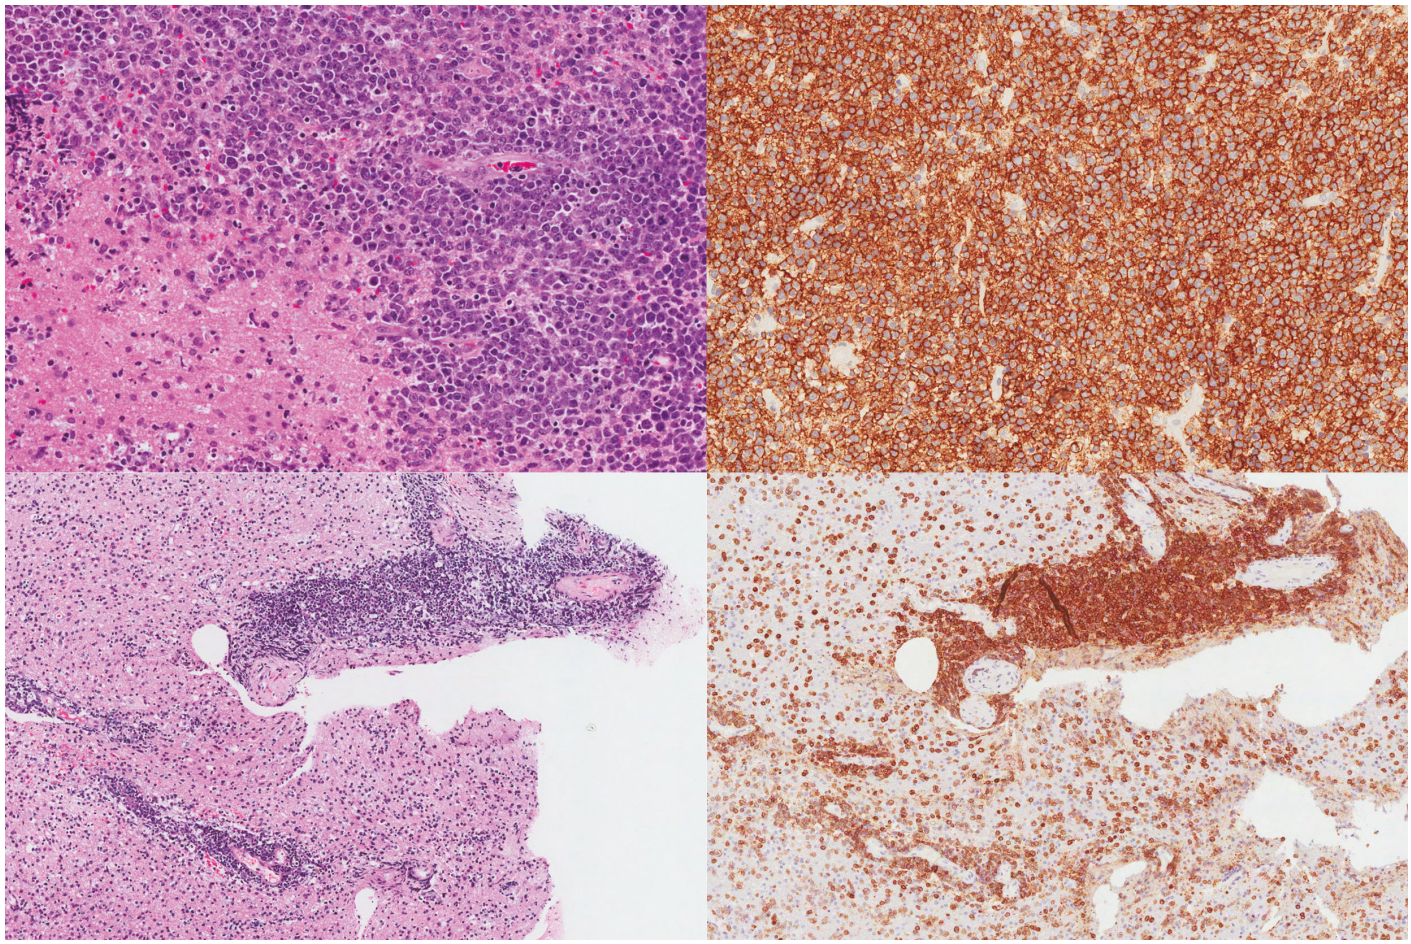

Fig. 9.3 Two examples of diffuse large B-cell lymphoma. Top left: Brain biopsy showing diffuse large B-cell lymphoma with viable tumour in the upper right region and necrosis in lower left region (H&E, original magnification ×20). Top right: CD20 immunohistochemistry.
Bottom left: Brain biopsy from the edge of a different lymphoma, which is tracking along perivascular spaces (H&E, original magnification ×10). Bottom right: CD79A immunohistochemistry.

CD20 (as well as CD79a, PAX5) immunopositivity, mostly BCL6 (60–80%) and MUM1/RF4 (90%) positivity, and only rarely CD10 expression (<10%). They carry rearranged and somatically mutated immunoglobulin (IG) genes with evidence of ongoing somatic hypermutation.

PCNSL is distinct from other lymphomas, which can also present primarily in the CNS, including lymphomas arising from the dura, intravascular large B-cell lymphoma, and lymphoma of T-cell or NK-cell lineage. It is also distinct from immunodeficiency-associated primary CNS lymphomas, which include immunodeficiency-associated CNS lymphoma (inherited or acquired), AIDS-related diffuse large B-cell lymphoma, EBV-positive diffuse large B-cell lymphoma, NOS (of elderly), and lymphomatoid granulomatosis.

Histologically, PCNSL resembles its systemic counterpart with cytoarchitectural features of diffuse parenchymal infiltration and angiocentric growth pattern (Mrugala et al., 2009). Small and medium-sized blood vessels are surrounded by cuffs of malignant lymphocytes and some may invade the blood vessel wall contributing to blood–brain barrier (BBB) disruption. These lymphoma cells lack intercellular cohesion and do not form glands or other structures (**Figs. 9.3 and 9.4**). They have prominent nucleoli surrounded by a scanty rim of basophilic cytoplasm. Confluent areas may show the presence of apoptotic cells or necrosis. In addition, there are varying numbers of reactive T-cells and astrocytes, mimicking the appearance of encephalitis.

Immunocompromised

The immunocompromised have an elevated risk of developing PCNSL compared to their immunocompetent counterparts, and can be separated into three distinct groups: acquired (HIV-associated), iatrogenic (transplant recipients), and congenital immunodeficient states (**Table 9.2**). The incidence and prognosis differ significantly between these groups. However, the principles of management are essentially the same—aim to reinstate immune competence.

Diagnosing PCNSL in the immunocompromised is no different from the current set of recommendations for the immunocompetent, where a tissue diagnosis remains the gold standard (**Fig. 9.3**). However, the potential morbidity faced by the patient and the potential risks towards the healthcare workers justifies pursuing a less invasive work-up for this group of patients in the first instance. A positive CSF polymerase chain reaction (PCR) for EBV DNA in the setting of typical MR features of PCNSL, coupled with demonstration of a hypermetabolic lesion on PET is highly likely

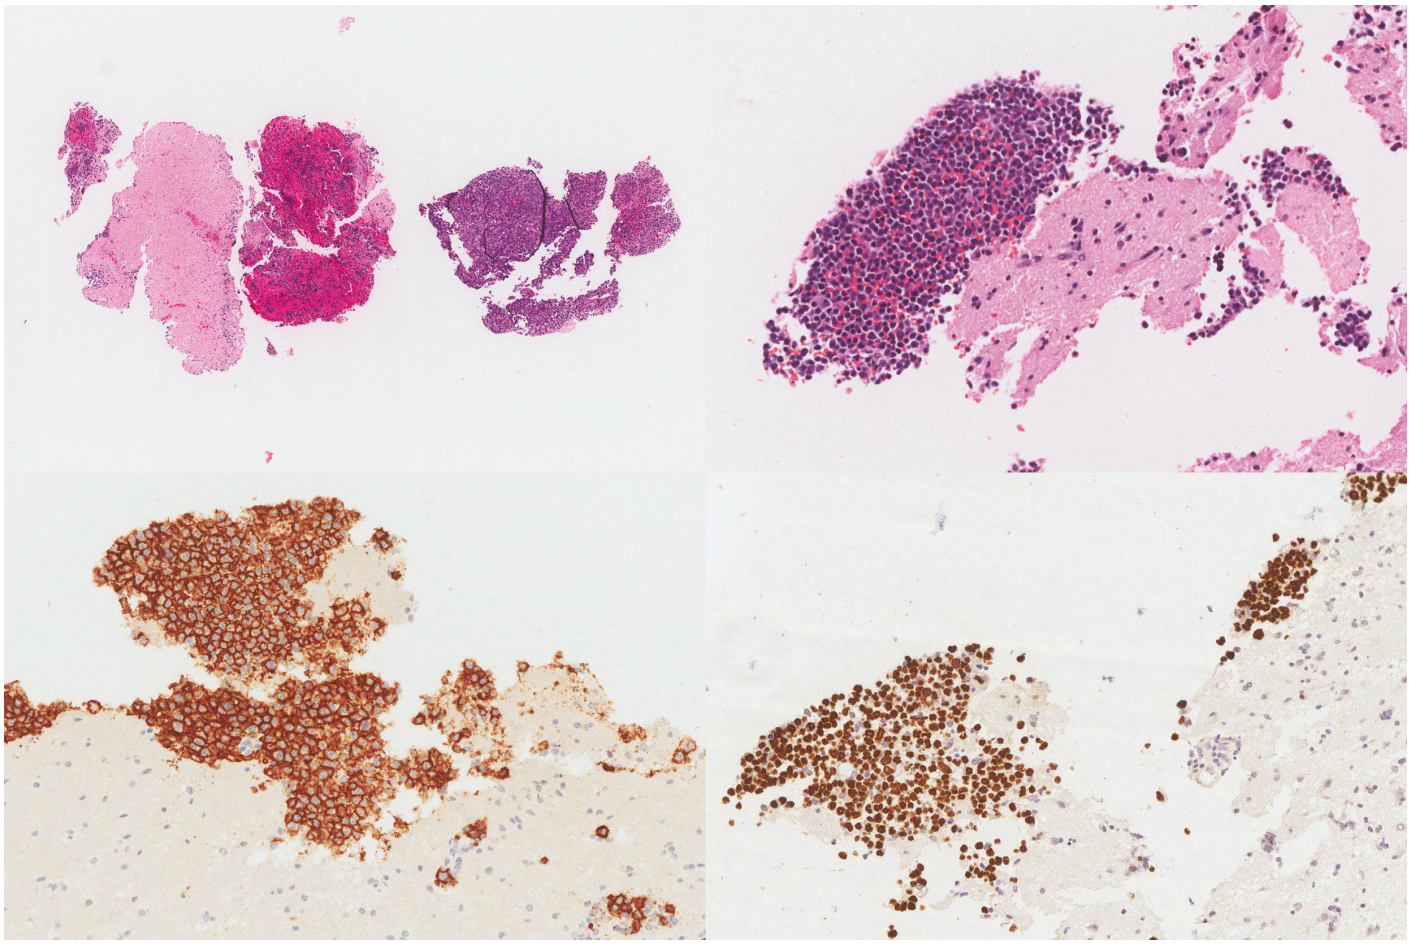

Fig. 9.4 Diffuse large B-cell lymphoma, EBV-positive. Top left: Low power image of three fragments of tumour showing, from left to right, necrosis, haemorrhage, and viable tumour (H&E, original magnification ×4). Top right: Separate area of viable tumour with adjacent brain tissue (H&E, original magnification ×20). Lower left: CD20 immunohistochemistry. Lower right: EBER *in-situ* hybridization.

to represent PCNSL. Alternatively, a negative response to a trial of antitoxoplasmosis treatment is suggestive of PCNSL but there are opponents to this approach for a few reasons. Firstly, a definitive histological diagnosis is not obtained. Secondly, the diagnosis is delayed and further neurological deterioration is common. Lastly, both toxoplasmosis and PCNSL may coexist.

Molecular tumour cell biology

Normal B cells arise from haematopoietic stem cells and emerge from the bone marrow as mature but naïve B cells. They subsequently undergo somatic hypermutation and affinity maturation upon encountering an antigen in peripheral lymphoid tissue and terminally differentiate into plasma cells or memory B cells (Fig. 9.5).

It has been hypothesized that the molecular pathogenesis of B-cell lymphomas is related to perturbation of the normal B-cell development pathway such as alterations to the genes critical to B-cell development or physiology. These alterations may occur at any stage of the differentiation process described earlier. Some of the important genes and mediators in PCNSL and their roles are summarized in Table 9.3. 10% of tumours express CD10, 50–90% express BCL2 and BCL6 (Braaten et al., 2003), and more than 95% stain positive for MUM1 (Camilleri-Broët et al., 2006), which means that these B cells are on the verge of exiting the germinal centre. However, as the brain is devoid of germinal centres, it is not known whether the malignant

Table 9.2 Risk of PCNSL in immune competent and compromised states

Immune status	Groups	Disorders/syndromes	Incidence/risk of PCNSL
Competent			~ 0.5 in 100 000
Compromised	Acquired	HIV-associated (AIDS)	2–6% incidence in HIV infected
	Iatrogenic (PTLD)	Renal, cardiac, lung, liver transplant	1–7% of transplant recipients
	Congenital	SCID, Wiskott–Aldrich syndrome, ataxia-telangiectasia	4% risk

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; PTLD, post-transplant lymphoproliferative disorder; SCID, severe-combined immunodeficiency disease.

Table 9.3 The role of genes and regulators in PCNSL

Gene/Mediator	Role	Authors
HLA (6p21)	Antigen processing, signalling pathway	Cady et al., 2008
PRDM1 (6q21)	Regulate B-cell differentiation into plasma cell	Courts et al., 2008
PTPRK	Cell adhesion	Cady et al., 2008
TNFAIP3	Regulator of nuclear factor NFKB signalling	Paik et al., 2013
MALT1	Activation of NFKB pathway	Schwindt et al., 2009
TBL1XR1	Transcriptional regulation of NFKB pathway	Nakamura et al., 2004
MYD88	Activation of NFKB pathway and JAK/STATb pathways	Nakamura et al., 2016
CD79B	B-cell receptor signalling pathway	Nakamura et al., 2016
CDKN2A	Cell cycle regulator	Schwindt et al., 2009
MYC	Transcription regulation	Rubenstein et al., 2006; Cady et al., 2008
IL4	Up-regulation promotes cell survival via JAK/STAT pathway	Rubenstein et al., 2006

CD, cluster of differentiation; CDKN, cyclin-dependent kinase inhibitor; HLA, human leucocyte antigen; IL, interleukin; JAK, janus kinase; PRDM, positive regulatory domain; PTPRK, protein tyrosine phosphatase receptor type K; MALT, mucosa-associated lymphoid tissue lymphoma translocation; MYC, myelocytomatosis; MYD, myeloid differentiation; NFKB, nuclear factor kappaB; STAT, signal transducer and activator of transcription; TBL1XR1, transducin (beta)-like 1 X-linked receptor 1; TNFAIP3, tumour necrosis factor alpha-induced protein 3.

Data from Wang CC, Carnevale J, Rubenstein JL. Progress in central nervous system lymphomas. *British Journal of Haematology*, volume 166, issue 3, pp. 311–25, Copyright © 2014 John Wiley & Sons; Nakamura M, Shimada K, Ishida E, Konishi N. Histopathology, pathogenesis and molecular genetics in primary central nervous system lymphomas. Histology and Histopathology, volume 19, pp. 211–9, Copyright © 2004.

transformation of B cells in PCNSL occurs prior to migration into the CNS.

The microenvironment plays a fundamental role in the pathogenesis of PCNSL where it contains chemokines that act as neurotropic or survival factors. Detection of these factors within CSF allows their utilization as biomarkers of PCNSL, aiding diagnosis and monitoring treatment response. Elevated levels of CXCL13 and IL-10 in CSF were found to be 99.3% specific for PCNSL, with good sensitivity (Rubenstein et al., 2013). The benefits of testing for these biomarkers may be more pronounced for high-risk patients, and in those with a potentially low-yield biopsy.

High levels of EBV DNA were detected in the CSF of almost 100% of HIV-positive patients with PCNSL in a study by Knowles (2003). The pathogenesis of AIDS-related PCNSL appears to occur when the CD4 + lymphocyte count falls below 100 cells/μl, and has been hypothesized to be different from its immunocompetent counterpart. It is perhaps due to impaired T-cell responses and malignant transformation of activated B cells.

Treatment

Clinical outcomes and survival rates have improved significantly since the advent of chemoradiation protocols, incorporating high-dose methotrexate (HD-MTX) and whole-brain radiation therapy (WBRT) were developed in the 1980s. However, disease relapse and neurotoxicity continued to pose major treatment challenges. The current paradigm shift in treatment focuses on accurate radiological, clinical, and molecular diagnosis and effective treatment regimens comprising novel cytotoxic combinations, monoclonal antibody therapy, and stem cell therapy in an attempt to improve disease control while reducing adverse neurocognitive side effects.

Steroids

Dexamethasone is cytotoxic to PCNSL cells and reduces vasogenic oedema by stabilizing the BBB. These effects are invariably short-lived and are responsible for certain cases of negative biopsies, with some cases demonstrating a dramatic decrease in enhancement and size of the lesions. It is therefore preferable for steroids to be withheld wherever possible until the diagnosis of PCNSL is established or refuted. Additionally, dexamethasone reduces the permeability of the BBB to chemotherapy and thus may impair the therapeutic benefit of this treatment.

Surgery

Biopsy

Stereotactic biopsy remains the gold standard for diagnosing and subtyping PCNSL. Biopsies are usually well tolerated and can be performed relatively quickly with minimal risk. The option of performing the procedure under local anaesthetic exists, and there is a theoretical reduction in the risk of tumour seeding along the path of the biopsy. It is important to target the centre of the suspected PCNSL lesion to reduce the chances of a negative biopsy. The adequacy of samples can be verified and the preliminary diagnosis can be made intraoperatively by a neuropathologist.

Debulking and excisional procedures

Anything more invasive than a biopsy is thought to risk neurological deficits while failing to improve overall survival (Bierman, 2014). However, additional analysis of the data from the German PCNSL Study Group-1 (G-PCNSL-SG-1) found that patients who underwent gross-total or subtotal resection were more likely to be in complete remission six months after surgery. Interestingly, patients harbouring single, surgically accessible lesions were more likely to undergo resection than biopsy (31% and 19%, respectively). The advantage of overall survival was lost after adjusting for the number of lesions despite having a better progression-free survival. The authors of this subanalysis concluded that surgery for PCNSL should be reconsidered especially for patients with single lesions that might be safely resected (Weller et al., 2012).

The patient with a rapidly deteriorating neurological status secondary to mass effect by PCNSL poses a unique challenge for a neurosurgeon. High-dose dexamethasone and mannitol are usually commenced, and a rapid decision to take the patient to the operating theatre could prove life-saving. An excisional or debulking procedure is invariably performed in such emergencies as the initial radiological features usually favour a glioma or metastasis. Interestingly, Lee et al. (2014) have described a case where surgery was avoided in a patient with rapid neurological deterioration using medical treatment with hyperosmolar therapy, dexamethasone, and chemotherapy. This resulted in a marked reduction of peritumoural oedema, the size of the tumour, and consequently mass effect.

Chemotherapy and radiotherapy

The current evidence favours a shift in treatment strategy away from WBRT or HD-MTX monotherapy to HD-MTX based combination chemotherapy regimens. This current standard of care has been accompanied by improved overall survival rates (OS), compared to results obtained by treatment with WBRT alone, or single-agent HD-MTX chemotherapy (**Table 9.4**).

Treatment is divided into two phases: induction and consolidation. HD-MTX based chemotherapy regimens constitute the induction phase, which are aimed at controlling the disease and inducing remission. Ongoing trials are assessing the role of concurrent immunotherapy using rituximab, an anti-CD20 monoclonal antibody (IELSG-32 and HOVON105 PCNSL/ALLG NHL24 trials). Intrathecal MTX was previously in fashion to treat PCNSL with evidence of disseminated meningeal disease and spinal involvement. However, the benefit of intrathecal chemotherapy is not clear, given that therapeutic concentrations of MTX are readily achieved via the intravenous route. The concept of BBB disruption followed by chemotherapy was a novel approach developed with the hope of improving effects of chemotherapy but has been limited to research centres equipped with appropriate facilities and technical capabilities (see *International Blood-Brain Barrier Disruption Consortium*). Using this technique, McAllister et al. (2000) showed comparable results to that of other studies utilizing HD-MTX-based regimens but reported four deaths, and increased seizure, TIAs, and stroke rates. While this treatment approach appears promising by potentially enhancing chemotherapy effectiveness and reducing chemotherapy doses, it requires further evaluation.

Table 9.4 Various combined modality regimens and survival rates

Year	Reference	Regimen	No. of patients	Median follow-up (months)	OS (%)	Median OS (months)	2-year PFS (%)	Median PFS (months)
2002	DeAngelis et al. (2002)	MTX, PCB, Vincristine, IT-MTX, WBRT	98	56	NA	37	NA	24
2006	Illerhaus et al. (2006)	MTX, ASCT, WBRT	30	63	(3 y OS) 68.5	NA	NA	NA
2007	Montemurro et al. (2007)	MTX, thiotepa, ASCT, WBRT	28	15	(2 y OS) 48	48	45	45
2009	Ferreri et al. (2009)	MTX, ARA-C, WBRT	79	30	(3 y OS) 46	NA	NA	NA
2012	Wieduwilt et al. (2012)	MTX, TMZ, rituximab, etoposide, ARA-C	31	79	NA	66	79	24
2013	Morris et al. (2013)	MTX, rituximab, vincristine, PCB, ARA-C, rd-WBRT	52	70	(5 y OS) 80	79	77	39
2015	Omuro et al. (2015)	MTX, rituximab, vincristine, PCB, ASCT	33	45	(2 y OS) 81	NR	79	NR

ARA-C, cytarabine; ASCT, autologous stem cell transplantation; IT, intrathecal; NA, not available; NR, not reached; OS, overall survival; MTX, methotrexate; PCB, procarbazine; PFS, progression-free survival; TMZ, temozolomide.

Data from Omuro A, Correa DD, DeAngelis LM, et al., R-MPV followed by high-dose chemotherapy with TBC and autologous stem-cell transplant for newly diagnosed primary CNS lymphoma, *Blood*, Volume 125, Issue 9, pp. 1403–10, Copyright © 2015 American Society of Hematology.

The rationale for the consolidation phase of treatment is to eradicate residual disease following induction chemotherapy. This commonly takes the form of WBRT and/or chemotherapy. In the younger and fitter patients, high-dose chemotherapy and autologous stem cell transplantation (HDT-ASCT) may be considered as an alternative treatment (Schorb et al., 2013).

The current treatment options have not proven to be robust in producing durable results by producing sustained complete remission or cure. Disease recurrence is almost inevitable and a particularly challenging area as no standard treatment approach exists. Options available are radiotherapy, if not already utilized as part of consolidation treatment, and second-line chemotherapy regimens.

Prognosis

Understandably, there is paucity of data in the literature regarding prognosis of treatment naïve patients with PCNSL as most of the data captured reflects the OS and PFS of treated patients. It is conceivable that the prognosis without treatment is dismal for this rare tumour, perhaps in the range of weeks to months. Henry et al. (1974) reported a survival of 3.3 months with supportive care alone. Norden et al. (2011) analysed data from the Surveillance, Epidemiology, and End Results (SEER) database and found that the median survival was 7.5 months for patients diagnosed in the 1970s. It also showed that the median survival following treatment for the immunocompetent patient is approximately 14 months, and a dismal 2 months for the HIV-associated PCNSL. Another population-based study in Korea that analysed data from 688 patients between 1999 and 2007 had a median survival of 21 months (Shin S-H et al., 2015) but did not specify the immune status of their subjects. Nevertheless, this data offers a realistic representation of the current survival pattern of patients with PCNSL.

Trial data, on the other hand, reports figures that are substantially better than epidemiology data (Table 9.4). This is mainly due to patient selection criteria. All trials on PCNSL treatment typically exclude immunocompromised patients and patients with diffuse involvement, while others would only include patients with localized disease. While selection criteria are necessary to ensure a uniform study population and in order to obtain meaningful results, the population studied is not always a true representation of PCNSL patients as a whole. Nevertheless, current data is encouraging, with improved survival rates following treatment.

Immunocompromised patients

By and large, HIV-associated PCNSL is uniformly fatal with a median survival of approximately 3 months. Commencement of HAART (Highly Active Anti-Retroviral Therapy) in the treatment naïve patients, or a change in the drug combination, has been associated with an improvement in disease control and overall survival. The treatment of the acquired and congenitally immunosuppressed associated PCNSL follows the same principle—improvement or elimination of the immunosuppressive state. This needs to be carefully balanced with the risks of transplant rejection and disease progression. Corticosteroids and WBRT form the mainstay of treatment. Other forms of treatment such as chemotherapy and reduced-dose WBRT (rdWBRT), although promising, should only be offered as part of investigational studies in appropriate tertiary centres. Jacomet et al. (1997) studied HD-MTX as sole therapy in HIV-associated PCNSL and demonstrated improved survival rates of 9.7 months. Ideal patients for this form of treatment are those in good neurological condition and without active opportunistic infection. CSF EBV DNA levels act as a surrogate tumour marker to measure response to chemotherapy.

Controversy: The role of radiotherapy in treatment of PCNSL

The case against radiotherapy

WBRT was historically utilized as the main treatment modality for PCNSL and despite the profound initial immediate response, Nelson et al. (1992) found that more than 60% of patients receiving WBRT as the sole form of treatment had progression within the radiation field. The median overall survival was only 11.6 months in this same group. With the introduction of HD-MTX, more encouraging outcomes were demonstrated when used in combination with WBRT. However, data from the G-PCNSL-SG-1 (Thiel et al., 2010) demonstrated that overall survival was not compromised with omission of WBRT from first-line chemotherapy. Additionally, patients with a sustained complete response to treatment suffered from significant delayed neurotoxicity with increased mortality and morbidity (Doolittle et al., 2013). Patients more than 60 years of age were particularly susceptible, and survivors often required custodial care. In an attempt to reduce this complication, the concept of rdWBRT as consolidation treatment was trialled but was met with mixed results. Bessell et al. (2002) reported inferior results for rdWBRT (at 30.6Gy) following combination chemotherapy. Morris et al. (2013), on the other hand, demonstrated encouraging results using combination chemotherapy followed by 23.4Gy radiotherapy but the subgroup older than 60 years had a significantly inferior outcome. A review by Wang et al. (2014) summarized three important limitations with WBRT: inadequate local control, dissemination of radiologically occult lymphoma cells outside of the radiation field, and deleterious effects of radiation on brain function.

The case for radiotherapy

The rationale for consolidation radiotherapy following combination chemotherapy regimens lies in the fact that PCNSL is a diffuse disease, and consolidation WBRT has been associated with increased PFS and OS. The G-PCNSL-SG-1 trial provided evidence of modest improvement in PFS with inclusion of WBRT but failed to demonstrate any significant improvement in OS. This study was criticized due to several flaws in its execution: failure in meeting its primary endpoint, protocol violations, and a high risk of bias. The Cochrane Collaboration published a review regarding the role of additional radiotherapy in treatment of PCNSL. The authors found insufficient data to draw any definitive conclusion that combination chemo-radiotherapy compared to chemotherapy alone have similar effects on OS. Also, the review judged the evidence for the outcome of PFS to be low (Zacher et al., 2014). Ferreri et al. (2009) compared chemotherapeutic modalities (HD-MTX vs. HD-MTX in combination with cytarabine) followed by WBRT. Although the effects of WBRT were not studied as a primary outcome, WBRT following either regime was accompanied by complete remission rates of 64% in the intervention arm, compared to 30% in the control arm. Prica et al. (2012) published results from a decision analysis study that suggested improvements in survival and quality adjusted life years for patients less than 60 years old who had received chemotherapy followed by consolidation WBRT.

Further studies and considerations

Three studies evaluating the role of WBRT in the treatment of PCNSL are ongoing at the time of writing of this chapter. PRECIS is a prospective randomized phase 2 study in France that aims to compare HD-MTX combined with WBRT to HD-MTX and haematopoietic stem cell rescue. The British initiated IELSG32 is a randomized phase 2 trial evaluating three different chemotherapy regimens, in which patients achieving complete remission undergo either WBRT or autologous stem cell transplantation. RTOG-1114 is a randomized phase 2 clinical trial in the United States evaluating treatment with R-MVP chemotherapy regime followed by either cytarabine alone, or cytarabine plus WBRT.

In the search for more effective treatment of PCNSL that gives similar results to the treatment of systemic NHL, it is foreseeable that radiotherapy will continue to play an important role. The role of radiotherapy with the availability of effective chemotherapy regimens remains unclear with data obtained from the G-PCNSL-SG-1 trial. But until higher quality evidence becomes available, the arguments 'for' and 'against' WBRT require careful consideration.

In patients under the age of 60 years, WBRT provides the attractive potential of improved remission rates, and lengthened PFS and OS when combined with effective chemotherapy regimens. However, the benefits need to be carefully weighed against the potentially devastating effects of delayed neurotoxicity, especially in patients over the age of 60 years. Furthermore, salvage WBRT is potential option as a treatment of disease relapse in WBRT-naïve individuals. Patient expectations and the potential impact of any form of treatment on the patient's quality of life must be factored in.

Glioneuronal and other epilepsy-associated tumours

Matthias Simon and Alexander Grote

Introduction

Neuronal and glioneuronal tumours account for less than 5% of all intracranial neoplasms. The most common variants, that is, *gangliogliomas* and *dysembryoplastic neuroepithelial tumours* (DNT), are frequently encountered in the setting of surgery for pharmacoresistant epilepsy. While any brain tumour can cause seizures, a rather specific subset of tumour types is associated with chronic or pharmacoresistant epilepsy. In addition to the already mentioned gangliogliomas and DNTs, this includes *pilocytic* and *pleomorphic astrocytomas*, the more recently described *angiocentric glioma* (ANET), and some *diffuse gliomas* of the WHO grades II and III. Together, these tumour entities have been referred to as LEATs (longstanding or long-term epilepsy-associated tumours), or more recently 'low-grade epilepsy-associated neuroepithelial tumours', since most cases undergo surgery before the criterion historically used to define 'long-term' epilepsy (>2 years) has been met (Blumcke et al., 2016).

The somewhat stereotypical clinical presentation with chronic or refractory epilepsy, the usually very benign clinical course, and the description of mixed (glioneuronal) tumours point to a true biological link between the various histological LEAT variants (Blumcke et al., 2014). However, most of the available molecular genetic and immunohistochemical studies suggest otherwise. Of note, oncological outcomes can be considerably worse in patients with a LEAT histology treated outside the epilepsy surgery context. This has important clinical implications. In our view, presumed LEAT patients with incidental findings or tumours diagnosed following (e.g. a single seizure) should be offered early surgery rather than simple neuroimaging follow-up. It is not clear if such cases will go on to develop long-term epilepsy and have a very benign clinical course, or if the tumour will behave a lot more like a true oncological disease.

The present chapter attempts to review the clinical, pathological, and imaging characteristics of neuronal and glioneuronal tumours as well as the non-glioneuronal LEAT variants. We describe the relatively common gangliogliomas and DNTs and a characteristic central nervous system (CNS) manifestation of a rare familial hamartoma syndrome (*dysplastic cerebellar gangliocytoma, Lhermitte-Duclos disease*). We also provide information on the other, much rarer (glio)neuronal tumour variants included in the current WHO classification (*papillary glioneuronal tumour, rosette-forming glioneuronal tumour of the fourth ventricle, desmoplastic infantile ganglioglioma/astrocytoma, extraventricular neurocytoma* and *cerebellar liponeurocytoma*) and on the non-glioneuronal LEATs. Finally, we include a brief discussion of the pros and cons of hippocampal resections when operating on temporal epilepsy-associated tumours.

Gangliogliomas

Gangliogliomas are most often diagnosed in children and young adults. Their incidence has been quoted as 0.3–5.2% in adult and up to 14% in paediatric brain tumour cohorts. The most common tumour location is the temporal followed by the frontal lobe. Rare but somewhat typical locations include the supratentorial midline, basal ganglia and thalamus, the cerebellum, brainstem, and spinal cord.

Histologically, gangliogliomas are composed of dysplastic ganglion cells and neoplastic glial elements (**Fig. 10.1**). The respective proportion may vary considerably resulting in a morphological spectrum ranging from tumours with a very prominent neuronal cell population (gangliocytoma) to lesions with a predominantly glial phenotype. The vast majority of gangliogliomas are assigned to the WHO grade I. Anaplastic (WHO grade III) tumours account for only 1–2.6% of all gangliogliomas. While the current WHO classification no longer recognizes an intermediate (i.e. non-benign non-anaplastic) 'atypical' grade II ganglioglioma, there is some clinical evidence to suggest a three rather than a two-tiered grading system. Gangliogliomas may evolve into outright glioblastomas. We have seen secondary glioblastomas in 5 of 11 patients undergoing surgery for recurrent ganglioglioma at our institution (Luyken et al., 2004; Majores et al., 2008). Specific BRAF oncogene mutations (BRAF *c.*1799T >A/ BRAF V600E) occur in possibly more than 50% of GG cases (Koelsche et al., 2013). BRAF V600E mutations may carry a negative prognostic impact (Dahiya et al., 2013). Gangliogliomas may very rarely harbour IDH1 mutations.

The typical ganglioglioma patient presents with symptomatic epilepsy. A non-epileptic presentation in a case with a presumed ganglioglioma should alert the treating clinician to the possibility of a non-benign clinical course. Deep-seated (**Fig. 10.2**), cerebellar, brainstem, or spinal gangliogliomas will present with location-dependent signs and symptoms. Gangliogliomas are hyperintense

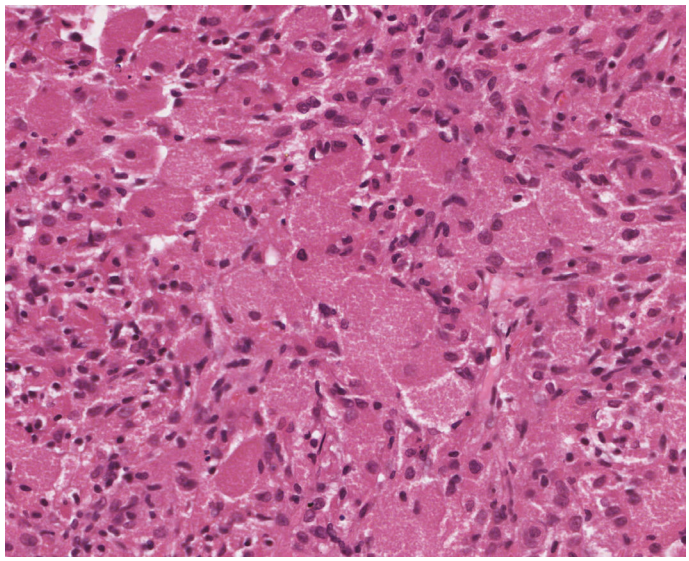

Fig. 10.1 Nests of abnormal ganglion cells are a feature of ganglion cell tumours, which may also have a neoplastic glial element. Less specific features include eosinophilic granular bodies and perivascular lymphocytes.

Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

on T2 and FLAIR, and hypo- to isointense on T1-weighted MR images. Tumour cysts and contrast enhancement ranging from patchy to nodular are common (**Figs. 10.4A** and **10.12A**). Calcifications are not infrequent. Anaplastic tumours typically have an uncharacteristic MRI appearance, while the atypical variants usually resemble benign gangliogliomas.

The treatment of choice for gangliogliomas is surgery. Complication rates are usually low and reflect tumour location and the generally young age and good general condition of most ganglioglioma patients. The epileptological results following surgical treatment are also very good. We have seen Engel class I outcomes (seizure-free or only occasional non-disabling seizures) in approximately 80% of LEAT cases during a 10 yrs. follow-up in a cohort of 207 patients (including 86 gangliogliomas) undergoing surgery for drug-resistant epilepsy of more than 2 years at our institution (Luyken et al., 2003). In our experience, a complete tumour resection will cure all but the very occasional patient with a ganglioglioma WHO grade I (Luyken et al., 2004). Quite in contrast, 5 yr. progression-free survival was only approximately 70% and 30% in our patients with atypical and anaplastic gangliogliomas, respectively. Presentation with long-term or refractory epilepsy is an immensely important clinical prognostic marker (Majores et al., 2008). Oncological results are substantially worse in centres, which see a higher proportion of cases outside the context of chronic epilepsy and epilepsy surgery. A recent report of

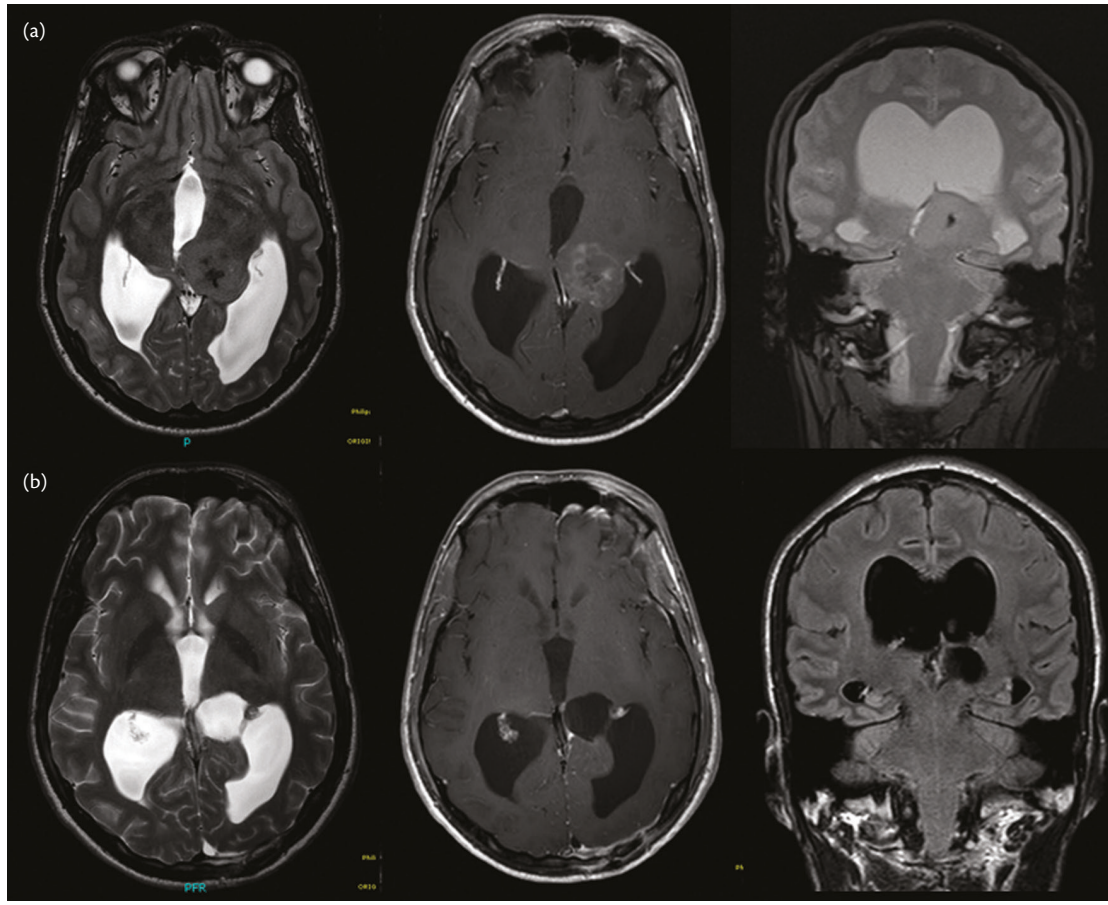

Fig. 10.2 Ganglioglioma WHO grade I of the left thalamus in a 26-year-old male who presented with signs and symptoms of obstructive hydrocephalus. The patient was operated through a parietal transventricular approach and recovered from surgery without neurological deficit. (A) Preoperative and (B) postoperative MR images.

88 such cases detailed a 5 yrs. progression-free survival rate of only 58% following surgery (Compton et al., 2012).

Given the relatively adverse prognosis of patients with anaplastic gangliogliomas WHO grade III radiotherapy should probably be routinely prescribed in such cases in analogy to other anaplastic gliomas even if this recommendation is not based on very substantial evidence. Radiotherapy may be an option in recurrent, unresectable, or incompletely resected tumours with histological signs of atypia, which do not fulfil the criteria for the diagnosis of a WHO grade III tumour. The evidence for the use of chemotherapy is anecdotal at best.

Dysembryoplastic neuroepithelial tumours (DNTs)

DNTs are the second most common glioneuronal tumour variant encountered in clinical practice. They seem to be slightly more frequent in males and patients usually come to medical attention in their second or third decade of life. Paediatric patients account for a substantial percentage of the cases. The most common tumour location is the temporal lobe, but DNTs can also grow in any other part of the supratentorial cortex. Deep-seated supratentorial (caudate nucleus, septum) and posterior fossa (brainstem, cerebellum) lesions have also been described.

DNTs are histologically characterized by a multinodular appearance and by the specific glioneuronal element, an admixture of oligodendrocyte-like cells arranged in columns perpendicular to the cortical surface and non-dysplastic neurons (**Fig. 10.3**). They are assigned to the WHO grade I. The WHO classification distinguishes between simple and complex subtypes. The existence of a diffuse variant is more controversial and may reflect the not uncommon difficulty to distinguish a DNT from a diffuse low-grade glioma. Mixed DNTs/gangliogliomas have also been described (Thom et al., 2011). We found neither BRAF V600E nor IDH1 mutations in a collection of 32 DNTs (Grote and Simon, 2015). There are some reports of rare LOH 1p/19q or IDH1 mutations in DNTs (Thom et al., 2011). Some DNT series report coexisting cortical dysplasias (FCDs) in up to 70–80% of cases. The pathogenetic relationship of FCDs to the actual tumour is not well understood. One hypothesis regards these changes as the remainder of a pretumorous bed which has partially transformed into the actual LEAT. More likely, FCDs coexisting with LEATs develop in synchronicity or secondary to the growth of the neoplasm (Thom et al., 2012).

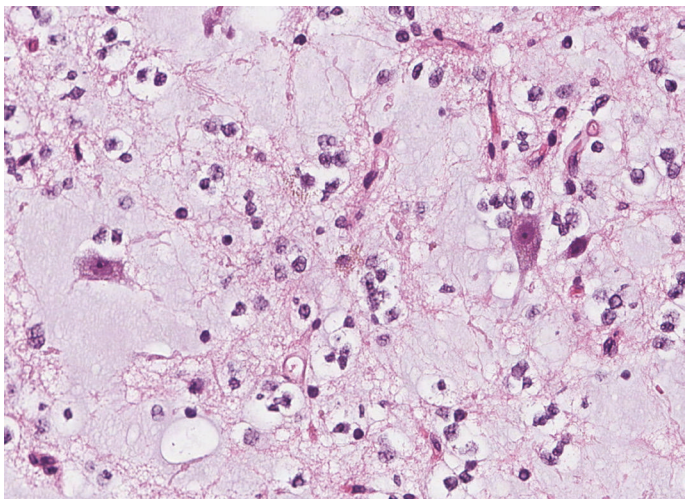

Fig. 10.3 Dysembryoplastic neuroepithelial tumour (H&E ×400). These neoplasms are often characterized by large pyramidal neurons 'floating' in pools of mucin. This feature is unusual in oligodendroglioma, the main histological differential diagnosis.

Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

DNTs most commonly present with (drug-resistant) epilepsy. We have not seen patients with neurological deficits related to tumour growth. DNT growing in eloquent cortical areas may lead to substantial functional reorganization, which can render them resectable despite their location. In our experience, incidental DNTs are not rare. MR imaging typically shows a multicystic tumour with little mass effect or oedema, which is hyperintense on T2 and FLAIR and hypointense on T1 weighted images. Contrast enhancement and calcifications are not infrequent (15–20%). Erosions of the adjacent skull have been variably described in 20–70%. The primary differential diagnosis is that of a ganglioglioma or other LEAT followed by a diffuse glioma. Some DNTs have been preoperatively misdiagnosed as cavernomas (**Figs. 10.4B** and **10.12B**).

DNTs should be treated by surgery. Complication rates are low similar to ganglioglioma patients. The epileptological results are gratifying with Engel class I outcomes of approximately 80% even in cases with refractory epilepsy which remain stable over many years (Luyken et al., 2003). Incomplete resections and the presence of an FCD are the main predictors of epilepsy persistence or recurrence. From an oncological perspective DNTs are most often extremely benign. We have only seen a single case of tumour recurrence (or rather growth of residual tumour following an incomplete resection of a complex DNT) in our cohort. Nevertheless, a small but growing number of cases are on record with recurrent tumour even after what was thought to be a complete resection, or with malignant transformation (Thom et al., 2011). It therefore seems wise to recommend serial imaging follow-up to DNT patients in particular in cases with residual tumour and following partial resections. There is no evidence to support radio- or chemotherapy for DNTs. Of note, adjuvant therapy has been associated with malignant transformation.

Dysplastic cerebellar gangliocytoma (L'Hermitte-Duclos disease)

The dysplastic cerebellar gangliocytoma (L'Hermitte-Duclos disease, LDD) is the major CNS manifestation of Cowden disease. Cowden disease (OMIM entry 158350) is an autosomal dominant disorder most often caused by PTEN germline mutations. LDD in the setting of Cowden syndrome may also be due to a PIK3CA mutation. The clinical spectrum is characterized by multiple hamartomas derived from all three germ cell layers classically including trichilemmomas and an increased risk for breast, non-medullary thyroid, and endometrial cancer. The lifetime risk for PTEN mutation carriers to contract breast, thyroid and endometrial cancer may be as high as 85%, 38% and 28%, respectively. Isolated and sporadic LDD may also occur and has been attributed to somatic PTEN mutations. No PTEN mutations have been identified in the rare cases with paediatric LDD (Pilarski et al., 2013).

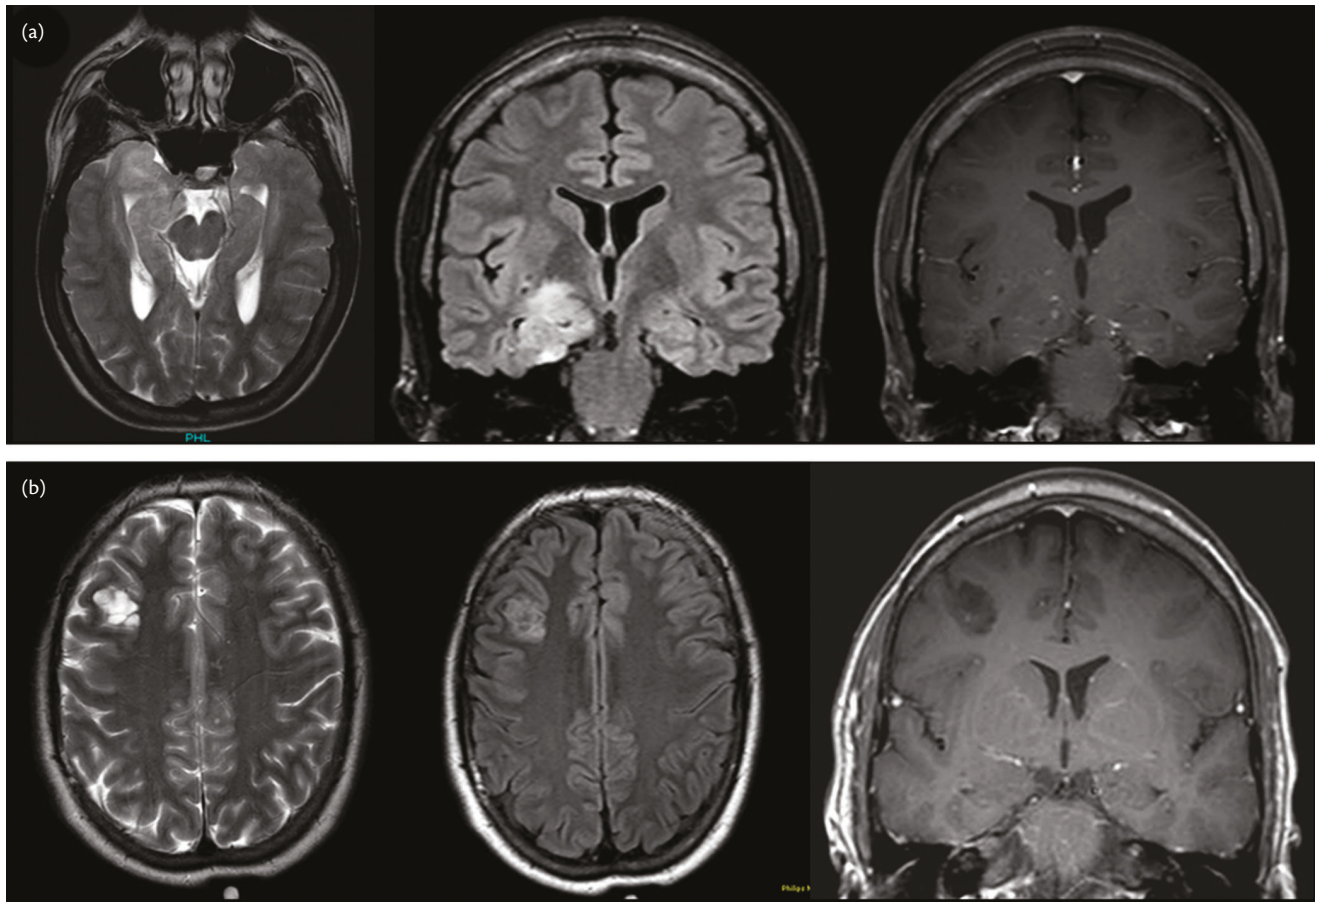

Fig. 10.4 Long-term epilepsy-associated gangliogliomas and dysembryoplastic neuroepithelial tumours (DNTs). (A) Left 'holo'-temporomesial ganglioglioma WHO grade I in a 19-year-old male with pharmacoresistant epilepsy since his first year of life. The tumour grows in the mesial temporal pole, the uncus, the amygdalum, the hippocampus, and parahippocampus, and extends posteriorly well beyond the level of the dorsal midbrain. (B) Right frontal dysembryoplastic neuroepithelial tumour (DNT) WHO grade I in a 22-year-old male with a 6-year history of eventually refractory epilepsy.

Dysplastic cerebellar gangliogliomas cause an enlargement of the molecular and the internal granular layers of the cerebellum filled with dysplastic ganglionic cells (Fig. 10.5). Macroscopically this results in thickened and dysmorphic cerebellar foliae.

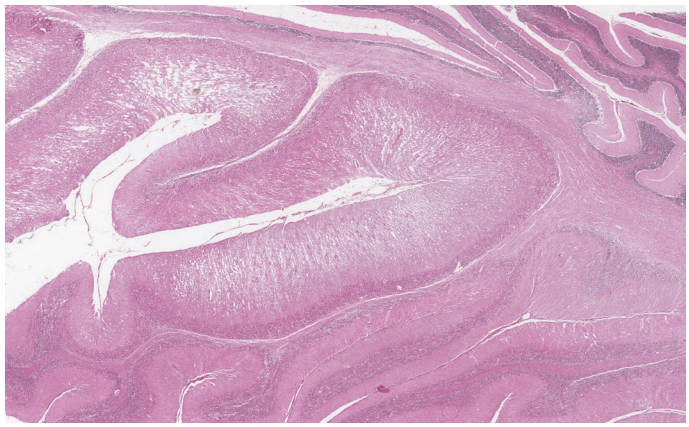

Fig. 10.5 Lhermitte-Duclos disease (dysplastic gangliocytoma of the cerebellum) is best appreciated at low magnification where the thickening of the affected cerebellar cortex and loss of the darkly-staining granular layer is most apparent. Compare with the normal cortex in the top right of the image.
Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

Correspondingly, MR imaging shows a characteristic 'tiger-striped' pattern on T2 weighted images. Patchy contrast enhancement may occur. The MRI features are often so characteristic as to obviate the need for a tissue diagnosis in many cases (Fig. 10.6). LDD may be accompanied by hydrocephalus, megalencephaly, syringomyelia, meningiomata, cavernomas, and venous angiomas. It is unclear if LDD is hamartomatous or truly neoplastic in nature. Some patients have been diagnosed with true glioneuronal tumours growing against the background of what was thought to be LDD. The clinical presentation of LDD may be that of an incidental finding or an expanding cerebellar mass. Decompressive surgery is the treatment of choice in the latter cases with poorly defined borders of the lesion being the major technical issue during the operation, and results in long-term survival. Radiotherapy has resulted in symptomatic stabilization, but also in progressive neurological deterioration (Prestor, 2006).

Non-glioneuronal LEATs

Diffuse astrocytomas and oligodendroglial tumours are not infrequently encountered in the epilepsy surgery setting. In a recent series from our institution 26/158 (16.5%) of cases could be assigned to this category (Grote and Simon, 2015). Histologically,

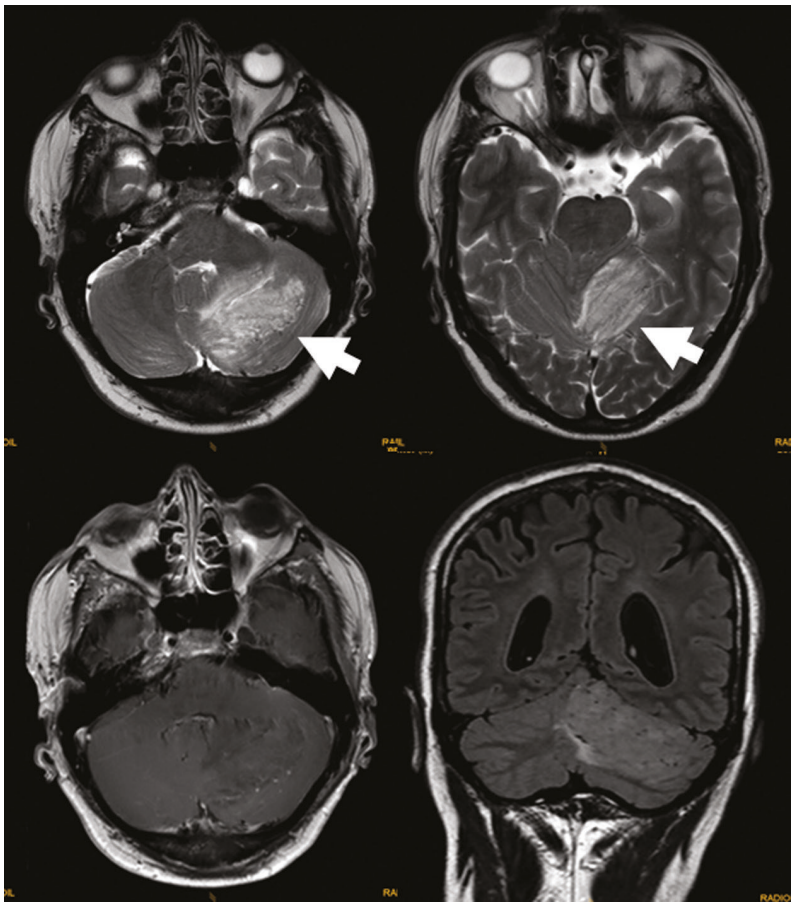

Fig. 10.6 Presumed dysplastic cerebellar gangliocytoma (L'Hermitte-Duclos disease) in a 50 yrs. old male with Cowden syndrome caused by a PTEN mutation. Note the characteristic striated appearance of the thickened cerebellar foliae (arrows).

these tumours can be classified as astrocytomas, mixed gliomas and oligodendrogliomas, and assigned to the WHO grades II and III. They frequently carry IDH1 mutations (39% in our series), however, this figure is markedly lower than the 60–90% IDH1 mutation rate found in unselected diffuse glioma series. This may point to a specific LEAT biology of these tumours. Tumours occur predominantly in the temporal and frontal lobe, but also in the paralimbic system (i.e. the insula). Imaging findings do not differ between LEAT and non-LEAT diffuse gliomas. The oncological as well as the epileptological prognosis is surprisingly good—calculated as 10 years progression-free with overall survival at 75% and 90%, respectively, in a series of 35 WHO grade II and 3 grade III astrocytomas undergoing surgery for their tumours and refractory epilepsy at our institution (Luyken et al., 2003). Around 70% were seizure-free one year after surgery. The *isomorphic astrocytoma* is a very rare diffuse astrocytoma variant with an exceedingly benign clinical course (Schramm et al., 2004).

Pilocytic astrocytomas account for 2.5% to more than 10% of cases in epilepsy surgery series. They are characterized by a biphasic growth pattern consisting of bipolar astrocytes and so-called Rosenthal fibres. The differential diagnosis between pilocytic astrocytomas and gangliogliomas may be difficult, which may in part explain the relatively variable incidence in published clinical cohorts. Pilocytic astrocytomas are associated with mitogen-activated protein kinase (MAPK) pathway alterations. Extracerebellar pilocytic astrocytomas harbour BRAF:KIAA1549 fusions and duplications (in approximately 60% of cases) or BRAF V600E, FGFR1, KRAS, NF1, and PTPN11 mutations or NTRK2 fusions (Jones et al., 2013). Epileptogenic pilocytic astrocytomas usually grow in the temporal lobe. MR imaging often shows cystic changes and evidence of recent haemorrhage. The classical picture is that of a large tumour cyst with a contrast enhancing wall and mural nodules. Contrast enhancement can range from strong to patchy and (rarely) none at all (**Fig. 10.7**). Oncological as well as epileptological outcomes for epilepsy surgery patients are generally very good and parallel the figures for gangliogliomas. This is not necessarily the case in patients encountered outside this setting. We found 5 yrs. PFS and OS rates of only 72% and 87%, respectively, in a series of 44 adult patients diagnosed with pilocytic astrocytomas. Histologically, 14% of cases displayed atypical and 6% anaplastic features. Patients benefited from a complete vs. a subtotal resection/biopsy, and we obtained some anecdotal evidence in favour of radio- and chemotherapy for aggressive tumours (Stuer et al., 2007).

Pleomorphic xanthoastrocytomas (PXA) most commonly affect children and young adults. The histological appearance is quite variable ('pleomorphic'). Spindly elements are intermingled with mono-and multinucleated giant astrocytes and xanthomatous cells ('xanthoastrocytoma') (**Fig. 10.8**). MR imaging shows an often-cystic mass with focal contrast enhancement and superficial cortico-leptomeningeal growth (**Fig. 10.9**). The vast majority of the tumours are found in the supratentorial compartment and in particular in the

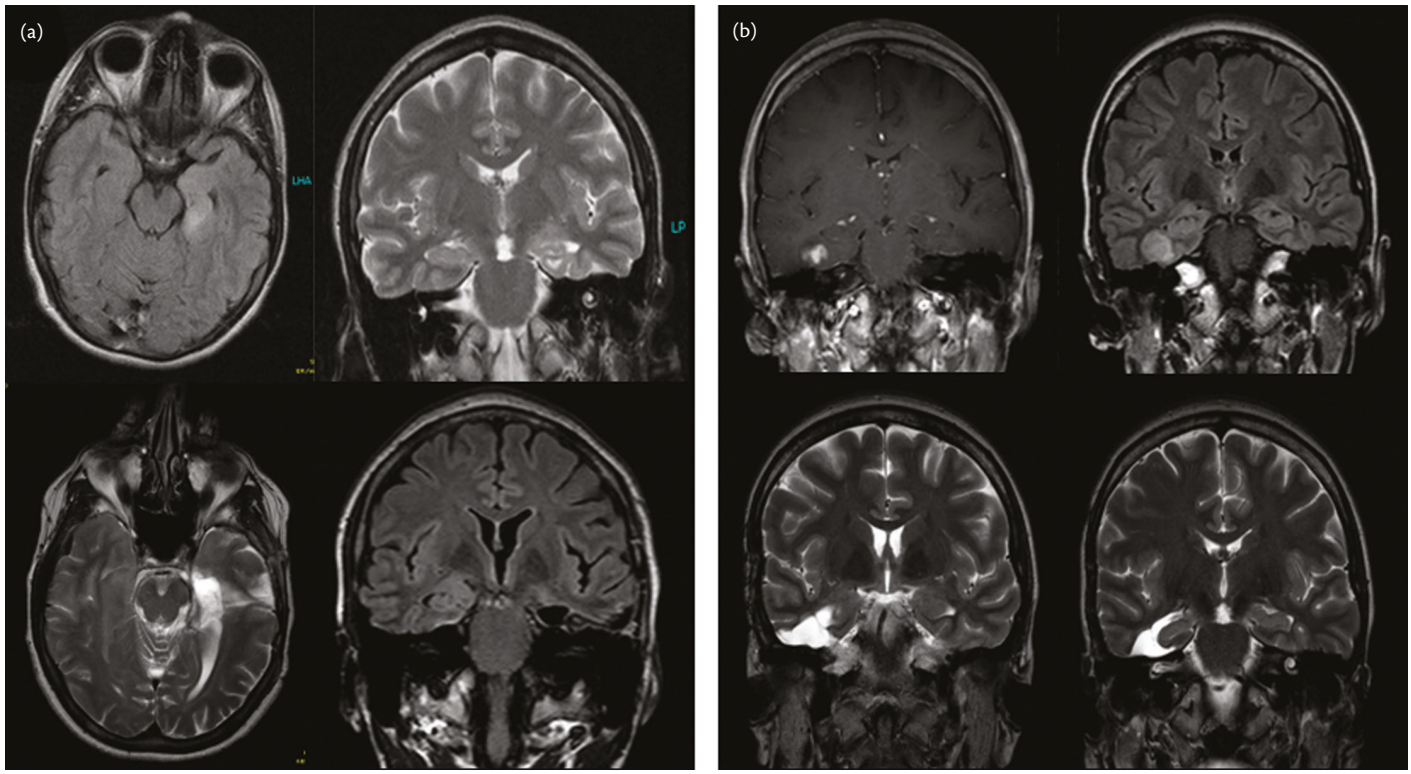

Fig. 10.7 (A) Right temporal pilocytic astrocytoma WHO grade I diagnosed and operated following a first generalized seizure in a 17-year-old female. (B) Upper panel: pilocytic astrocytoma WHO grade I of the dorsal amygdalum/basal ganglia. This 55-year-old female patient presented with cephalgias and other unspecific symptoms. Lower panel: postoperative MR images show no residual tumour. There was no new postoperative neurodeficit.

temporal lobe. The majority of PXAs are assigned to the WHO grade II. Lesions with anaplastic features and increased mitotic activity (>5 mitoses/10 HPF) account for approximately a third of cases. PXAs frequently (65–80%) harbour BRAF V600E but no IDH1 mutations. BRAF V600E mutations are more frequent in grade II than in anaplastic tumours, and correlate with a temporal tumour location and possibly younger age. Patients mostly present with seizures (>60–80%) and PXA may comprise more than 5% of tumours in epilepsy surgery series (Luyken et al., 2003; Ida et al., 2014; Grote and Simon, 2015). Surgery is the treatment of choice for PXAs and PXA associated epilepsy. None of the five PXA cases in the epilepsy surgery series reported by Luyken et al. recurred after a median follow-up of 8 years in the overall cohort (Luyken et al., 2003). The prognosis in unselected cohorts (i.e. including cases without long-term epilepsy) is worse: 5 years progression-free and overall survival for PXAs WHO grade II in a recent study was reported as 71% and 90%, respectively. The corresponding figures for anaplastic PXA were 49% and 57% only. A gross total resection seems to confer a significant survival benefit when compared to STR/biopsy cases (Ida et al., 2014). There are some data to support radiotherapy and treatment with alkylating chemotherapy for anaplastic PXA. The BRAF inhibitor vemurafenib has been used in a few cases with otherwise treatment resistant PXA.

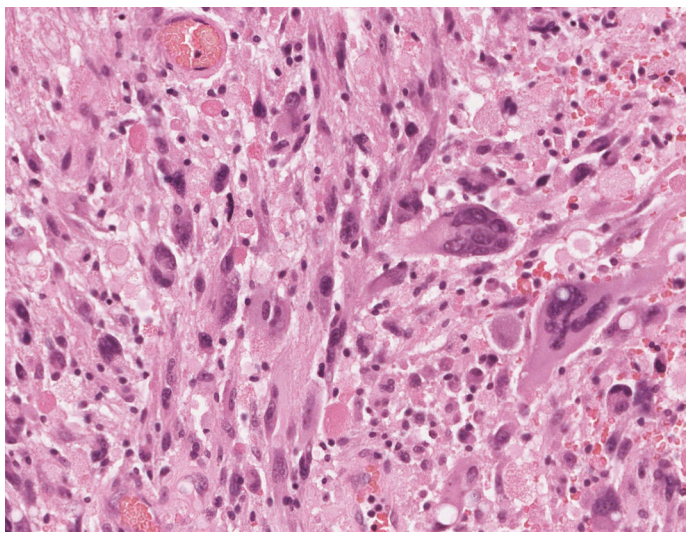

Fig. 10.8 Pleomorphic xanthoastrocytomas combine spindle shaped astrocytes and large, multinucleated, pleomorphic cells. Lipid vacuoles, eosinophilic granular bodies, and perivascular lymphocytes are also common features.

Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

Angiocentric gliomas (ANETs) accounted for 5/158 (3.1%) of cases in a recent series of epilepsy-associated tumours from our institution (Grote and Simon, 2015). ANETs typically occur in children and (young) adults and patients almost exclusively present with refractory epilepsy. Histologically, ANETs are characterized by an angiocentric growth pattern of bipolar cells, and ependymoma-like features such as pseudorosettes, and they are assigned to the WHO grade I. Tumours are found predominantly in the frontal and temporal lobe (Chen et al., 2014). We found no BRAF V600E or IDH1 mutation in five cases from our institution. MYB or MYBl1

abnormalities have been detected in several ANETs (Zhang et al., 2013b). LOH 1p/19q has not been described in these tumours. Neuroimaging usually reveals a non-enhancing cortical lesion involving the subcortical white matter (Fig. 10.10). Reported oncological outcomes are very good, but a few cases with anaplastic features (and tumour recurrence) are on record (Chen et al., 2014).

Other glioneuronal tumours

The *papillary glioneuronal tumour* (PGNT) has been recognized as a very rare separate tumour type of mostly young adults only very recently. Histologically, these tumours are characterized by prominent pseudopapillary growth and interpapillary sheets or focal collections of neuronal cells. MR and CT imaging features resemble those of gangliogliomas, however, rim-like contrast enhancement is not uncommon, and in comparison to gangliogliomas they are not as frequently located in the temporal lobe, while periventricular growth is rather common. A FGFR1 mutation has been found in one tumour (Gessi et al., 2014a). Prognosis after a complete resection is good. However, even though PGNTs are assigned to the WHO grade I tumour recurrence is not uncommon. A recent review analysed 71 cases and found an 82% 2 yrs. PFS rate. Even a case with primary metastatic dissemination is on record. A few patients (mostly cases with residual tumour) have undergone radiotherapy (Schlamann et al., 2014).

The *rosette-forming glioneuronal tumour of the fourth ventricle* (RGNT) has been initially described as DNT of the cerebellum, but is now included as a specific disease in the WHO classification. It is assigned to the WHO grade I. Approximately 20% of cases are located outside the posterior fossa, often close to the third ventricle and even in the spine. The histological picture is that of a biphasic neoplasm with uniform neurocytes forming rosettes and perivascular pseudorosettes on the one hand, and an astrocytic component resembling a pilocytic astrocytoma on the other. FGFR1 mutations were found in two of eight tumours tested (Gessi et al., 2014b). MR imaging usually reveals a mixed cystic/solid and not always contrast enhancing mass. Treatment is usually surgical and aims a complete resection, however, different views are also held, and a recent series of 41 cases failed to show the superiority of a gross total over a subtotal resection (Zhang et al., 2013a). Surgery may be difficult because of tumour location and adherence and/or infiltration of adjacent structures resulting in relatively high rate of new postoperative deficits. Metastatic dissemination has been seen in as many as 7% of cases in a 2014 review. 6% of the assessable patients in this review reportedly died during follow-up (Schlamann et al., 2014).

Desmoplastic infantile gangliogliomas (DIG) and *astrocytomas* (DIA) are very rare frontoparietal meningocerebral WHO grade

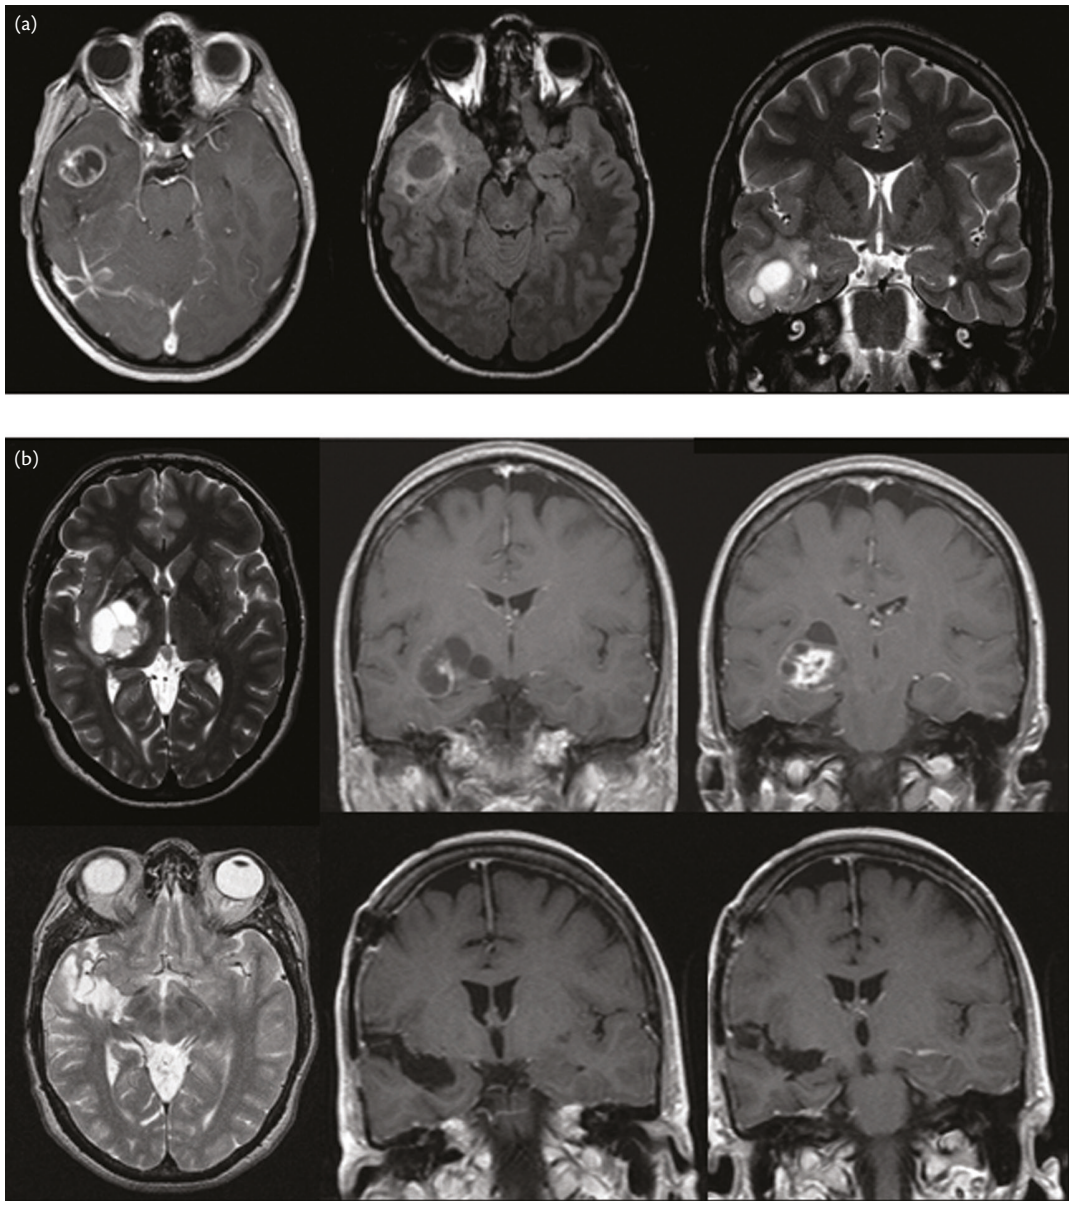

Fig. 10.10 Right parietal angiocentric glioma (ANET) in a 20-year-old male with a 3-year history of medically refractory epilepsy. Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

I tumours of infancy. Most cases have been diagnosed within the first year of life. They are slightly more common in males. Histological investigation typically reveals a prominent desmoplastic stroma with intermingled neoplastic astrocytes, a variable component of neuronal cells, and aggregates of undifferentiated cells. A subset of DIG/DIA contains BRAF V600E mutations (Koelsche et al., 2014). Neuroimaging usually shows a large, dura-based, cystic, and often septated mass (**Fig. 10.11A**). The solid tumour typically appears attached to the cortex and dura. Contrast enhancement can be intense and is commonly restricted to the solid part of the tumour. Patients usually present with signs of increased intracranial pressure. Treatment is surgical, and may be quite challenging because of tumour size and location. Complete resection often results in long-term tumour control. However, up to 40% of cases may require adjuvant chemotherapy and possibly radiotherapy in older children. Patients with disseminated disease are not altogether uncommon (Hummel et al., 2012).

The WHO classification lists several tumour variants, which are histologically characterized by small, isomorphic neuronal cells, and therefore termed *neurocytomas. Central neurocytomas* are covered elsewhere in this text. Tumours with a similar histology but growing without association with the ventricular system are termed *extraventricular neurocytomas* (EVN). They occur throughout the cerebrum, but may also grow outside the cranial vault. EVN are usually assigned to the WHO grade II. Imaging findings include cysts, heterogenous contrast enhancement, mass effect and oedema (**Fig. 10.11B**). Atypical histological features and/or increased mitotic activity (i.e. MIB-1 index >3%) are seen in approximately a quarter of the patients. Patients with atypical EVN appear to have a substantially worse prognosis than those with typical tumours. A recent literature review reported 5 yrs. recurrence rates of 36% and 68% for cases with atypical and typical EVNs, respectively (Kane et al., 2012). Complete resections are helpful in controlling EVNs, but may be difficult to achieve because of tumour size or location.

Radiotherapy may compensate to some extent for an incomplete resection with respect to progression-free survival.

Many *cerebellar liponeurocytomas* are typical posterior fossa tumours. They usually originate from the vermis or the cerebellar hemispheres. Growth in or onto the cisterns has been observed. Tumours consist of isomorphic neuronal cells ('neurocytoma') with focal lipomatous differentiation and are assigned to the WHO grade II. MR imaging features reflect the distribution and proportion of lipidized tissue. The tumours usually show heterogenous contrast enhancement. The main differential diagnoses both for the neuroradiologist and the neuropathologist are medulloblastoma and ependymoma. Indeed these tumours have initially been referred to as lipidized medulloblastomas. Cerebellar liponeurocytomas seem to carry a rather substantial recurrence rate and reduced overall survival. A review of 19 published cases reported a 5 yrs. survival rate of only 48% and the literature contains several case reports describing an aggressive clinical behaviour and/or histologically anaplastic variants. Extracerebellar supratentorial liponeurocytomas have been described. Surgery is considered the treatment of choice (Chakraborti et al., 2011). The role of radiotherapy is debatable.

Controversies

Surgical management of temporal LEATs—with or without hippocampectomy?

Operative treatment for LEATs usually aims more at controlling tumour-related epilepsy than tumour growth. To this end various surgical strategies have been employed ranging from simple tumour removal or 'lesionectomy' to tumour resections together with a surrounding rim of cortex ('extended lesionectomy') and resections including an additional corticectomy or removal of temporomesial structures in order to excise an extended epileptogenic zone (Zaghloul and Schramm, 2011). This latter approach necessitates a formal and at times even invasive preoperative epileptological work-up or intraoperative electroencephalograph (EEG) recordings (ECoG).

If and when resections involving more than the tumour itself are indicated remains a contentious and controversial issue. The first argument in favour of simple lesionectomies is the often good epileptological outcome seen after such surgery. According to a recent literature review almost 80% of patients with temporal low-grade tumours and epilepsy will become seizure-free following gross total tumour resections (Englot et al., 2012). The second argument is the preservation of neurological function. Even in experienced hands temporomesial resections carry a quite low but nevertheless measurable risk of hemiparesis, dysphasia, and significant visual field cuts. Neuropsychological outcomes following surgery for temporal lobe epilepsy may be better following more restricted resections when compared to temporal lobectomies (Schramm, 2008). Resection of MR imaging and histopathologically negative hippocampal tissue carries a significant risk for memory impairment (especially if the dominant hemisphere is involved), while patients

with a diseased hippocampus have deficits usually already before surgery and memory deterioration is less frequent (Helmstaedter et al., 2011). Interestingly, more extensive hippocampal resections did not result in better epileptological outcomes in a randomized trial of 207 patient with mesial temporal lobe epilepsy (>95% due to mesial temporal lobe sclerosis) (Schramm et al., 2011).

However, a case can also be made for an additional temporomesial resection during surgery for a temporal LEAT. Firstly, more patients may become seizure-free if a hippocampectomy and/or corticectomy in addition to a gross total resection is performed (86–87% as compared to 79% according to a recent survey) (Englot et al., 2012). Of note, these figures likely underestimate the impact of extended resections on seizure outcomes, since cases with more difficult epilepsy will probably more often undergo more extensive surgeries. Secondly, the appropriate surgical strategy will have to take into account the pathophysiology of the epilepsy. Patients with pharmacoresistant epilepsy and glioneuronal LEATs not uncommonly harbour additional epileptogenic pathologies. As detailed earlier, cortical dysplasias can be found in association with up to a quarter of gangliogliomas and are even more frequently together with DNTs (Thom et al., 2012). Additional hippocampal sclerosis may be seen in LEAT cases (Fig. 10.12A). Also, tumours may not only cause seizures through pressure on and irritation of surrounding brain (the rationale behind the concept of a simple lesionectomy). Tumour-associated seizures may commonly originate in the border zone (sometimes termed 'collision zone') between the tumour and surrounding normal brain, as well as distant brain areas as evidenced, for example, by ECoG recordings (Zaghloul and Schramm, 2011).

Our policy has always been to perform 'extended' lesionectomies for extratemporal and temporolateral LEATs causing neocortical temporal lobe epilepsy (i.e. gross total tumour resections with removal of a 0.5–1 cm rim of surrounding cortical tissues). If the lesion lies within or borders eloquent cortex, we restrict ourselves to simple lesionectomies. Appropriate preoperative neuroimaging is vitally important in order to identify additional epileptogenic lesions (i.e. to properly delineate the epileptogenic vs. tumorous lesion). Tumours involving the temporomesial structures should be resected together with any abnormal hippocampus/parahippocampus and a rim of adjoining temporomesial tissues (**Fig. 10.12**). The results of preoperative depth electrode recordings or ECoG recordings may suggest taking the resection more dorsally if the epileptological

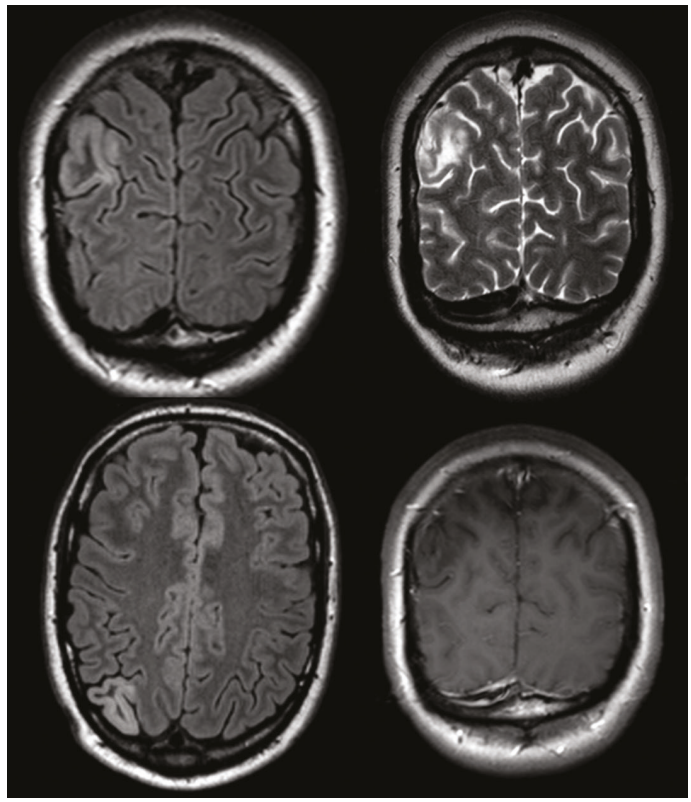

Fig. 10.12 Surgical treatment for temporo-mesio-basal long-term epilepsy-associated tumours—with and without hippocampectomy. (A) Upper panel: left parahippocampal ganglioglioma WHO grade I in a 36-year-old female with a 32-year history of epilepsy. The tumour either also involves part of the hippocampus or there is associated hippocampal sclerosis. Lower panel: we performed an extended lesionectomy including amygdalohippocampectomy. The patient has been completely seizure-free for three years and is working full-time as a kindergarten teacher. Resection of diseased hippocampus is required for epilepsy control in such cases and not associated with adverse neuropsychological sequelae. (B) Upper panel: dysembryoplastic neuroepithelial tumour (DNT) WHO grade I of the lateral temporo-occipital gyrus. The tumour was diagnosed in a 34-year-old female following a 5-year seizure history. Lower panel: an extended lesionectomy *sparing the hippocampus and amygdalum* was performed, since neither neuroimaging nor seizure semiology or EEG recordings suggested a hippocampal seizure origin. The patient has been completely seizure-free for the last three years.

Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

benefit is felt to outweigh the potentially adverse neuropsychological sequelae. Experience suggests that dominant hippocampal surgery may carry higher risks for neurocognitive deterioration (e.g. memory deficits).

Radiotherapy and radiosurgery for brain tumours

Susan Short

Case history: Management and work-up of patients with malignant brain tumours

All patients with suspected brain tumours should be reviewed and managed through a multidisciplinary team comprising all relevant clinical and allied healthcare specialists. Prior to discussion the clinical history and relevant imaging needs to be available and in most instances, this is a contrast-enhanced MRI brain scan.

In most cases, surgery is first-line management. This serves to provide material for histological diagnosis as well as remove tumour tissue, which may be beneficial for relieving mass effect and other symptoms. Since these tumours are typically highly invasive, surgery cannot address subclinical microscopic disease and is rarely curative in isolation. Nevertheless, in the majority of malignant tumours there is a well-described positive correlation between extent of surgery and overall outcome although randomized studies to address the value of different extents of surgery directly have not been undertaken and would be ethically challenging.

Recent data addressing the utility of using fluorescence-guided or image-guided resection with 5-aminolevulinic acid (5-ALA) or intraoperative MRI have supported the role of maximal safe resection (Schatlo et al., 2015). Following surgery, the histopathology in context of the clinical history and radiology is presented and discussed at a multidisciplinary meeting where decisions on likely recommendations for additional treatment can be made and appropriate referral expedited. In most cases this will involve referral for adjuvant radiotherapy and/or chemotherapy, the details of which depends on the tumour histology as well as clinical factors including patient age and performance status. This is also an important opportunity to consider eligibility for clinical studies to test the effect of new treatment approaches.

Following surgery, radiotherapy remains the most effective treatment for primary brain tumours and its contribution in grade III and IV gliomas has been confirmed in meta-analyses of outcome data. In GBM, the commonest adult glioma, the standard of care was established in a landmark EORTC study in 2005, in which six weeks of radiotherapy (60 Gy total dose, given as 30 2 Gy fractions Monday to Friday) with concomitant temozolomide chemotherapy, was shown to be superior to radiotherapy alone (Stupp et al., 2005). The median survival after combined treatment was 14 months.

In anaplastic astrocytoma (WHO Grade III astrocytoma), maximal surgery followed by external beam radiotherapy using a similar dose regime remains standard treatment. Whether combined modality treatment will improve outcome further, as it has in GBM remains to be seen and relevant studies are ongoing (EORTC 26053-22054). In grade III oligodendrogliomas, radiotherapy is also a central component of treatment. Long-term follow up data from two trials (EORTC 26951, RTOG 9402) comparing radiotherapy with and without adjuvant chemotherapy (procarbazine, CCNU, Vincristine (PCV)) demonstrate very favourable survival outcomes (greater than 10 years) with combination treatment postsurgery.

In low-grade gliomas the role of radiotherapy remains more open to debate. Radiotherapy remains the standard approach in patients deemed to need treatment and who are not suitable for radical surgery, for example, due to high-risk clinical features. A recent Phase III European study (EORTC 22033-26033) has addressed whether chemotherapy with temozolomide is as effective as radiotherapy as first line treatment in these patients, these data suggest that the two approaches are similar in terms of progression-free survival, additional data pertaining to subgroups of tumours defined by molecular pathology are awaited (Baumert et al., 2016). The limitations of radiotherapy in this patient group is often the extensive nature of these tumours, meaning that large volumes of brain need to be treated at the relatively young age at which these patients present. It is not established that these tumours require such high doses as those used in high-grade tumours and large studies have not demonstrated a dose response between 45 and 60 Gy. Low-grade oligodendrogliomas, defined using integrated molecular pathology as described in WHO 2016 (Louis et al., 2016), with 1p 19q chromosomal loss appear to respond particularly well to combined radiotherapy and PCV chemotherapy in line with their higher-grade counterparts.

Basic science of radiotherapy

Principles of radiobiology

Radiation causes cellular damage when it interacts with cells and is an effective treatment because cancer cells are less tolerant of damage than normal cells and are therefore selectively killed. The

principle toxic lesion following irradiation of nucleated cells is a double-strand break (DSB) in the DNA double helix and all cells have a complex series of mechanisms to recognize and attempt to repair these lesions. The two major DNA DSB repair pathways in mammalian cells are non-homologous end-joining (NHEJ) and homologous recombination (HR). NHEJ is active throughout the cell cycle, whereas HR functions in S and G2 phases when a sister chromatid is present to act as a template for repair of the damaged strand, however the balance of repair carried out by each pathway can be influenced by the kinetics of initial repair and the presence of other proteins that affect chromatin structure. An important difference between these repair pathways is that HR is generally error free since a normal template is used to regenerate damaged DNA, whereas NHEJ is error prone since DNA sequence can be lost between re-joined strand ends. Repair by NHEJ may therefore be mutagenic and contribute to radiation-induced malignancy. The signalling events and major effector proteins in each pathway are summarized in **Figure 11.1A**.

In principle the cytotoxic effects of radiation can be augmented specifically in cancer cells by targeting repair pathways unique to them or pathways on which they exhibit overreliance compared to normal cells. The concept of synthetic lethality is an example of this approach, in which a repair inhibitor is targeted at the specific repair processes that are active in tumour cells with abnormal repair capacity. In glioma, although combination treatment with radiotherapy and temozolomide chemotherapy has been shown to significantly improve outcome in patients with GBM (Stupp et al., 2005; Stupp et al., 2009), there is little evidence to support that this is directly due to radiosensitization, with most preclinical data suggesting an additive effect when these two agents are combined. The detailed molecular biology of DNA repair is still being investigated, and this work is likely to identify new targets for treatment that may be effective radio and chemosensitizers.

The effects of radiation on cells can be assessed in a variety of ways, including visualization of protein relocalization at sites of damaged DNA using immunofluorescent (IF) staining. IF for the phosphorylated histone protein H2AX has proven extremely useful since this protein is rapidly phosphorylated at sites of DNA DSB and dephosphorylated when DSB are repaired. Individual foci of phosphorylated protein can be visualized in nuclei and the number of these are linearly related to induced DNA DSB, allowing quantification of damage and analysis of repair kinetics. Foci numbers visualized early after radiation can also be used as an indirect measurement of radiation dose. A representative image using this approach is shown in **Figure 11.1B**.

Cellular survival following radiation has a more complex relationship to dose, reflecting the varying capacity of cells to repair damage. For most cells exposed to X-rays the dose–response relationship for survival, for example, measured using a clonogenic survival assay is linear-quadratic, with an inflection of the survival curve at a dose above which cells become more sensitive per unit dose. This inflection point varies between cell types, but tends to be lower in normal tissue than in tumour cells. This leads to the important and long-established radiobiological principle that large total radiation doses are better tolerated when delivered as a series of small doses given 5 days per week. This allows normal tissue, which is less able to tolerate large single doses, to repair and regenerate following treatment. Hence a standard radiotherapy regime is given as daily doses (fractions) of around 2 Gy and a radical dose (around 60 Gy) is achieved during a 6-week treatment course. In circumstances where normal tissue is excluded from the treatment field, larger doses per day or single large doses, known as radiosurgery may be tolerated.

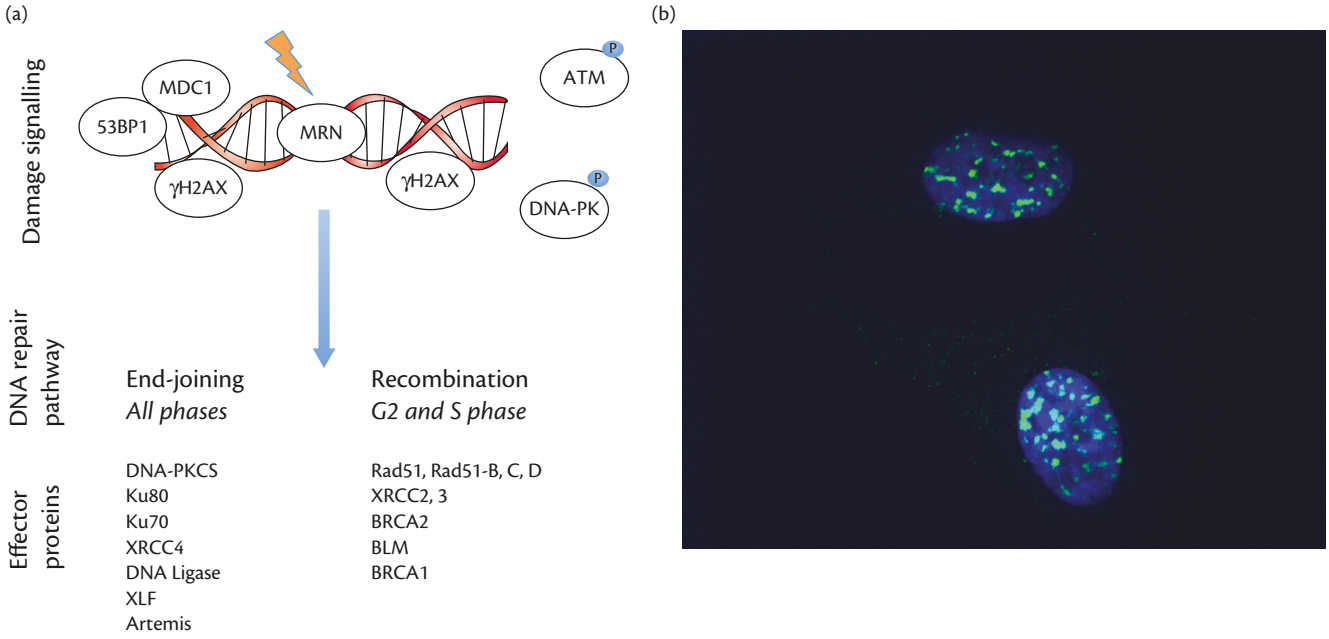

Fig. 11.1 (A) A summary of the two major DNA damage repair pathways in mammalian cells that are activated after DNA double-strand breaks caused by radiation and the major signalling and effector proteins involved. (B) Representative image of glioma cells stained for the repair protein γH2AX following exposure to radiation. Nucleus stained with 4′,6-diamidino-2-phenylindole (DAPI) (blue) and phosphorylated protein foci stained green.

Physics of radiotherapy

Modern radiotherapy makes optimal use of the physics of high energy (kilovoltage range) X-rays to deliver treatment. Clinical beams are most commonly generated in linear accelerators in which an electron beam is accelerated to a metal target, producing secondary X-rays which are then filtered and collimated to produce a homogenous beam of a set energy range and shape. The beam energy determines the depth in tissue where most of the beam energy and therefore cellular damage is deposited. For high energy beams, this is in the range of several centimetres. In order to produce a high-energy deposition region at depth, multiple beams from different directions are focused on the tumour target, permitting dose build up where the beams cross and reducing dose to non-target tissue in the beam entry paths. A treatment plan is designed in 3D space to place the target at the intersection of the beams where the additive dose is highest and to spare normal tissue, which lies outside this region, and so will receive a lower dose. Further differential sparing of normal tissue can be achieved by increasing the number of incident beams or by delivering treatment in a dynamic manner so that a smaller volume of normal tissue is exposed for any given tumour dose.

Radiotherapy techniques

Conformal external beam radiotherapy

Conventional conformal radiotherapy utilizes three-dimensional diagnostic imaging, usually from a combination of MRI and computed tomography (CT). Importantly one of these data sets (usually CT) is derived when the patient is in the intended treatment position, so that the anatomy can be cross-reference to the treatment situation. The secondary imaging data set (usually MRI, or sometimes positron emission tomography (PET)) is then digitally superimposed on the CT image. The patient is immobilized in a personalized plastic mask for both CT imaging and for subsequent treatment, permitting accurate, conformal, and reproducible treatment for many tumour types. The treatment beams are then designed as described earlier to deliver a high dose to the tumour target and avoid as much normal tissue exposure as possible. In this approach 3 or 4 static beams are generally used and the dose is delivered proportionately from each beam direction sequentially. The limitations of this approach are apparent when complex 3D targets are defined or when radiosensitive organs at risk of radiation damage are located in concavities close to the tumour. 3D-conformal treatment cannot then deliver high doses to the tumour while sparing normal tissue. In the central nervous system (CNS) this is particularly relevant in regions close to the posterior orbit and the skull base.

Intensity-modulated radiotherapy

Intensity-modulated radiotherapy (IMRT) delivers treatment using dynamic modulation of the radiation beam. This is achieved by using multileaf collimators that are moved within the beam path as it exits the machine head so that the beam is modulated in 3D before it reaches the patient. This permits much more complex shapes to be treated in a highly conformal way and specifically enables dose to be delivered around concave structures.

The applicability of IMRT for treatment of brain cancers has been evaluated in clinical and dosimetric studies, which show that it can be used to target these tumours effectively (Khoo et al., 1999; Narayana et al., 2006). Further developments in technology including approaches in which IMRT is delivered more rapidly in an arc-mode have optimized IMRT delivery by reducing the beam 'on time' to reduce the period that the patient needs to be on the treatment couch. This approach also lowers the total body dose due to internal scatter which can be high when multiple beam directions are used. A comparison of 3D conformal and IMRT plans for a glioma patient is shown in Figure 11.2.

Stereotactic radiosurgery

Radiosurgery is used to describe delivery of highly focused radiotherapy given as a single dose with the aim of producing local tumour ablation. As discussed earlier, normal tissue has a limited capacity to recover from large single radiation doses, which means that this approach is generally limited to small, well-defined targets where local normal tissue can be excluded from the irradiated

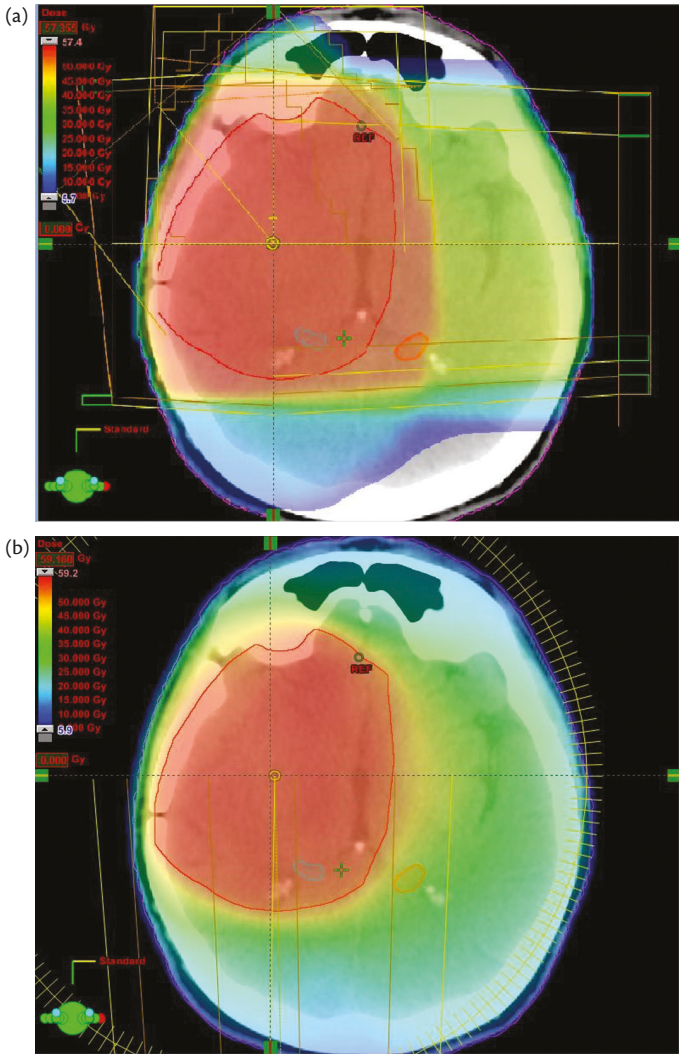

Fig. 11.2 An axial image of a 3D conformal radiotherapy plan for a patient with glioma, showing isodose lines in different colours superimposed on the CT (A) and the same target volume treated using IMRT (B). The target volume is shown outlined in red. High-dose volume is shown as red colour wash. Blue colour wash represents the low-dose (<30%) region outside the tumour target. Hippocampus is outlined separately as an organ at risk (left, orange outline, right, blue outline).

volume. Historically, radiosurgery has been most commonly delivered using cobalt-based technology (Gamma Knife) in which multiple sources are targeted at a single point, producing a very high dose at the intersection of the radiation beams (isocentre) with a steep dose fall off beyond. In this approach patients are immobilized in a head-frame to ensure accurate delivery in 3D space. Equivalent treatments can also be achieved using other technologies, for example the Cyber Knife, which uses image guidance to deliver radiosurgery through a robotic gantry without the need for an immobilization frame.

For most malignant brain tumours, radiosurgery is not useful as the tumour volume is large and rather poorly defined due to the infiltrating nature of the disease. Clinical studies that have used radiosurgery to deliver a boost dose to high-grade gliomas by targeting smaller subregions for a higher total dose have not demonstrated any advantage (Baumert et al., 2003; Baumert et al., 2008). However, radiosurgery is now a standard approach for treating brain metastases as these are frequently small, well defined lesions (Fig. 11.3).

Brachytherapy

Brachytherapy refers to treatment in which a radioactive source is placed directly in contact with the tumour or tumour bed target. In the brain this is not a commonly used method although there are a significant number of historical studies which have used different brachytherapy techniques, most often in an attempt to deliver high local doses to poor prognosis tumours. Overall the response to this approach has been disappointing with few studies demonstrating good local tumour control, but most demonstrating an increased risk of radionecrosis. More recently brachytherapy has been explored as an alternative to surgery for tumours at eloquent sites, however confirmation of the utility of this approach awaits assessment in randomized studies (Ruge et al., 2013).

Boron neutron capture therapy

Boron neutron capture therapy is based on the principle of local enhancement of radiation dose. This is achieved by delivering a boron-containing compound (usually a boronated amino acid such as phenylalanine) to the tumour then delivering a local low-dose neutron beam to activate emission of alpha particles from boron. Since tumour cells selectively uptake boron-amino acid compounds due to enhanced amino acid membrane transport systems, this approach can selectively sensitize tumour cells to neutron irradiation. In principle this will also apply to scattered invading cells anywhere in the irradiated volume, making this an appealing approach. The challenges inherent in this model include effective delivery of boronated compounds in sufficient quantities for efficacy at the time of irradiation and the specialist equipment required to produce and target the low energy neutron beam. Several groups worldwide are investigating this technique, but it is not yet widely available and has not been formally compared to conventional radiotherapy in clinical studies (Miyatake et al., 2009).

Proton beam therapy

Proton beam radiotherapy utilizes charged proton particles in place of X-rays for the treatment beam. The advantage of this approach comes from the specific dose profile of charged particles in tissue. There is a small range over which the proton energy is deposited called the Bragg peak, which is dependent on the energy of the beam and the tissue that the beam traverses. This can be used to target a beam that delivers high-energy irradiation at a very specific point with practically no effect on deeper tissues. This is advantageous in situations in which normal tissue sits very close to a tumour target, or where large volumes of radiosensitive tissue lie in the exit path of the beam. Proton beam radiotherapy can therefore be used in situations where conventional X-ray beam treatment would lead to an unacceptably high risk of normal tissue toxicity, for example at the

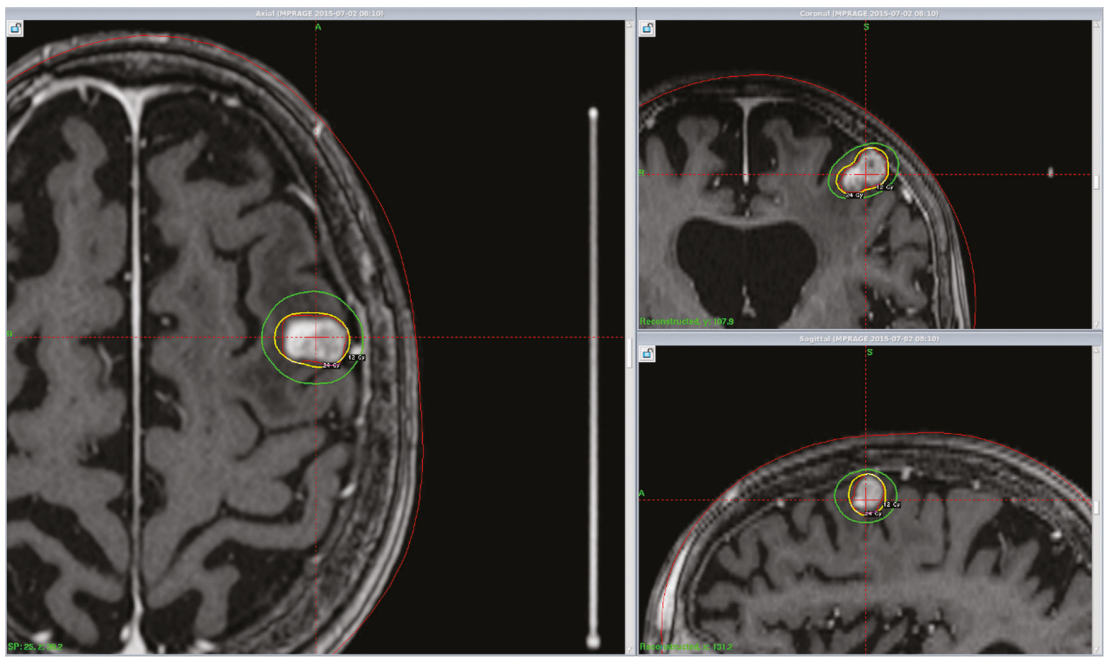

Fig. 11.3 A representative panel of images (axial, coronal, sagittal) of a radiosurgery treatment plan for a patient with brain metastases. The high-dose target is outlined in yellow and high-dose envelope in green, showing steep dose fall off in all planes beyond the tumour.

skull base, close to the optic pathway and brain stem or close to the spinal cord. It is also an advantage for many paediatric tumours, where developing normal tissue is particularly sensitive to radiation exposure so removing the exit beam dose reduces long-term toxicity risks significantly. Figure 11.4 is a representation of the dose deposition in tissue using proton beam (A) and a proton beam treatment plan for a patient with a base of skull tumour (B).

Limitations and side effects of radiotherapy

Despite optimization of complex radiotherapy delivery methods, non-tumour tissue can rarely be totally excluded from exposure to radiation during treatment. In the CNS, the relevant normal tissues are the skin and hair on the scalp, non-involved eloquent brain, the optic and auditory apparatuses, the pituitary gland, and the cerebral vasculature. All of these tissues show dose-dependent toxicity, expressed over a time course that depends on the tissue involved. Side effects are conventionally grouped according to the time at which they are expressed, early effects in weeks, and late effects in months to years. An additional effect may occur at an intermediate time, manifesting as a somnolence syndrome (Powell et al., 2011). Common early toxicities include hair loss and skin erythema, within 3–4 weeks of commencing treatment. Late effects include pituitary hormone failure, damage to visual and auditory pathways, and cognitive deficit. A set of data describing the acute side effects of radiotherapy and their time course is shown in Figure 11.5.

An important radiation-induced pathology in normal brain expressed as normal tissue necrosis, can occur between 6 months and several years after treatment. The incidence of this complication is related to the total dose, fraction size, and the volume of normal brain irradiated. Radionecrosis may be asymptomatic but can cause raised intracranial pressure or focal neurological symptoms. The best estimates of incidence suggest that this occurs in less than 5% of patients treated with conventional fractionation regimes, but a higher proportion when large doses per fraction are used and when larger volumes of normal brain are included. This is most relevant after radiosurgery where the incidence of radionecrosis has been documented as up to 25%. The major diagnostic challenge in this context is differentiating between radionecrosis and high-grade tumour progression on standard MRI scans. Radionecrosis typically

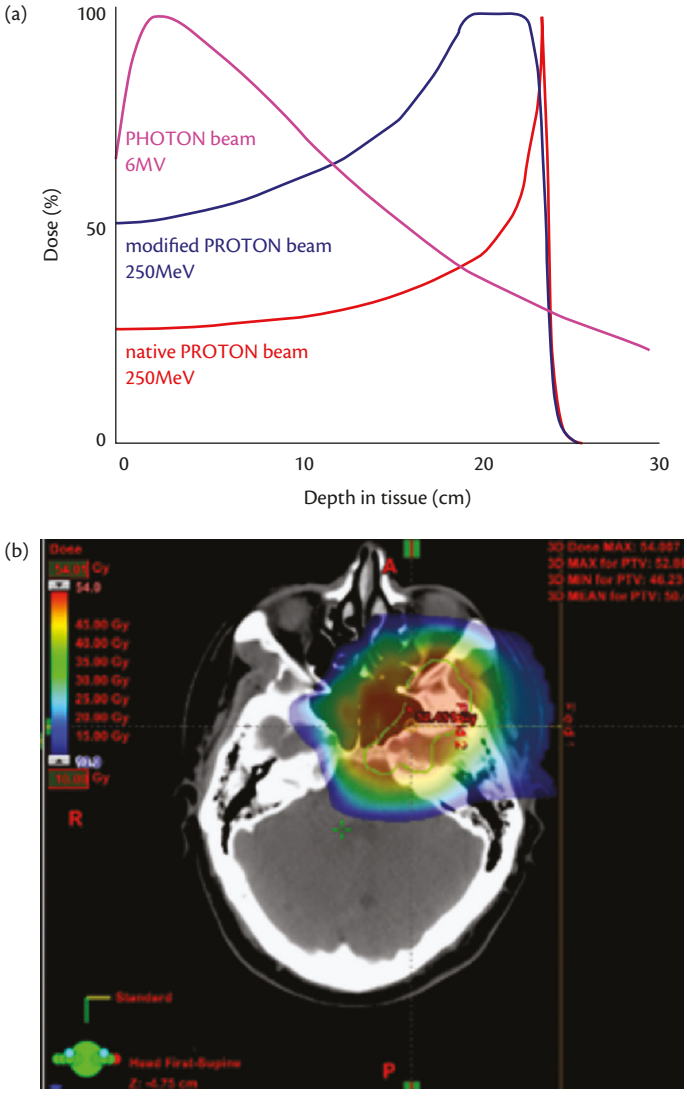

Fig. 11.4 (A) A graphic representing the different dose deposition in tissue using a photon beam, with the maximal dose near the surface and significant dose beyond the tissue maximum (pink line). In comparison a proton beam deposits dose over a narrow range of depth in tissue at the Bragg peak, with a steep dose fall off beyond (native proton beam, red line). This can be modified to spread the Bragg peak over a wider range in tissue (modified proton beam, blue line) at the cost of some increased dose closer to the surface. (B) A representative image from a proton beam plan for a patient undergoing treatment for a skull base tumour. The blue isodose line represents the low-dose region, which falls off very steeply beyond the tumour target.

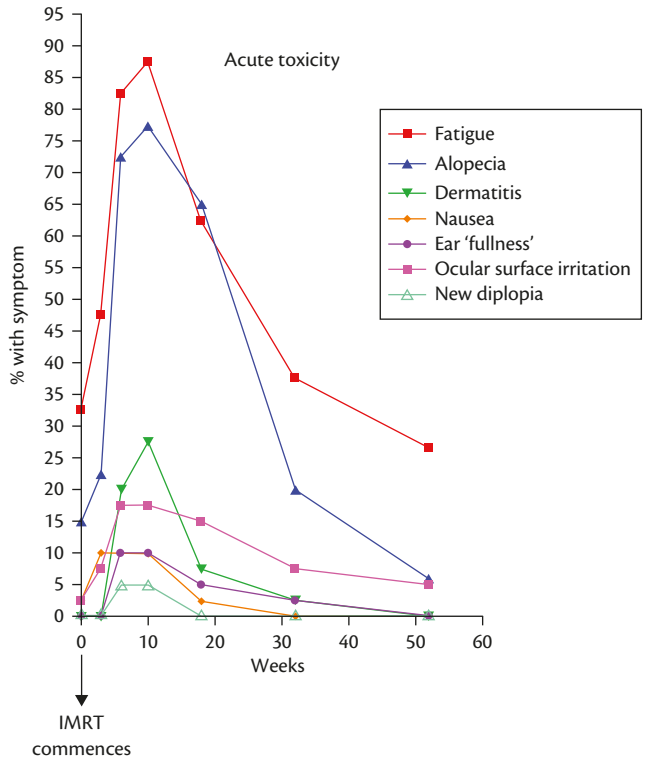

Fig. 11.5 A graphical representation of the time course and incidence of acute radiotherapy side effects in a series of patients (N = 50) undergoing intensity-modulated radiotherapy to the skull base.
Reproduced by agreement with Dr J. Maclean.

appears as an enhancing area due to disruption of the blood–brain barrier which is indistinguishable from active tumour and occurs at a time when there is a significant risk of tumour recurrence. Developing imaging protocols that can reliably distinguish between radiation necrosis and tumour recurrence using PET, SPECT, or advanced MRI techniques is an active area of research. In cases where management decisions would be critically altered by the presence of active tumour, biopsy remains the only definitive way to distinguish between these two conditions.

In most cases management of suspected radionecrosis is supportive, using steroid medication to reduce accompanying oedema, antiseizure medication as required with close clinical and radiological surveillance. There is a developing literature on the use of vascular endothelial growth factor (VEGF) inhibition in this context and several small studies have reported good outcomes using Bevacizumab, a humanized anti-VEGF monoclonal antibody in patients with symptomatic radionecrosis who do not respond to steroids. Small series have also reported favourable outcomes using hyperbaric oxygen therapy (HBO), the rationale for this being that enhancing oxygen delivery to damaged tissue by increasing plasma oxygen carriage enhances recovery. A course of HBO sessions is usually recommended which may require up to 20 attendances. This is not widely available, and HBO is generally reserved for patients with limited other treatment options. In cases presenting with mass effect that does not respond to steroid treatment or other medical management, consideration should be given to surgical removal of the lesion.

The phenomenon of 'pseudoprogression' in patients who have received surgery and adjuvant radiotherapy or radiochemotherapy is thought to be a related issue. MR imaging appears to show an increased enhancing tumour volume at early follow up, 1–2 months postradiotherapy, which is often asymptomatic and resolves without specific intervention. This suggests that the underlying cause is a treatment induced effect on blood–brain barrier permeability associated with neural or vascular tissue damage. The current recommendation for treatment is for supportive management and re-evaluation after 4–6 weeks, when pseudoprogression is likely to begin to resolve.

Over much longer time frames, of many years, radiation-induced tumours, most commonly meningiomas, but rarely also radiation-induced malignant tumours including gliomas and sarcomas occur (Brada et al., 1992; Minniti et al., 2005). The incidence of true radiation-induced malignancy is difficult to determine, particularly in a population with rather short median survival. Data from paediatric populations implies a significant risk following brain irradiation, probably 5–10-fold higher than non-irradiated cohorts, although younger age at exposure is also recognized as an important factor that inflates risk for a given dose. Epidemiologic data, for example A-bomb survival data confirm a malignancy risk that is proportional to dose, but these whole-body doses are challenging to convert to risk estimates in patients who have been exposed to high-dose treatment to only partial organ volumes, in whom risk is likely to be lower. However, the established mutagenic potential of radiation and available data, particularly in survivors of childhood cancer make it clear that mitigating risk of radiation-induced malignancy is an important challenge as treatment efficacy improves. Modern radiotherapy techniques contribute to this since they deliver dose more accurately to tumour volumes and reduce high-dose exposure to surrounding normal tissue. However some of these techniques, including IMRT, may also increase the volume of normal tissue that is exposed to very low-dose radiation and the contribution of this dose component to overall long-term risk is unknown. To date no studies have reported on second cancer risk after brain radiotherapy using IMRT or proton beam therapy.

Mechanisms of late toxicity are related to damage to the endothelial as well as the glial compartment in the CNS (Benczik et al., 2002; Otsuka et al., 2006). The majority of cells within the CNS are postmitotic and therefore not expected to exhibit sensitivity to radiation. The most sensitive differentiated cell type in the CNS is the oligodendrocyte population, and demyelination occurs following relatively low radiation doses (Panagiotakos et al., 2007). Current models of late toxicity following radiotherapy to the brain include the effects of loss of a population of stem-like cells that inhabit specific anatomic and biological niches including the subventricular zones and hippocampi. In rodent models, loss of these cells is associated with cognitive deficit and studies are ongoing to address whether specifically excluding stem-cell-rich areas from radiation may reduce these long-term side effects. It is a concern that clinical data sets suggest that stem cell populations are sensitive to very low radiation doses (Marsh et al., 2010). These data have led to radiotherapy planning approaches that specifically exclude these brain regions from high-dose exposure during treatment if this is compatible with delivering high dose to the tumour volume. Hippocampal sparing approaches have been shown to be deliverable using IMRT techniques, in which the hippocampus is defined as an avoidance structure, but as yet no prospective randomized data on the impact of this approach on neurocognitive outcomes are available. An alternative approach is to use drugs that may act as neuroprotectants for example memantine, during radiotherapy. The randomized studies that have reported this approach have not thus far shown significant benefit.

Case history

A 70-year-old patient presented to his general practitioner with episodes of confusion when driving. On examination the patient had reduced motor power on the left as well as left sided inattention. Investigations including an MRI brain were arranged and representative images are shown in **Figure 11.6**. The right frontal lesion was biopsied and found to be a grade III oligodendroglioma with loss of heterozygosity (LOH) of 1p19q.

Standard treatment for grade III gliomas is external beam radiotherapy with additional chemotherapy for those with 1p19q LOH. This approach has not been assessed in randomized studies in patients over the age of 70. For multifocal disease, as in this case, radiotherapy can be challenging to deliver since the total tumour volume is large and multiple organs at risk may be in close proximity. In this case the concern was how to encompass the whole tumour volume, which includes multiple lobes, and is close to the optic chiasm. An alternative approach in these cases can be to treat with chemotherapy to attempt to reduce the tumour volume, which may then be encompassable in a radiotherapy field with lower risks of toxicity. Not all of these tumours respond to chemotherapy but most cases with 1p19q loss of heterozygosity are thought to be chemosensitive.

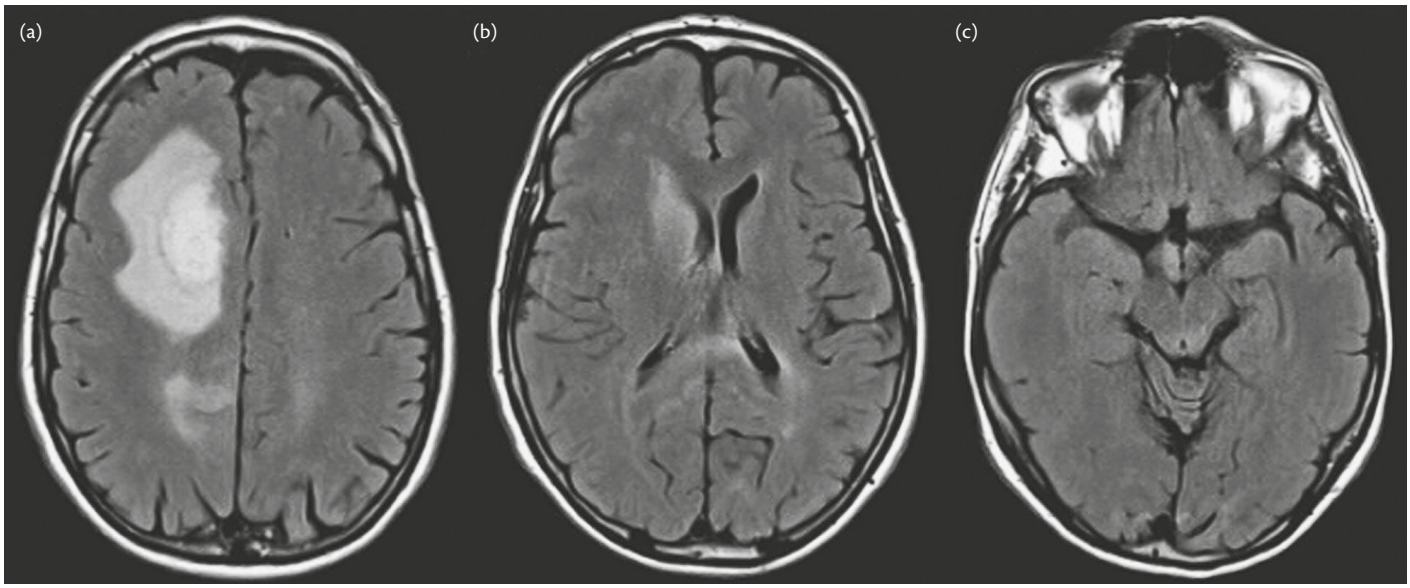

Fig. 11.6 MRI images including fluid-attenuated inversion recovery (FLAIR) images showing multifocal signal hyperintensity change in the right frontal and bilateral parietal lobes (A), right head of caudate and splenium of the corpus callosum (B) and, right fornix and right mammillary body (C).

Chemotherapy for brain tumours

Nicholas F. Brown, Daniel Krell, and Paul Mulholland

Introduction

Surgical resection is the cornerstone of the initial management of brain tumours. However, the infiltrative and invasive nature of malignant brain tumours means that complete resection is unattainable, and so while the extent of surgical resection improves prognosis (Lacroix et al., 2001), it must be balanced against the potential for disabling neurological deficits. Furthermore, recurrence after initial therapy is frequently due to malignant cells migrating into normal brain tissue, which are not amenable to other focal treatments such as radiotherapy. Thus chemotherapy offers an additional treatment to prolong survival and maintain the functional status of patients with brain tumours.

The role of chemotherapy in brain tumours is currently fairly limited in comparison to cancers originating outside the brain. The poor prognosis and lack of effective treatments for high-grade tumours means that novel therapies are required. Several innovative chemotherapeutics are currently in clinical trials and may provide the basis for future treatment.

In this chapter, we outline the basic concepts of chemotherapy, the use of molecular markers, how response to treatment is monitored, the pharmacology of chemotherapeutics used in neuro-oncology, the evidence for chemotherapy in gliomas, and potential future treatments. The use of chemotherapy in non-glioma primary brain tumours and the treatment of metastatic disease in the brain is not discussed.

Concepts in chemotherapy

Aims

The rationale for chemotherapy in treating cancer is based upon our understanding of how a single transformed cell develops into a malignant tissue through an accumulation of genetic instability and mutations. These acquired 'hallmark' characteristics of cancer include: developing sustained proliferative signalling; evading growth suppressors; immunosuppression; preventing cell death; enabling replicative immortality; and inducing angiogenesis, invasion, and metastasis (Hanahan and Weinberg, 2011). Each of these hallmarks represent targets for current and potential future treatments.

The aim of chemotherapy in brain tumours is to prolong survival or control symptoms (*palliative*). It is often used as an adjunct to increase the effectiveness of other therapies (*adjuvant*). There is no proven role in brain tumours for administering chemotherapy prior to surgery (*neoadjuvant*) or with the aim of cure (*curative*), although chemotherapy has this role in other tumour locations.

Mechanisms of action

Cytotoxic drugs target processes of cellular division, killing cells through blocking crucial stages in the synthesis of DNA or its nucleotide precursors, or by assaulting the structural integrity of DNA. The rationale for their use in cancer is that cancer cells are more likely to be replicating. However, normal tissues contain dividing cells, and so cytotoxic agents are non-selective, which accounts for the common and widespread toxicities associated with chemotherapy, notably myelosuppression, gastrointestinal symptoms, fatigue, neuropathy, infertility, teratogenicity, cognitive symptoms, and alopecia. Similarly, cancer cells that are quiescent within the resting phase of the cell cycle (G0) when chemotherapy is delivered will not be targeted by cytotoxic chemotherapy and can be recruited into the next cell cycle to cause tumour growth (Chabner and Loeffler, 2015).

Principles of use

Exposing tumours to a defined dose of chemotherapy for a defined time period, results in a constant fraction of tumour cells killed, independent of the size of tumour, termed 'fractional kill' (Berenbaum, 1972). Poor tumour penetration reduces the fraction killed, and systemic toxicities reduce the dose that can be delivered. Thus current regimens deliver chemotherapy in repeated 'cycles' with the aim of eliminating the cancer cell population through successive fractional kills. The dose delivered is typically the maximum tolerated dose, with the interval between dosing sufficient to allow recovery from toxicities. These parameters are determined in early phase trials. Chemotherapeutics are often delivered as combinations of drugs in order to increase efficacy (additive or synergistic) through different mechanisms of action, with minimal overlapping toxicities. Practically, the dose limiting toxicity of most chemotherapeutics is myelosuppression, and this is the most frequent limitation of combination dosing.

Limitations

There are several limitations to chemotherapy. Intrinsic or acquired resistance can limit the effect of chemotherapy. Resistance mechanisms include the development of efflux pumps on cancer cell surfaces, gene amplification, or modification of chemotherapy targets, defects in apoptotic pathways, and upregulation of DNA repair genes. Intratumour genetic heterogeneity reduces the likelihood of killing all cancer cells within a tumour, and further 'spatial' genetic heterogeneity between tumours in different locations and 'temporal' heterogeneity as the tumour evolves with time further compounds this. Disruption of the normal vascular architecture can limit the access to the tumour of systemically delivered drugs. With brain tumours the blood–brain barrier presents a unique barrier to chemotherapy, although it is disrupted to a variable extend by the tumour itself. Tight junctions between capillaries in the blood–brain barrier can prevent transport of large and hydrophilic molecules, and efflux pumps can remove drugs from the brain into the cerebrospinal fluid, limiting the access of potential efficacious chemotherapeutic agents. While most chemotherapeutics are delivered systemically through intravenous or oral administration, the blood–brain barrier has resulted in the development of alternate methods of delivery in the treatment of brain tumours, including topical administration at surgery and experimental techniques such as convection enhanced delivery.

Other chemotherapies

Non-cytotoxic drugs that are variably considered chemotherapy include targeted therapies and immunotherapy. Targeted therapies use small molecules or monoclonal antibodies against intracellular proteins or cell surface receptors that are either mutated or overexpressed in tumour cells, with the aim of increasing cancer cell kill with fewer systemic toxicities. Immunotherapy aims to use the innate and adaptive immune systems to target cancer cells, and is discussed in more detail later in this chapter.

Clinical trials

Novel chemotherapeutics and innovative combinations are in constant development. Clinical trials form the basis for the introduction of new treatment. *Good Clinical Practice* (GCP) is an international quality standard that provides a framework to ensure that human trials are conducted in a regulated, ethical, and scientifically robust fashion.

- In phase 1 trials the primary objective is to assess the safety and toxicity of a new compound, with determination of a maximum tolerated dose through a dose escalation design. Secondary objectives will include pharmacokinetic data, and clinical activity and efficacy.
- A phase 2 trial assesses the activity of the compound, as well as continuing to assess safety and tolerability. These may be randomized, often against placebo.
- Phase 3 trials establish efficacy compared with the current standard of treatment. This forms the basis for licensing of drugs by regulatory authorities (Medicines and Healthcare Regulatory Agency in the United Kingdom, Food and Drug Administration in the United States, and the European Medicines Agency in the European Union).

Glioblastoma is the most common intrinsic brain tumour and so is the most frequently studied tumour within clinical trials. Short life-expectancy means that a primary endpoint of survival is attainable more efficiently than with other tumour types. Data from glioblastoma trials is often extrapolated for use on the basis for clinical trials in other brain tumours. Stratification of patients using molecular markers allows identification of subgroups who do or do not benefit from treatment.

Chemotherapeutics

The decision to start chemotherapy is typically made by an oncologist with the written consent of the patient, following discussion of the rationale and intention of treatment, and common and serious toxicities. The regimen and dose will be calculated and adjusted according to the patients' weight or body surface area (BSA), performance status, organ function (particularly bone marrow, kidney, liver), comorbidities, and toxicities experienced during previous chemotherapy. These parameters are monitored frequently during the treatment, with delay or reduction of dose as required. High-frequency toxicities are pre-empted with prophylactic supportive medication. Patients are monitored closely by physicians and nurses who are specifically trained in chemotherapy administration, and toxicities are treated actively to avoid dose-delays, omissions, or reductions where possible. Blood tests are monitored before each cycle, and at prespecified time points within cycles. Patients have 24-hour telephone access to chemotherapy trained nurses to discuss management of toxicities, and are advised to monitor themselves for signs of infection which may require urgent hospital admission and commencement of intravenous antibiotics. Response to therapy is monitored with imaging at prespecified time points.

Table 12.1 provides a summary of the pharmacology of the most frequently used chemotherapeutics licensed for use in gliomas, with their frequently occurring side effects. Comprehensive details can be found in each drug's summary of product characteristics available online from the European Medicines Agency (EMA), or the U.S. Food and Drug Administrating (FDA). Evidence for their use is discussed later in this chapter.

Molecular markers and chemotherapy

Molecular markers are used routinely in oncology as diagnostic and prognostic indicators. Concordance between local diagnosis and central neuropathology is as low as 50% (Stupp et al., 2014) and so molecular markers aid accurate diagnosis which is vital in predicting likely benefit from chemotherapy. Furthermore, molecular markers can be independently prognostic of a response to chemotherapy, and so can be used to identify whether individual patients are more or less likely to respond to chemotherapy. Markers that aid chemotherapy treatment decisions are discussed next. Other useful diagnostics markers (e.g. ATRX, TERT) that aid diagnosis, but are not independently linked to chemotherapy response are not discussed. The 2016 WHO Classification of Tumours of the Central Nervous System has incorporated molecular markers into the diagnostic algorithms for gliomas (Louis et al., 2016). All gliomas are now defined

Table 12.1 Chemotherapeutics commonly used in the treatment of gliomas

Mechanism of action	Characteristics	Regimen	Side effects
Temozolomide			
An oral derivative of dacarbazine. Both are pro-drugs of the alkylating agent 3-methyl-(triazene-1-yl)imidazole-4-carboxamide (MTIC). Alkylating agents irreversibly attach an alkyl group to guanine base on DNA disrupting DNA replication and leading to arrest of cell replication and induction of apoptosis.	It is a relatively small lipophilic molecule (194 Da), is highly bioavailable, and crosses the blood–brain barrier where it spontaneously hydrolyses to its active metabolite. Generally well tolerated.	In glioblastoma it is delivered orally in combination with radiotherapy at 75 mg/m² BSA per day for 42 days, and then as maintenance therapy for six cycles at 150–200 mg/m² BSA for days one to five of a 28-day cycle. Prophylactic antibiotics are given to prevent pneumocystis jirovecii pneumonia (PCP).	Very common (>10%): anorexia, constipation, nausea, vomiting, rash, dry skin, infertility, alopecia, fatigue. Common (1–10%): anaemia, leucopoenia, thrombocytopenia, abnormal liver function tests, oral candidiasis, dysphagia, stomatitis, hyperglycaemia, dysgeusia, cough, dyspnoea, musculoskeletal pain, myasthenia, fatigue, urinary incontinence, oedema, DVT, blurred vision, hearing impairment, tinnitus, anxiety, depression, insomnia, headache, convulsions. Azoospermia is reported.
Lomustine (CCNU, 1-(2-Chloroethyl)-3-cyclohexyl-1-nitrosourea)			
An alkylating nitrosourea. Nitrosoureas are compounds that contain both a nitroso (R-NO) group and a urea. Non-enzymatic degradation of nitrosoureas yield products with alkylating and carbamoylating activities that lead to intra- or interstrand cross links of DNA and mitotic arrest.	Lipophilic, therefore can cross the blood–brain barrier.	In gliomas is used as monotherapy, or in the PCV regimen in combination with procarbazine and vincristine. It is delivered by capsule orally, and is usually given as a single dose on the first day of each cycle (every six to eight weeks) for six cycles.	Very common: (>10%) rash, dry skin, diarrhoea, abnormal liver function, thrombocytopenia (relatively late nadir at four weeks post dose), and leucopoenia (nadir at five to six weeks). Common (1–10%): fatigue, nausea, vomiting, anorexia, loss of fertility, and anaemia. Other significant side effects include liver and renal impairment, lung infiltrates, coordination difficulties, and confusion.
Carmustine (BiCNU, bis-chloroethylnitrosourea)			
A mustard-gas related nitrosourea alkylating agent (see Lomustine).	Can be given intravenously, but also available as a gel wafer (Gliadel®) licensed in the UK in glioblastoma (Arbor Pharmaceuticals, 2014).	Following surgical tumour resection up to eight wafers can be implanted into the cavity floor and deliver a controlled release of carmustine over approximately five days with the aim of avoiding systemic toxicities.	Gliadel® wafers: new or worsening seizures (54%), cerebral oedema (23%), delayed wound healing (16%), and meningitis (4%). Tonsillar herniation and wafer migration causing obstructive hydrocephalus have been reported.
PCV			
A chemotherapy regimen combining procarbazine, lomustine (CCNU), and vincristine.		Typically given in a 42-day cycle for six cycles. On day one patients receive intravenous vincristine and oral lomustine, and a 10-day course of oral procarbazine is commenced on day 1 or 2.	
Procarbazine			
An alkylating agent (see temozolomide) whose individual mechanism of action is not fully understood.	A cytochrome P450 inhibitor with multiple drug interactions, and a monoamine oxidase (MAO) inhibitor and thus can produce a disulfiram-like reaction with alcohol.		Very common (>10%): nausea, vomiting, and anorexia. Common (1–10%): leucopoenia, anaemia, thrombocytopenia, fatigue, flu-like symptoms, depression, insomnia, neuropathy, amenorrhea, and loss of fertility. Hypersensitivity and tyramine reactions can occur, thus tyramine containing foods should be avoided, and patients should be provided with a list of foods to avoid.
Vincristine			
A vinca alkaloid derived from the Madagascar periwinkle. It binds to tubulin dimers inhibiting microtubule structure and thus arresting mitosis in metaphase.	It is for intravenous use only and designated; **FATAL IF GIVEN INTRATHECALLY** due to neurotoxicity. Multiple deaths have occurred due to inadvertent intrathecal administration.		Very common (>10%): neuropathy, fatigue, severe constipation, abdominal pain, nausea, vomiting, and alopecia. Common (1–10%): leucopoenia, infection, myasthenia, injections site reactions, urinary retention, allergic reactions, mouth ulcers, jaw pain, paralytic ileus, and rash.
Bevacizumab			
A recombinant humanized monoclonal antibody to vascular endothelial growth factor A (VEGF-A). Angiogenesis is common in glioblastoma. Hypoxia is the principle driver and leads to tumour expression of proangiogenic factors including VEGF that stimulate endothelial cell proliferation, migration, and invasion. Antiangiogenics cause vascular normalization and decrease the permeability of the blood–brain barrier (Friedman et al., 2009).		Intravenously every two to three weeks.	Very common (>10%): hypertension, nausea, vomiting, fatigue, leucopoenia, neuropathy, anorexia, constipation, and headaches. Common (1–10%): proteinuria, deep-vein thrombosis, bowel perforation, bleeding, fistula, impaired healing, posterior leukoencephalopathy, cardiac failure, and arrhythmia.

by their IDH status. Tumours that were previously considered 'oligoastrocytoma' due to mixed histological features are now classified as either oligodendrogliomas or astrocytomas depending on the respective presence or absence of 1p19q codeletion. However, tumour heterogeneity (Forshew et al., 2013) confounds interpreting the clinical consequences of any molecular marker results, and leads to clinically insignificant positive results if the molecular marker is present in the area of tumour biopsied but not elsewhere, and similarly may lead to false-negative results.

Chromosome 1p/19q codeletion

Genetic loss on chromosomes 1p and 19q with codeletion or loss of heterozygosity occurs due to an unbalanced translocation of chromosomes 1p and 19q (Cairncross et al., 2013). It is a distinct tumour entity whose pathological consequences are as yet unclear, but indicates an oligodendroglioma and is uncommon in glioblastomas (<5%) (present in 15% of grade II diffuse astrocytomas, 30–60% of grade II oligodendroglioma/oligoastrocytomas, 15% of grade III anaplastic astrocytoma, and 50–80% or oligodendroglioma/oligoastrocytomas) (Stupp et al., 2014). It is associated with an increased sensitivity to chemotherapy and survival (Cairncross et al., 2013).

6-methylguanine-DNA methyl transferase (MGMT) promoter methylation

The primary cytotoxic effect of temozolomide is due to DNA methylation at the O6 position of guanine. MGMT is a ubiquitous DNA repair enzyme that removes methyl groups from the O6 position of guanine and thus reverses alkylation and inhibits the cytotoxic effect of temozolomide. Methylation of the promotor that initiates transcription leads to epigenetic silencing of MGMT which increases susceptibility of tumours to alkylating agents such as temozolomide (Weller et al., 2010). Methylation-specific polymerase chain reaction (MSP) is used to determine MGMT-promotor methylation, due to lack of standardization with immunohistochemistry. It is present in 40–50% of grade II diffuse astrocytomas, 60–80% of grade II oligodendroglioma/oligoastrocytoma, 50% of grade III anaplastic astrocytomas, 70% of anaplastic oligodendrogliomas, and 35% of glioblastoma (Stupp et al., 2014). It is a positive prognostic marker in anaplastic glioma and glioblastoma and is correlated with an improved prognosis in anaplastic gliomas treated with alkylating chemotherapeutics. It confers increased likelihood of response to chemotherapy, discussed in detail below.

Isocitrate dehydrogenase (IDH) 1 and 2 mutations

Mutations in IDH 1 or 2 lead to production of an abnormal metabolite, 2-hydroxyglutarate, which produces epigenetic changes through hypermethylation. IDH 1 and 2 mutations are hallmarks of low-grade glioma and if found in high-grade tumour suggest transformation from a low-grade precursor. IDH mutations are found in 70–80% of grade II diffuse astrocytomas and oligodendrogliomas, 50–80% of astrocytomas and anaplastic oligodendrogliomas, but only 5–10% of glioblastomas. Around 90% of mutations are the R132H mutation on IDH1 and can be visualized on immunohistochemistry. If negative gene sequencing can be performed to exclude IDH2 and IDH1 mutations at other sites (Stupp et al., 2014). IDH mutation is a positive prognostic marker, and has been shown to predict response to temozolomide in anaplastic oligodendroglioma (van den Bent et al., 2013). Furthermore, IDH is being investigated as a therapeutic target for inhibitors (AG-221), in immunotherapy, and 2-hydroxyglutarate can be detected by magnetic resonance spectroscopy offering a potential imaging molecular marker (Kang and Adamson, 2015).

Epidermal growth factor receptor (EGFR)

EFGR amplification/mutation is found in multiple tumour types, with targeted therapies as standard practice in colorectal, lung, and head and neck cancers. Half of glioblastomas have EGFR amplification or mutation, with half of these being EGFRvIII mutation, which confers a negative prognosis. It is unusual in other gliomas, found in only 9% of anaplastic astrocytomas (Kang and Adamson, 2015). It is a promising therapeutic target and although no phase 3 trial of EGFR targeted agents have shown survival benefit, several EGFR targeted agents remain in development and are being evaluated in clinical trials.

BRAFV600

BRAF mutations have been identified as key drivers of oncogenesis in several cancers. Over 95% are missense mutations with substitution of valine to glutamate at amino acid position 600E (BRAFV600E). While overall BRAF mutations are uncommon in glioma, there are more frequently observed in pleomorphic xanthoastrocytoma, and pilocytic astrocytomas (9%) (Schindler et al., 2011). The 2016 WHO Classification of CNS tumours includes a new variant of IDH wild type glioblastoma, epithelioid glioblastoma, that frequently harbours a BRAF mutation (Louis et al., 2016). Patients with BRAFV600 mutant tumours can be treated with small molecule inhibitors of mutated BRAFV600E.

Monitoring for response

The most frequent reported measures of response are median overall survival (mOS), progression free survival (PFS), and objective response (OR). Overall survival (OS) and PFS are frequently reported at time points (e.g. 6 or 12 months) after treatment initiation. Cognitive function, quality of life, symptoms, functional independence, and the requirement for steroids are used as additional markers of clinical response (Lin et al., 2013).

Radiological outcomes are categorized into complete response (CR), partial response (PR, 30% unidimensional or 50% bidimensional shrinkage), stable disease (SD, not meeting the criteria for response or progression), and progressive disease (PD, 20–25% increase).

The Response Evaluation Criteria in Solid Tumour (RECIST) guidelines are the standard evaluation for tumours originating outside of the CNS and categorize response based on change in target lesion size (Eisenhauer et al., 2009). The Macdonald criteria for supratentorial malignant glioma (Macdonald et al., 1990) allowed for objective radiological assessment of tumour response to be classified with recognition of glioma specific considerations such as steroid use and clinical symptoms. While designed for computerized tomography, it was extrapolated for use with MRI. The Response Assessment in Neuro-Oncology working group (RANO) criteria (Table 12.2) were developed to resolve perceived limitations

Table 12.2 RANO and iRANO criteria. iRANO recommends confirming disease progression with repeat imaging three months after initial radiological progression if it is six months or less from commencing immunotherapy if there are no new or substantially worsened neurological deficits that are not due to comorbid events or concurrent medication.

	Malignant glioma	Low-grade glioma
Complete response	Disappearance of all enhancing disease for ≥4 weeks; no new lesions; stable or improved T2/FLAIR; no more than physiological steroids; clinically stable or improved	Disappearance of all enhancing and T2/FLAIR disease for ≥4 weeks; no new lesions; no more than physiological steroids; clinically stable or improved
Partial response	≥50% decrease in the sum of biperpendicular diameters of enhancing disease for ≥4 weeks; no new lesions; stable or improved T2/FLAIR; stable or decreased steroid dose; clinically stable or improved	≥50% decrease in the sum of biperpendicular diameter of T2/FLAIR disease for ≥4 weeks; no new lesions; stable or decreased steroid dose; clinically stable or improved
Minor response	Not applicable	25–49% decrease in the sum of biperpendicular diameters of T2/FLAIR disease for ≥4 weeks; no new lesions; clinically stable or improved
Stable disease	Does not qualify for complete response, partial response, or progressive disease; no new lesions; stable or improved T2/FLAIR; stable or decreased steroid dose; clinically stable or improved	Does not qualify for complete response, partial response, or progressive disease; no new lesions; stable or improved T2/FLAIR; stable or decreased steroid dose; clinically stable or improved
Progressive disease	≥25% decrease in the sum of biperpendicular diameters of enhancing disease; or new lesions; or substantial worsened T2/FLAIR; or substantial clinical decline	≥25% decrease in the sum of biperpendicular diameters of T2/FLAIR disease; or new lesions; or substantial clinical decline

Data from Wen PY, Macdonald DR, Reardon DA, et al. Updated response assessment criteria for high-grade gliomas: response assessment in neuro-oncology working group, *Journal of Clinical Oncology*, Volume 28, issue 11, pp. 1963–72, 2010.

Data from van den Bent M, Wefel J, Schiff D, et al. Response assessment in neuro-oncology (a report of the RANO group): assessment of outcome in trials of diff use low-grade gliomas. *Lancet Oncology*, volume 12, issue 6, pp. 583–93, 2011.

of the Macdonald criteria including the lack of assessment of non-enhancing components and the use of increased contrast enhancement as a surrogate for tumour growth.

Contrast enhancement reflects the passage of contrast across the blood-tumour barrier, and changes may reflect non-tumoural processes such as inflammation, radiation necrosis, seizures, steroid dose, and antiangiogenics. 'Pseudoprogression' is a non-tumoural increase in imaging lesions that may actually reflect response to treatment and occurs in 20–30% of patients treated with temozolomide chemoradiotherapy (Wen et al., 2010). 'Pseudoresponses' are non-tumoural decrease in lesions, that may reflect decrease permeability of the blood-tumour barrier to contrast, such as with antiangiogenics. To account for these occurrences, the RANO criteria requires repeated imaging for any responses within 12 weeks after the completion of therapy, unless progression is outside of the radiotherapy field or pathologically confirmed. In patients with potential pseudoprogression, treatment should continue until response is clarified with subsequent imaging.

Immunotherapy, currently in clinical trials in gliomas, presents several new challenges for determining response. Due to the time required to develop an immunological response, tumour progression may occur first, which may itself be masked by the inflammatory changes. These have been addressed with the immunotherapy iRANO criteria (Table 12.2) (Okada et al., 2015).

Glioblastoma (WHO grade IV)

Carmustine was the first chemotherapeutic to become standard therapy in addition to surgery and radiotherapy following the RTOG-8302 trial in 1980. This randomized trial in patients with malignant glioma demonstrated improved survival with carmustine and radiotherapy combined versus radiotherapy or chemotherapy alone (Walker et al., 1980). Nitrosourea chemotherapy use was substantiated with a systematic review of 12 randomized trials involving 3004 patients with high-grade glioma (grade III and IV) that confirmed a modest increase in survival in patients receiving chemoradiotherapy versus radiotherapy alone [Hazard radio (HR) 0.85, 95% confidence interval (CI) 0.78–0.91, P <0.0001] with OS at 1 year increasing from 40 to 46% and at 2 years from 15 to 20%, and a significant 17% reduction in the risk of progression or death (HR 0.83; 95%CI 0.75–0.91, P <0.0001) (Stewart, 2002).

The current standard of treatment following surgery in glioblastoma is chemoradiotherapy with 60 Gray in 30 fractions of radiotherapy with concurrent daily temozolomide for six weeks, followed by a four-week break, and then up to six cycles of adjuvant temozolomide. This was introduced following the EORTC-NCIC trial in 2005. This was a phase 3 trial in 573 patients with glioblastoma randomized to temozolomide chemoradiotherapy versus radiotherapy monotherapy. It demonstrated a significantly improved median OS with chemoradiotherapy of 14.6 months vs. 12.1 months (HR 0.63, 95%CI 0.52–0.75, P <0.001) (Fig. 12.1) and an improvement in 2-year survival with chemoradiotherapy from 10.4 to 26.5%. MGMT-promotor methylation was a favourable prognostic factor for OS both independently (HR 0.45, 95%CI 0.32–0.61, P <0.001) and also as predictor of response to chemotherapy with an increase in OS from 15.3 months (95%CI 13–20 months) in the unmethylated patients to 21.7 months (95%CI 17.4 to 30.4) in those with methylated promotors (P = 0.007). In the absence of methylation there was a smaller and non-significant difference in survival between the two treatment groups (Stupp et al., 2005).

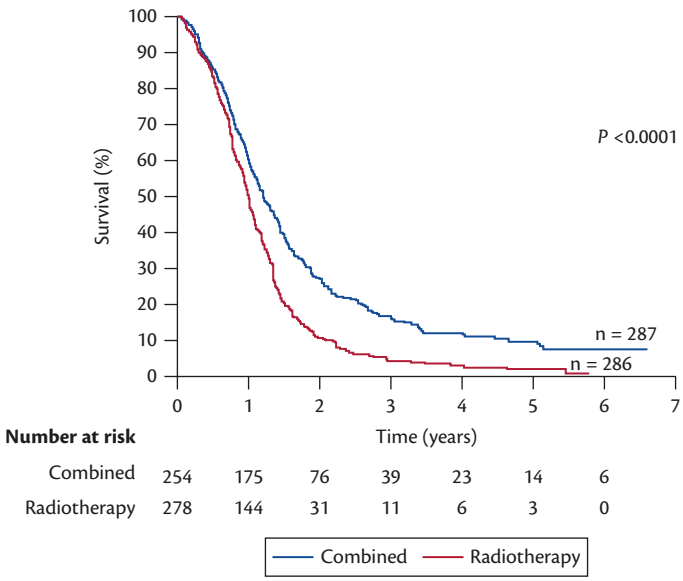

Fig. 12.1 Overall survival in radiotherapy with concomitant and adjuvant temozolomide versus radiotherapy alone in glioblastoma.
Reprinted from *The Lancet Oncology*, Volume 10, issue 5, Stupp et al., Effects of radiotherapy with concomitant and adjuvant temozolomide versus radiotherapy alone on survival in glioblastoma in a randomised phase III study: 5-year analysis of the EORTC-NCIC trial, pp. 459–66, Copyright (2009), with permission from Elsevier.

Dose-dense temozolomide (dosing on days 1–21 of a 28-day cycle) leads to prolonged depletion of MGMT. However, in a phase 3 randomized trial in 833 patients with GBM it was not superior to standard adjuvant therapy (days 1–5) regardless of MGMT status (OS 14.9 vs. 16.6 months (HR 1.03 $P = 0.63$); PFS 6.7 vs. 5.5 months HR 0.87 $P = 0.06$), and was associated with increased severe toxicities (34 vs. 53%; $P < 0.01$) (Gilbert et al., 2013).

The landmark chemoradiotherapy trial excluded patients over 70 years of age, but reported decreased benefit from chemotherapy in patients over 60 (Stupp R. et al., 2009). However, while elderly patients have a poorer performance status and are more prone to toxicities from chemotherapy, clinical trials in older patients have demonstrated survival benefits of chemotherapy. The NOA-08 phase 3 trial randomized 373 patients older than 65 years with high-grade glioma (89% glioblastoma) to temozolomide or radiotherapy with crossover salvage therapy as appropriate at progression (Wick et al., 2012). This trial reported temozolomide as non-inferior to radiotherapy with median OS of 8.6 months in the temozolomide group and 9.6 months in the radiotherapy group (HR 1.09, 95%CI 0.84–1.42, $p_{\text{non-inferiority}}=0.0330$). Event free survival was longer in patients with MGMT-promotor methylation in the chemotherapy group (8.4 months (95%CI 5.5–11.7) vs. 4.6 (4.2–5.0)), with the opposite in patients without MGMT-promotor methylation (3.3 months (3.0–3.5) vs. 4.6 months (3.7–6.3)). The Nordic phase 3 trial randomized 291 patients older than 60 years with glioblastoma to temozolomide or radiotherapy (hypofractionated or standard) (Malmström et al., 2012). mOS was significantly longer with temozolomide than with standard radiotherapy (8.3 vs. 6.0 months HR 0.7; 95%CI 0.52–0.93, $P = 0.01$). Survival between patients treated with hypofractionated radiotherapy and temozolomide was similar. Patients treated with temozolomide with MGMT methylated tumours had significantly longer survival than those without methylation (9.7 vs. 6.8 months, HR 0.56 95%CI 0.34–0.93 $P = 0.02$), but no difference was noted in patients in the radiotherapy group (HR 0.97 95%CI 0.69–1.38 $P = 0.81$). Thus, while these trials support temozolomide use in elderly patients with MGMT-promotor methylated tumours, benefit in unmethylated tumours is unclear with some evidence suggesting inferiority. The EORTC 26062-22061 phase III trial randomized 562 elderly patients (>65 years) with newly diagnosed glioblastoma to short-course radiotherapy (40 Gy in 15 fractions) with or without concomitant and adjuvant temozolomide (Perry et al., 2016). The addition of temozolomide was well tolerated and increased mOS from 7.6 to 9.3 months (HR 0.67 (95%CI 0.56–0.8) $P < 0.0001$). mOS almost doubled in patients with MGMT methylation (13.5 vs. 7 months; HR 0.53 (0.38–0.73) $P = 0.0001$), but was not statistically significant in patients with MGMT unmethylated tumours (10 vs. 7.9 months, HR 0.75 (0.56–1.01, $P = 0.055$).

Thus in patients unlikely to tolerate chemoradiotherapy, such as the elderly, a potential treatment strategy is to consider temozolomide in those with MGMT-promotor methylated tumours, and radiotherapy in those with unmethylated tumours.

Recurrence

There is no standard treatment for recurrent disease and clinical trials have failed to establish significant clinical benefit, although lomustine or PCV (Table 12.1) are most frequently used. Investigational clinical trials are appropriate if patients have already received chemotherapy.

Modest benefit of single-agent lomustine has been confirmed following use as a control group in several trials. For example, the REGAL phase 3 trial investigated cediranib (a VEGF inhibitor) with or without lomustine versus lomustine monotherapy. The mOS was 9.8 months and PFS was 82 days, with no additional benefit in cediranib containing arms (Batchelor et al., 2013).

Controversies

Bevacizumab

Use of bevacizumab as standard therapy varies. Bevacizumab is licensed for recurrent disease in the United States. However, it failed to meet the requirements for licensing in the EU. A non-comparative randomized phase 2 trial of bevacizumab monotherapy versus combination with irinotecan in 167 patients with recurrent glioblastoma (Friedman et al., 2009) demonstrated a 6-month PFS of 42.6% with bevacizumab versus 50.3% in combination with irinotecan, compared with a stated historical control of 15%. The primary endpoint of radiographic response was 28.2% with bevacizumab and 37.8% in combination, compared with a stated historical control of 5–10%. There was no difference in overall survival. It is difficult to determine the clinical significance of these imaging-based end-points due to the potential for pseudoresponse. However, there was a trend for patients taking corticosteroids to take stable or decreasing doses over time. The only reported study including a control arm without bevacizumab is the BELOB phase 2 trial of single-agent bevacizumab or lomustine versus a combination in 153 patients with recurrent glioblastoma. This trial did not show a survival benefit with bevacizumab monotherapy versus lomustine, although an OS at 9 months of 63% (95%CI 49–75) with bevacizumab in combination with lomustine (versus 43% (29–57) with lomustine alone, and 38% (25–51) with bevacizumab alone), met the prespecified criteria for the phase 3 study which is ongoing (Taal et al., 2014).

Two phase 3 trials have studied the use of bevacizumab in addition to temozolomide chemoradiotherapy in newly diagnosed glioblastoma. The AVAGlio study randomized 921 patients to receive either bevacizumab or placebo until progression (Chinot et al., 2014). The RTOG0825 trial randomized 637 patients to either bevacizumab or placebo for up to 12 cycles (Gilbert et al., 2014). Both trials showed no difference in OS with bevacizumab but a significant increase in PFS (10.5 vs. 6.2 months in AVAGlio (HR 0.64 95%CI 0.55–0.74 P <0.001); 10.7 vs. 7.3 months in RTOG0825 (HR 0.79 95%CI 0.66–0.94 P = 0.007)). Given the uncertainty with pseudo-response, quality of life assessment was included as a secondary endpoint in both trials, with contradictory results. While the AVAGlio study reported longer maintenance of baseline health-related quality of life, performance status, and reduced use of glucocorticoids with bevacizumab, the RTOG0825 study found an increased symptom burden and worsened quality of life with bevacizumab. Thus, the use of bevacizumab in newly diagnosed glioblastoma remains unclear.

Carmustine wafers (Gliadel®)

There have not been any prospective trials comparing interstitial carmustine wafers (Gliadel®) to the current standard of temozolomide chemoradiotherapy. Surgery with or without Gliadel® wafer insertion followed by temozolomide chemoradiotherapy was evaluated in a single retrospective study of 65 patients with high-grade glioma and found no difference in median relapse free survival in those with Gliadel® insertion versus those without (12.9 vs. 14 months P = 0.89) (Noël et al., 2012). A Cochrane systematic review studied the clinical effectiveness in newly diagnosed high-grade gliomas of Gliadel® versus placebo wafers, in combination with adjuvant radiotherapy (Hart et al., 2011). Two randomized controlled trials meeting the inclusion criteria were identified (n = 32 and 240). Overall, Gliadel® increased OS (14 vs. 11.5 months HR 0.65, 95%CI 0.48–0.86, P = 0.003) with no significant increase in side effects apart from increased intracranial hypertension in one study (P = 0.019). Although reporting improvements in OS similar to temozolomide chemoradiotherapy these should be interpreted with caution. In the larger trial grade III tumours (associated with both increased survival and response to chemotherapy) were more frequent in the Gliadel® group (16 vs. 12%). In a subgroup analysis of glioblastoma patients the treatment benefits of Gliadel® were not statistically significant (P = 0.1), although became significant (P = 0.04) if adjusted for baseline prognostic factors (age, performance status).

No survival benefit of Gliadel® wafer use at recurrence was found by the Cochrane review in a single identified trial which randomized 222 patients with recurrence of high-grade glioma treated with surgery and radiotherapy to Gliadel® wafers or placebo (mOS 31 vs. 23 weeks HR 0.83 95%CI 0.62–1.10 P = 0.19), although the authors reported a significant treatment effect if prognostic factors were considered (Brem et al., 1995).

Thus the benefit of Gliadel® wafer insertion is unclear and use varies between different centres. See **Box 12.1**.

WHO grade III glioma

Anaplastic oligodendroglioma (IDH mutant, 1p19q codeleted), anaplastic astrocytoma (IDH mutant), and anaplastic astrocytoma (IDH wild type) are the most common grade III gliomas in the 2016 WHO Classification of CNS Tumours (Louis et al., 2016). Traditionally, grade III tumours were treated with surgery followed by adjuvant radiotherapy, with chemotherapy given at relapse. However, there is accumulating evidence that the addition of chemotherapy to radiotherapy improves survival, particularly in molecularly favourable subgroups.

The EORTC-26951 trial compared radiotherapy with or without PCV chemotherapy in 368 patients with anaplastic oligodendroglioma (van den Bent et al., 2013) and demonstrated improved overall survival with the addition of chemotherapy (42.3 vs. 30.6 months HR 0.75 95%CI 0.6–0.95). In a subgroup analysis of 80 cases where 1p19q codeletion status could be tested, increased benefit from the addition of chemotherapy was found in patients with codeleted tumours (mOS not reached vs. 112 months, HR 0.56 (0.31–1.03)) compared to those without codeleted tumours (mOS 25 vs. 21 months, HR 0.83 (0.6–1.10)). The RTOG9402 phase 3 trial further compared radiotherapy with or without PCV chemotherapy in 289 patients with anaplastic oligodendroglioma (Cairncross et al., 2013). Although overall the increase in survival with PCV was not statistically significant (4.6 vs. 4.7 years HR 0.79 95%CI 0.61–1.04 P = 0.1), the median survival in patients with 1p/19q codeleted tumours receiving PCV-RT was twice that receiving RT alone (14.7 vs. 7.3 years HR 0.59 95%CI 0.37–0.95 P = 0.03), with no difference found in non-codeleted tumours. Subsequent analysis identified that patients with IDH mutated tumours also derived benefit from the addition of PCV (mOS 9.4 vs. 5.7 years HR 0.59 95%CI 0.40–0.86 P = 0.006) (Cairncross et al., 2013). Of note, survival benefit only became apparent after long-term follow-up, both trials initially reported no increase in survival with chemotherapy.

The addition of temozolomide to radiotherapy, improved survival in the published interim analysis of the CATNON trial which enrolled 748 patients with anaplastic gliomas without 1p19q codeletion (HR 0.645 (95%CI 0.45–0.926), P = 0.0014) (Van Den Bent et al., 2016).

The current practice in grade III tumours is surgery with radiotherapy. Additionally, patients with 1p/19q codeleted tumours receive adjuvant PCV chemotherapy. Those without 1p/19q codeletion receive temozolomide, and the final results from the CATNON trial are awaited. The clinical outcomes of patients with IDH wild type anaplastic astrocytoma are similar to glioblastoma, and many clinicians therefore feel it is appropriate to treat these patients with the same regimens used in glioblastoma. This approach is being investigated in the CATNON trial, with three chemotherapy subgroups: RT with concurrent temozolomide, RT followed by adjuvant temozolomide, and RT with both concurrent and adjuvant temozolomide.

See **Box 12.2**.

Low-grade glioma (WHO grades I and II)

Grade I tumours are considered benign, with no identified role for chemotherapy. While traditionally grade II tumours were not treated with chemotherapy until relapse, there is accumulating evidence that earlier chemotherapy improves survival.

The RTOG-9802 phase 3 randomized trial in 254 patients with high-risk grade II gliomas found an improvement in mOS from 7.8

Box 12.1 Case study 1

The patient in **Figure 12.2** was diagnosed with glioblastoma multiforme (Panel A) after presenting with dysphasia. He had surgical debulking in October 2011 followed by adjuvant chemoradiotherapy and six cycles of maintenance temozolomide, completed in August 2012 (B). Following tumour progression in February 2014 (C) he had a second surgical debulking with three cycles of adjuvant temozolomide. After a further recurrence in May 2014 (D), he commenced a combination of lomustine, bevacizumab, and valganciclovir, followed by ipilimumab. He had a clear response to treatment (E), but relapsed in February 2015. He subsequently commenced further therapies. He died in September 2015.

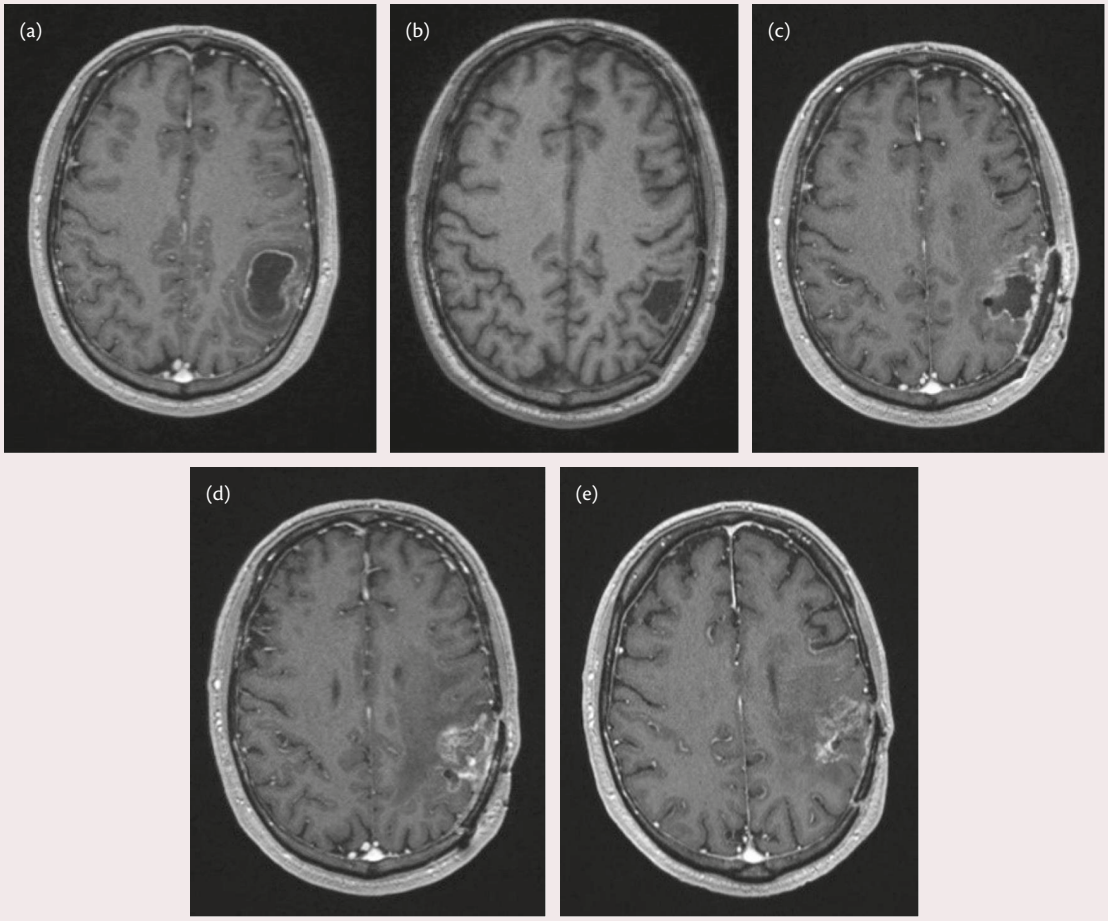

Fig. 12.2 MRI brain (T1 + gadolinium).

to 13.3 years (HR 0.59 $P = 0.03$) and PFS from 4 to 10.4 years (HR 0.5 $P = 0.002$) with radiotherapy followed by PCV chemotherapy compared with radiotherapy alone, with increase in 10 year survival to 60% from 40% (Buckner et al., 2016). Oligodendrogliomas were the most sensitive to chemotherapy, with non-significant benefit in astrocytomas. Patients with IDH mutated tumours had significant survival benefit from the addition of PCV (HR 0.42 (0.2–0.86) $P = 0.02$) but conclusions were not drawn for patients with IDH wild type or 1p19q codeleted tumours.

Chemotherapy alone versus radiotherapy alone is under investigation in the EORTC-22033 phase 3 randomized trial of temozolomide chemotherapy versus radiotherapy in 477 patients with progressive, symptomatic, or high-risk low-grade glioma. Preliminary analysis has shown no difference in progression free survival, with a trend for a reduced PFS in patients without 1p deletion treated with temozolomide and a possible increased OS in patients with 1p-deletion treated with temozolomide (Baumert et al., 2013).

In relapsed disease, the EORTC-26972 prospective phase 2 trial demonstrated the clinical efficacy of temozolomide in 28 patients with oligodendroglioma who had relapsed after initial treatment with PCV (van den Bent et al., 2003). Some 25% of patients had an objective response (95%CI 11–45%) with a 6- and 12-month PFS of 19 and 11%, respectively, and a median time to progression for responding patients of 8 months.

Patients with low-grade tumours that are deemed low-risk adopt a 'watch-and-wait' approach and do not receive adjuvant chemotherapy or radiation. However, there are no standard criteria to determine risk. Subtotal resection, age over 40 years, and new or worsening symptoms were among inclusion criteria for the aforementioned trials in an attempt to stratify patients as high risk. Molecular profiling of tumours can assist in identifying those at

Box 12.2 Case study 2

Following diagnosis with an anaplastic oligodendroglioma (WHO grade III, 1p/19q deletion), the patient in **Figure 12.3** had a left craniotomy and debulking in February 2006 followed by adjuvant chemoradiotherapy and maintenance temozolomide chemotherapy. The patient remained clinically stable despite subtle incremental growth on serial imaging until September 2014 when she developed focal seizures and weakness in her right arm (MRI, A), She received six cycles of PCV chemotherapy with almost complete resolution of the tumour (B).

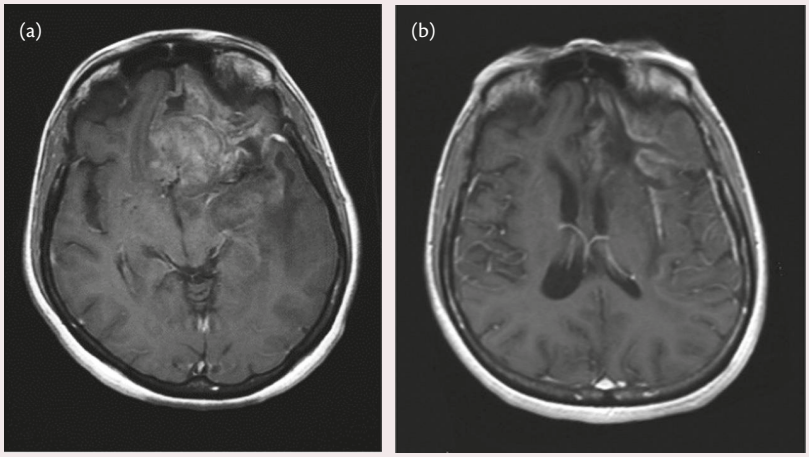

Fig. 12.3 MRI brain (T1 + gadolinium) prior (A) and following (B) PCV chemotherapy with almost complete resolution of the midline mass

high risk with poor prognosis, and those more likely to respond to chemotherapy.

Novel chemotherapeutics

The poor prognosis in patients with high-grade gliomas and limited benefit from current therapies, particularly in the recurrent setting, necessitate the development of novel therapies. The expansion of our understanding of molecular markers, gene expression, and epigenetics should afford multiple new targets for therapies. It will be vital to accurately determine individual patients that are likely to benefit from novel therapeutics to gain access to otherwise prohibitively expensive new medications.

Alternative delivery mechanisms are also in development to expose tumours to therapies that are unable to penetrate the blood–brain barrier. Examples include nanoparticles which increase blood–brain barrier penetration through reduced adhesive interactions, and convection enhanced delivery which administers chemotherapy directly into a resection cavity through intraparenchymal catheters inserted at surgery.

Targeted therapy

Despite identification of suitable molecular targets with efficacy in other tumour types, results from clinical trials of targeted therapies in brain tumours have been disappointing.

For example, EGFR is overexpressed in approximately 40% of glioblastomas, and EGFR targeted therapies are used routinely in lung, head, neck, and colorectal cancers. Despite promising activity in earlier trials, phase 3 trials of the EGFR targeted monoclonal antibody nimotuzumab and EGFRvIII targeted vaccine rindopepimut failed to show any survival benefit. While first generation tyrosine kinase inhibitors (e.g. erlotinib, gefitinib, lapatinib) have been ineffective in glioblastoma, second generation inhibitors are currently in clinical trials (Kang and Adamson, 2015).

Antiangiogenics are the only targeted therapies to demonstrate even limited benefit in clinical trials, as described earlier with bevacizumab. Other agents that target angiogenesis and invasion, such as cilengitide (an integrin inhibitor) have failed in clinical trials (CENTRIC, Stupp et al., 2014), although other therapies that target this pathway are being investigated in early phase clinical trials (e.g. the FAK inhibitor GSK2256098).

BRAF inhibitors such as dabrafenib and vemurafenib have revolutionized the treatment of BRAFV600 mutated tumours, with enhanced efficacy with the addition of the MEK inhibitor trametinib to overcome BRAF resistance (Robert et al., 2015). Case studies and 'basket' clinical trials have reported efficacy in progressive BRAFV600 mutated gliomas following treatment with radiotherapy and cytotoxic chemotherapy (Hyman et al., 2015; Brown et al., 2016). However, it is unclear whether patients would receive increased benefit from earlier use of BRAF inhibitors.

There are several reasons for the repeated failures to demonstrate efficacy in clinical trials despite promising preclinical activity. In order to be an effective target for therapy, targets must be present in all malignant cells, and the target must be critical for growth or invasion of the tumour. Despite an increased understanding of the molecular profiles of gliomas, no molecular driver has yet been established (Kang and Adamson, 2015). Are failures inevitable because the colossal mutational load within brain tumours creates tumour heterogeneity with no single driver mutation to target, or have we simply not yet identified a potential therapeutic target? Could potentially beneficial drugs be hidden within unsuccessful trials, as they were administered to overly-heterogeneous patient groups, hiding a cohort of patients that may benefit if an appropriate molecular marker is identified (note **Box 12.3**)?

Box 12.3 Case study 3

The patient in **Figure 12.4** had primary surgical resection of a right parietal glioblastoma multiforme in October 2008, with adjuvant chemoradiotherapy and maintenance temozolomide. She subsequently relapsed and had surgical debulking in June 2009, but relapsed shortly after (MRI, A) and started cilengitide. She remained clinically stable with a significant reduction in enhancing disease for over 3 years (MRI, B). Her tumour progressed and she stopped cilengitide in December 2012. She subsequently started carboplatin chemotherapy in February 2013 with no objective response and died three months later.

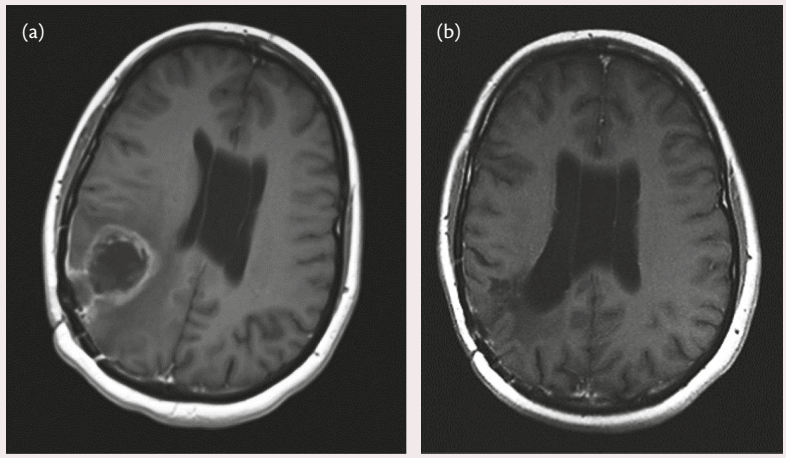

Fig. 12.4 MRI brain (T1 + gadolinium) prior to starting cilengitide (June 2009, A) and during treatment (March 2011, B) showing significant reduction in tumour enhancement

Immunotherapy

The immune system can potentially identify and selectively target specific tumour antigens and lead to durable response through immunological memory. It is thus an attractive therapeutic strategy that has led to breakthroughs in the management of melanoma and lung cancer, and is an exciting research area in other tumour types including brain tumours. Despite having active T cells against tumour antigens, most patients do not produce an adequate immunological response to destroy tumour cells. Cancer cells induce an immunosuppressive micro-environment through MHC down-regulation, production of inhibitory cytokines, regulatory T-cell infiltration, and increased expression of immune checkpoint receptors. This leads to tolerance and evasion from cells capable of inducing an effective immune response such as dendritic cells, natural-killer cells, and effector T cells. The CNS was historically considered an immunoprivileged site, distinct from the systemic immune system, due to the perceived inability of leucocytes to penetrate the blood–brain barrier, an absence of native T cells within the CNS, and no overt lymphatic drainage. However, there is disruption of the blood–brain barrier in gliomas, and it is now recognized that the CNS fully interacts with the systemic immune system. Lymphatic drainage from the CNS has been found in deep cervical lymph nodes (Reardon et al., 2014). Immunotherapy aims to modulate the immunosuppressive tumour micro-environment (*passive*) or stimulate tumour-specific immunity (*active*). A limited selection of examples are outlined next.

Passive immunotherapy

Programmed-death 1 (PD-1) is a protein receptor expressed on the surface of T cells and pro-B cells. When bound to its ligands (PD-L1/PD-L2), it dampens the immune response, through promoting apoptosis in antigen specific T cells and reducing apoptosis in regulatory T cells. It functions as an *immune checkpoint*: promoting self-tolerance and preventing autoimmunity. Cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) is a further immune checkpoint that down-regulates immune responses when bound to CD80 or CD86 on antigen-presenting cells. Increased tumour expression of checkpoint receptors contributes to tolerance of tumours by the immune system. Nivolumab and ipilimumab are monoclonal antibodies against anti-PD-1 and CTLA-4 (*checkpoint* inhibitors) licensed for use in melanoma and squamous-cell lung cancer, with trials underway in brain tumours. Non-specific T-cell proliferation in patients using these drugs can lead to toxicities including colitis, hepatitis, diffuse rash, ocular changes, and endocrine dysregulation (Reardon et al., 2014). The Checkmate-143 trial is evaluating nivolumab with or without ipilimumab in recurrent glioblastoma. Published preliminary data in 20 patients report an encouraging OS at 6 months of 75% (Sampson et al., 2015).

Other potential immunomodulators under investigation include the use of cytokines such as interferon interleukin-1 to generate a pro-inflammatory state, and the suppression of regulatory T cells through inhibitors such as basiliximab against CD25 and IL-2 (Kang and Adamson, 2015).

Active immunotherapy

Peptide therapy involves the use of vaccines against tumour-specific or tumour-associated antigens. IMA-950 is a vaccine containing 11 HLA-binding tumour-associated peptides identified on human leukocyte antigen (HLA) surface receptors in primary human glioblastoma tissue. A phase 1 trial of 45 patients reported promising results with a 6-month PFS of 74% (Halford et al., 2014).

Adoptive therapies activate immune cells ex-vivo. Dendritic cells (DCs) are the most potent antigen-presenting cells and can mediate

long-lasting immunity, but are not frequently activated against tumour antigens due to the immunosuppressive tumour microenvironment. Several dendritic cell vaccine therapies are in development to overcome this local immunosuppression. With DCVax-L (currently in phase 3 trials), dendritic cells are isolated from the patient by leukapheresis, exposed to tumour antigens from a lysate taken at surgery, and then re-administered to the patient (Northwest Biotherapeutics, 2014).

Chimeric antigen receptors insert receptors for tumour-associated antigens onto effector T cells. Several targets are currently under investigation in clinical trials in glioblastoma, including HER-2 (overexpressed in 80% of glioblastoma) (NCT01109095) and EGFRvIII (NCT01454596).

Key points

- Chemotherapy can improve survival of patients with brain tumours
- Temozolomide chemoradiotherapy is the current standard of care in newly diagnosed glioblastoma following surgery. In elderly patients unlikely to tolerate chemoradiotherapy with a MGMT-promotor methylated tumour receive more benefit from chemotherapy than radiotherapy
- Gliadel® wafer use has not been prospectively tested against temozolomide chemoradiotherapy
- At recurrence of glioblastoma, there is modest benefit from lomustine or temozolomide re-challenge. Bevacizumab may prolong PFS and decrease use of corticosteroids
- Anaplastic oligodendrogliomas (WHO grade III) with 1p/19q codeletions are treated with PCV chemotherapy following radiotherapy
- 'High-risk' low-grade gliomas, particularly with 1p/19q codeletion should be treated with chemotherapy
- Targeted therapies and immunotherapy may form the basis of future treatment regimens.

Surgical techniques in the management of intrinsic tumours

Shawn Hervey-Jumper and Mitchel Berger

Introduction

Surgical resection plays a central role in the management of intrinsic brain tumours, and there is a growing body of evidence concerning the value of extent of resection to improve patient outcome and quality of life. Maximal resection can be difficult to achieve due to tumour proximity to eloquent structures and uncertainty as to tumour margins. Direct stimulation mapping, functional neuronavigation, intraoperative MRI, and fluorescence-guided surgery are all useful tools to improve the extent of tumour resection while minimizing morbidity. Current evidence suggests that a more extensive surgical resection is associated with longer survival and improved quality of life for patients with either low- or high-grade gliomas. This chapter emphasizes the evidence supporting the role of surgery for intrinsic brain tumours, their surgical neuroanatomy, and techniques to maximize the extent of resection while minimizing morbidity.

Surgical neuroanatomy

Cerebral hemispheres and cranio-cerebral relationship

(See Fig. 2.2, Chapter 2.)

The adult cerebrum is divided into two hemispheres containing frontal, parietal, central, temporal, occipital lobes, and the insula. There are six principal sulci, which are continuous: the Sylvian, callosal, parieto-occipital, collateral, central, and calcarine sulci. There are two interrupted sulci: the precentral and inferior temporal sulci.

The frontal lobe is separated by two main sulci: the superior and inferior frontal sulci, which divide the lateral surface of the frontal lobe into the superior, middle, and inferior frontal gyri. These extend from the precentral sulcus and are oriented in the anterior-posterior direction. Running parallel to the central sulcus is the precentral sulcus, which lies at the posterior end of the frontal lobe. The inferior frontal gyrus is further divided by the anterior ascending, and the posterior rami of the Sylvian fissure into the pars orbitalis, triangularis, and opercularis. A readily recognizable landmark seen at the intercepting point between the superior frontal and precentral sulci is the hand region of the motor cortex, which has the morphology of the Greek letter 'Ω' (omega).

Boundaries of the parietal lobe include the interhemispheric fissure medially, the Sylvian fissure and temporal-occipital line inferiorly, the central sulcus anteriorly, and the lateral parietal-temporal line posteriorly. There are two main sulci in the parietal lobe: postcentral and intraparietal sulci. The intraparietal sulcus divides the surface of the parietal lobe into the superior and inferior parietal lobules. The superior parietal lobule is superomedial and smaller and continues as the precuneus medially, whereas the inferior parietal lobule comprises the supramarginal and angular gyri. The supramarginal gyrus is the posterior continuation of the superior temporal gyrus, and the angular gyrus is the posterior continuation of the middle temporal gyrus.

The superior limitation of the temporal lobe is the Sylvian fissure. The temporal lobe has the superior and inferior temporal sulci, which divide the temporal lobe into superior, middle, and inferior temporal gyri. These three temporal gyri converge anteriorly to form the temporal pole. Boundaries of the occipital lobe include the calcarine sulcus medially and the parietal-temporal line laterally. The occipital lobe is composed of several short horizontal sulci, which divide the lateral occipital lobe into superior and inferior occipital gyri.

Separating the frontal, parietal, and temporal lobes is the Sylvian fissure, which is composed of a deep and a superficial portion. Deep to the Sylvian fissure lies the insula. The superficial portion of the Sylvian fissure contains a stem and three rami. The stem extends medially from the uncus to the lateral end of the sphenoid wing, where it divides into the anterior horizontal, anterior ascending, and posterior rami. The deep portion of the Sylvian fissure is divided into sphenoidal and operculoinsular compartments (Ribas et al., 2015). The sphenoidal compartment arises anteriorly in the region of the limen insula and extends laterally towards the anterior perforated substance. The operculoinsular compartment is formed by an opercular cleft (between the opposing lips of the frontoparietal and temporal operculae) and an insular cleft (with a superior limb located between the insula and frontoparietal opercula, and an inferior limb between the insula and temporal operculum) (Ribas et al., 2015). At

the threshold between the carotid cistern medially and the Sylvian fissure laterally is the limen insula. The central sulcus of the insula divides the lateral surface of the insula into an anterior zone, which is divided into three short gyri and a posterior zone formed by the anterior and posterior long gyri (Ribas et al., 2015). Encircling the insula is the circular sulcus, which separates it from the overlying opercula.

White matter tracts

(See Fig. 35.5, Chapter 35.)

The contemporary view of human brain function has shifted from a rigid organization to a more dynamic view of brain processing. Large-scale subcortical white matter networks facilitate complex functions such as language, movement, and cognition. Association fibres connect cortical areas of different lobes in the same hemisphere and can be divided into short and long association fibres. Short association fibres connect adjacent gyri, whereas the long association fibres (also known as fasciculi) connect distant gyri and form distinct compact bundles. The primary fasciculi of clinical importance are (1) the superior longitudinal fasciculus, (2) uncinate fasciculus, (3) inferior fronto-occipital fasciculus, and (4) the cingulum. The superior longitudinal fasciculus curves around the insula and connects the frontal, parietal, and temporal lobes. The uncinate fasciculus lies within the anterior insula along the limen insulae, and connects the basal frontal lobe with the temporal lobe. The cingulum resides below the rostrum of the corpus callosum to the parahippocampal gyrus. Connecting the frontal and occipital lobes, as well as the posterior portion of the temporal and parietal lobes, is the inferior fronto-occipital fasciculus (IFOF). The IFOF converges from the frontal lobe just lateral to the basal ganglia, before running alongside the uncinate fasciculus.

Perhaps the most relevant white matter tracts of importance from a neurosurgical perspective are those related to language function. Early models of language organization were derived from language deficits after cortical lesions. In 1861 Jean-Baptiste Bouillaud published a series of patients with long-term speech loss after frontal lobe lesions. These findings were followed by Broca's observation that speech arrest was separate from motor language activations, but represented a distinct inability to articulate language (Chang et al., 2015). Several years later Karl Wernicke described lesions in the posterior superior temporal lobe which caused impaired repetition, naming, and comprehension but intact fluency. Aphasia, or the impairment of language affecting the production or comprehension of speech, can be classified as global aphasia, Broca's aphasia, Wernicke's aphasia, mixed non-fluent aphasia, or anomic aphasia.

Global aphasia is the most severe form of aphasia and describes patients who can produce very few recognizable words and comprehend only occasional spoken language. Patients with global aphasia can therefore neither read nor write. Broca's aphasia have reduced laborious and clumsy speech output marked by shorter sentences including less than four words. Patients with Broca's aphasia typically comprehend speech and maintain their ability to read, but are unable to write.

The hallmark of Wernicke's aphasia is impaired comprehension while speech fluency is preserved. Reading and writing are often impaired with Wernicke's aphasia. Mixed non-fluent aphasia is classified scant, effortful speech similar to severe Broca's aphasia however patients have limited comprehension resulting in difficulties reading and writing. Patients with anomic aphasia have an inability to name nouns and verbs, which results in relatively normal fluency but speech content is vague as patients have difficulty finding words.

Current models of language organization are based on dorsal and ventral stream processing (Chang et al., 2015). The dorsal stream is located primarily within the dominant hemisphere and critical for sensorimotor integration while the ventral stream is bilateral and essential for language comprehension. Using subcortical electrical stimulation mapping we now have an evolving but more complete understanding of the functional networks essential for language processing. The superior longitudinal fasciculus (SLF) is composed of four major components (SLF I, II, III, and SLF-temporoparietal (tp)) (Chang et al., 2015). While SLF I is not involved in language processing, SLF II connects the premotor cortex to the angular gyrus, SLF III connects the ventral prefrontal cortex with the supramarginal gyrus and SLF-tp connects the inferior parietal lobule with the posterior superior temporal lobe. Stimulation mapping of the SLF II and III causes dysarthria while stimulation of both SLF III and SLF-tp causes errors or language repetition. The arcuate fasciculus was classically thought to connect Broca's and Wernicke's areas. It is now understood that the arcuate fasciculus connects fronto-opercular and posterior temporal cortical sites in a much more diverse fashion then originally appreciated. Stimulation of the arcuate fasciculus causes anomia and phonemic paraphasias, while lesions to this subcortical pathway results in conduction aphasia (intact comprehension, fluent speech production but poor repetition; see Chang et al., 2015).

Neurological deficits

Neurological deficits from intrinsic brain tumours are highly variable depending on tumour location and the extent of disease. Non-specific physical findings can occur with elevated intracranial pressure, including papilloedema (oedema of the head of the optic nerve associated with engorgement of retinal veins) and oculomotor palsy (due to uncal herniation). Frontal tumours may result in impaired gait, abulia, personality changes, and hemiparesis. Aphasia suggests involvement with cortical language centres located in the dominant frontal or temporal lobes. Temporal lobe tumours may also result in memory loss, impaired auditory discrimination, seizures, or contralateral superior quadrantanopia. Parietal lobe tumours may lead to impaired sensory function, distractibility, contralateral inferior quadrantanopia, aphasia, or anosognosia. Occipital lobe tumours result in visual deficits, while brainstem tumours may impair cranial nerves and lead to long-tract signs. Pineal tumours that compress the midbrain tectum result in Parinaud's syndrome, which includes upgaze palsy, eyelid retraction (Collier's sign) or ptosis, loss of pupillary light reflex (light-near dissociation where the pupil does not respond to light but constricts on accommodation), and retraction-convergence nystagmus.

Headaches are the most common symptom in brain tumour patients, occurring in at least 50% of patients at some point. Classically, brain tumour patients present with headaches that are worse upon waking in the morning and may often be severe enough to wake a patient from sleep.

Headaches are thought to occur as a result of temporary increases in intracranial pressure caused by recumbency and elevations in the partial pressure of carbon dioxide (PCO_2) during sleep. The combination of elevated intracranial pressure due to mass effect from

the presence of tumour and cerebral vasodilation due to increased pCO_2 causes additive increases in intracranial pressure, ultimately resulting in headache.

Preoperative surgical management

Preoperative planning

Preoperative clinical evaluation should include baseline sensorimotor and language assessment performed 24–48 hours prior to surgery (Hervey-Jumper et al., 2015).

Preoperative imaging includes brain MRI with and without gadolinium enhancement, DTI of white matter pathways (including the corticospinal tract, superior longitudinal fasciculus, arcuate fasciculus, uncinate fasciculus, and interior orbitofrontal fasciculus), task-based functional brain MRI (fMRI) (Deng et al., 2015; Ille et al., 2015) (Fig. 13.1) and perfusion MRI.

Preoperative anatomical imaging provides information regarding tumour location, vascularity, mass effect, peritumoural oedema, and proximity to areas of potential functional significance. Additionally, these anatomical studies can be reconstructed to create three-dimensional models that can be used during surgery (neuronavigation). DTI defines the integrity of white matter tracts surrounding a tumour and is commonly used in the planning of both surgical and radiation therapy (Alexander et al., 2007; Berman et al., 2007; Bello et al., 2008). Task-based fMRI uses the blood oxygenation level dependent (BOLD) signal to identify cortical and subcortical regions of activation to create an operative corridor or plan for resection that minimizes risk to eloquent surrounding structures (Bogomolny et al., 2004; Nimsky et al., 2004). Finally perfusion MRI is useful for evaluating tumour angiogenesis, endothelial permeability, and response to treatment.

In combination anatomical MRI, functional MRI, DTI tractography, and perfusion MRI enable clinicians to make more accurate preoperative diagnoses and provide information regarding the interface of tumour tissue with the adjacent functional cortical and subcortical pathways.

Medical management

The management of intrinsic brain tumours begins with surgery aimed at establishing the pathological diagnosis and maximizing safe resection. Preoperative medical management and surgical planning are critical to the success of any surgical intervention. Corticosteroids are commonly used preoperatively to reduce symptoms of mass effect and peritumoural vasogenic oedema. Though timing and dose of corticosteroids vary by surgeon preference, a common regimen for adults is 4–6 mg of dexamethasone intravenously or by mouth every six hours.

Patients presenting with seizures should be initiated on an anticonvulsant. However, with few exceptions, there is no data to suggest that the prophylactic use of anticonvulsants reduces the risk of new onset seizures in patients with intrinsic brain tumours (Chang et al., 2005; Chang et al., 2008; de Oliveira Lima, 2015). Even so, in cases of tumour involvement in highly epileptogenic areas such as the motor cortex, patients with low-grade gliomas, multiple metastatic tumours with large amounts of vasogenic oedema, or leptomeningeal disease are often treated with prophylactic seizure medications. Phenytoin was historically the first-line antiepileptic agent; however, phenytoin levels must be monitored to ensure a therapeutic serum drug concentration. Levetiracetam is now commonly used due to its low toxicity, minimal side-effect profile, and lack of need to monitor serum levels.

Intraoperative surgical management

Biopsy and extent of resection

In recent years, a number of studies have enhanced our understanding of the impact of tumour resection on progression-free overall survival in patients with intrinsic brain tumours (Hervey-Jumper and Berger, 2014). However, the initial goal of surgery is to establish a definitive histological diagnosis. The decision to offer surgical resection versus biopsy depends on tumour location and size, patient age, and performance status. One must balance the natural history of the tumour and its propensity to transform and grow over

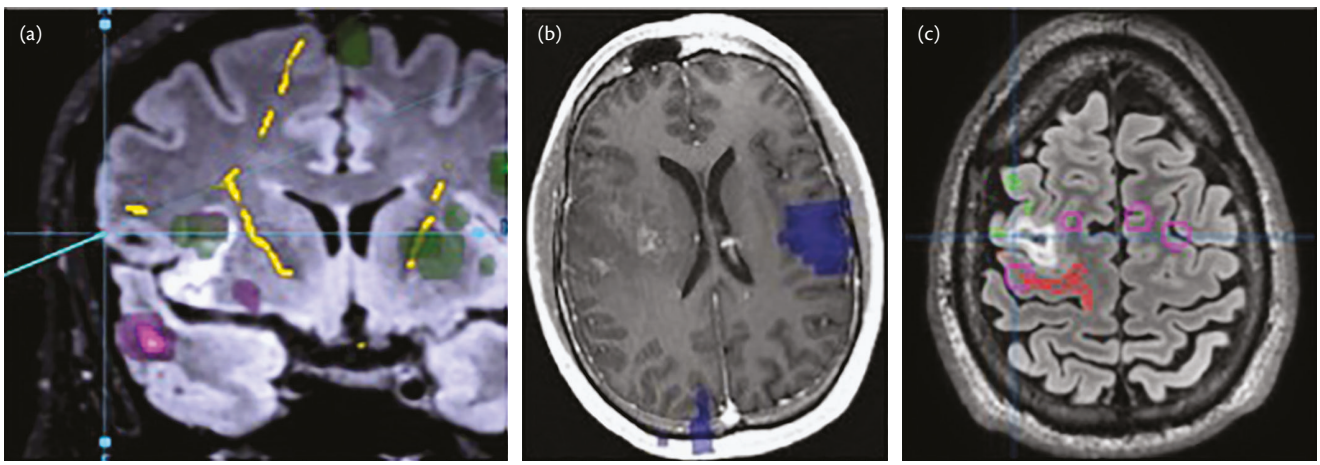

Fig. 13.1 Imaging modalities such as fMRI, MEG, and DTI provide valuable information for both preoperative and intraoperative use. (A) fMRI reveals language activation sites in purple. (B) MEG similarly identifies activation of verb generation in blue. (C) DTI identifies corticospinal fibres running posterior and superior to longitudinal fasciculus fibres lateral to the glioma.

time. Recent data places maximal safe surgical resection alongside patient age, tumour histology, tumour performance status, and molecular markers as predictive of long-term outcome (Hervey-Jumper and Berger, 2014). For this reason, maximal safe resection is preferred over biopsy.

The value of surgical resection for intrinsic brain tumours (particularly low-grade glioma) has been validated by a number of studies illustrating a survival benefit of 60–90 months with greater than 90% resection (Smith et al., 2008). In a large population-based series of Norwegian patients, early maximal resection was superior to biopsy and watchful waiting with respective 5-year survival rates of 74% and 60%, illustrating the advantage of resection over watchful waiting (Jakola et al., 2012). Additionally, 90% extent of resection in low-grade gliomas delays and reduces malignant transformation and improves survival. Seizure control is also enhanced after gross total resection of intrinsic brain tumours (Chang et al., 2008).

Image-guidance

For the brain tumour surgeon, functional and anatomic image-guidance is an essential part of determining the risks associated with surgery and for consulting patients about potential postoperative neurological outcomes. Image-guidance also allows for a generalized preoperative impression of where a functional pathway might be displaced by a space-occupying lesion. Neuronavigation is widely used in brain tumour surgery and can be integrated with DTI tractography, magnetoencephalograpy (MEG), or fMRI (commonly referred to as 'functional neuronavigation') to identify cortical and subcortical areas of potential sensory, motor, language, and visual significance (Trinh et al., 2014) (**Fig. 13.1**). Neuronavigation can therefore generate individualized maps of functional areas and their relationship with mass lesions within the brain. Variability in individual neuroanatomy, distortion due to mass lesions, and functional re-organization caused by plasticity make classic anatomic identification of functional areas insufficient (Thiel et al., 2001; Duffau, 2006). Compared with direct cortical stimulation, fMRI has a sensitivity and specificity of 91% and 64% for identification of Broca's area, 93% and 18% for identification of Wernicke's area, and 100% and 100% in motor areas, respectively (Bizzi et al., 2008).

Resting state coherence measured with MEG or MRI is capable of mapping functional connectivity of the brain. Intrinsic brain tumours with decreased resting state connectivity have a relatively low risk of postoperative neurological deficits, while those with increased resting state connectivity are associated with higher risk of postoperative neurological deficits (Guggisberg et al., 2008). These studies are helpful for determining the risks associated with surgery, the optimal surgical approach, and advising patients about potential postoperative neurological outcomes. Identification of subcortical pathways is critical in preventing injury to white matter pathways and preserving function (Sarubbo et al., 2015). While the current gold standard for assessing functional tissue in the cortex and subcortically is intraoperative stimulation testing, it is advantageous to preoperatively and intraoperatively 'visualize' white matter tracts and their spatial relationship to the brain tumour.

Awake craniotomy and neurophysiological monitoring

First employed by Wilder Penfield, direct cortical stimulation mapping allows for the identification of language, motor, and sensory function during surgery for removal of intrinsic brain tumours (Hervey-Jumper et al., 2015). Individual variability and pathway distortion from intrinsic brain tumours makes neuronavigation less reliable. Speech arrest, anomia, and alexia are often located far outside the anatomic boundaries of Broca's area (Sanai et al., 2008). Direct stimulation mapping is the gold standard for identification and preservation of functional areas.

Cortical stimulation depolarizes a focal area of brain, which excites local neurons via diffusion of current using both orthodromic and antidromic propagation. Bipolar stimulation using a 2-mm tip with 5 mm of separation allows for local diffusion and more precise mapping (Nathan et al., 1993). Early mapping techniques utilized large craniotomies with the goal of identifying positive functional sites; however, one can also use smaller exposures with reliance on negative mapping (Sanai et al., 2008). Negative mapping strategies represent a shift in mapping techniques, keeping eloquent areas untouched and free from exposure. The tumour surgeon must balance the goal of maximal resection with preservation of motor and language functional sites.

Specialized neuroanaesthesia is critical for completion of a safe awake craniotomy (Taylor and Bernstein, 1999). Clear communication between neurosurgeon, anaesthesiologist, speech pathologist, and other members of the mapping team ensures accuracy and patient safety. Surgery commences with the application of patient monitors (axillary temperature probe, blood pressure cuff, arterial line) and premedicating with midazolam, fentanyl, or dexmedetomidine prior to positioning (Hervey-Jumper et al., 2015). Sedation is achieved with propofol (up to 100 μg/kg/min) or dexmedetomidine (up to 1 μg/kg/min) and remifentanil (0.07–2.0 μg/kg/hr) (Herrick et al., 1997; Bekker et al., 2001; Olsen, 2008). Sedation continues during Foley catheter insertion and Mayfield head holder pin placement. A scalp block using a mixture of 1% lidocaine with 1:100 000 epinephrine, 0.5% bupivacaine, plus 8.4% sodium bicarbonate is applied by the neurosurgeon. The optimal head positioning that allows for ease of operation, patient comfort, and potential insertion of a laryngeal mask airway must be discussed by neurosurgery and anaesthesia. After skin incision and removal of the bone flap, all sedatives are stopped, after which the patient is asked to take multiple deep breaths to decrease hypercapnia before dural opening. A dedicated intravenous line is filled with a 1 mg per kg bolus of propofol if needed for suppression of an intraoperative grand mal seizure. Topical ice-cold Ringers lactate solution is available on the surgical field at all times for seizure suppression.

Mapping begins with a stimulation current of 1.5–2 mA and increases to a maximum of 6 mA if necessary. A constant current generator delivers 1.25 millisecond biphasic square waves in 4 second trains at 60 Hz. Numerical markers are placed on the surgical field spaced 1 cm apart (**Fig. 13.2**). Continuous electrocorticography is used to improve mapping accuracy, monitor for subclinical seizure activity, and detect after-discharge potentials. All language testing is repeated at least three times per cortical site, and a positive site is defined as the inability to count, name objects, or read words during stimulation at least two out of three times. Language mapping seeks to identify sites responsible for speech arrest, anomia, and alexia with stimulation testing. Speech arrest is defined as discontinuation in number counting without simultaneous motor response. Dysarthria can be distinguished from speech arrest by an absence of involuntary muscle contractions affecting speech (Sanai et al., 2008).

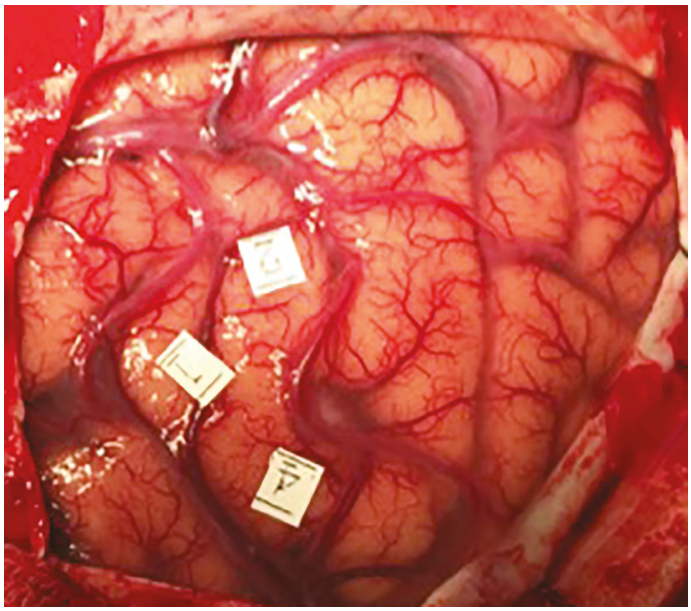

Fig. 13.2 Direct cortical and subcortical stimulation mapping is the gold standard for identification of functional language and sensorimotor areas. Cortical mapping uses numbered markers placed at 1-cm intervals to test regions overlying and directly adjacent to tumour.

5-aminolevulinic acid (5-ALA)

Gross total resection of intrinsic brain tumours can be challenging and it has been well-established that the majority of tumour recurrences occur within a centimetre of the prior resection cavity. Most neurosurgeons overestimate the degree of resection they are able to achieve. 5-ALA is a non-fluorescent amino acid precursor that produces an accumulation of fluorescent porphyrins (mainly protoporphyrin IX) in high-grade gliomas (Stummer et al., 2006). Exogenous 5-ALA results in accumulation of intracellular fluorescent protoporphyrins in malignant glioma, which peak six hours after administration and remain elevated for 12 hours (Stummer et al., 2003). Protoporphyrin IX has an absorption band strongest in the 380 +/- 420 nm spectrum, emitting red fluorescence at 635 nm and 704 nm in the brain. The most common established protocol is 5-ALA administration orally 3 hours before surgery with a goal of tumour removal 4 to 5 hours after 5-ALA administration. A long-pass filter mounted to the surgical microscope allows for tumour visualization as the operator switches between white and violet light (Fig. 13.3).

Several studies have examined the efficacy of 5-ALA to improve the extent of resection and prolong survival for patients with malignant glioma. Complete removal of all fluorescent material ('5-ALA complete resection') offers greater six-month and overall survival in malignant glioma without an increase in postoperative neurological deficits (Stummer et al., 2006). A phase III clinical trial of patients with suspected malignant glioma receiving either conventional white light microsurgery or fluorescence-guided surgery assisted with 5-ALA found 65% of 5-ALA patients received a gross total resection compared with 36% of patients treated with conventional white light microsurgery. Study patients therefore experienced a 50% improvement in six-month progression-free survival (41.0% vs. 21.1%) (Stummer et al., 2006).

Gliadel wafers

Carmustine wafers, also known as Gliadel wafers (GW) (Arbor Pharmaceuticals, LLC, Atlanta, GA) are approved for treatment of newly diagnosed and recurrent high-grade glioma (WHO grades III and IV). Carmustine is an alkylating agent that interferes with DNA synthesis and repair. GWs are biodegradable polymers containing 3.85% carmustine. These polymers are implanted into the resection cavity following surgery for tumour resection, releasing 7.7 mg of drug for roughly 5 days. Widespread use has been limited for several reasons. The safety and efficacy of GW has been an issue of debate, with some published reports illustrating excellent patient tolerance and improved survival, while others have found no improvement in survival by adding carmustine wafers to standard therapies (Xing et al., 2015). Currently the use of carmustine wafers is limited in most settings, given concern regarding wound healing and the likelihood that it will preclude enrolment in subsequent clinical trials.

Deep-seated tumours

Deep-seated tumours remain challenging to treat due to their proximity to important vascular structures and location around

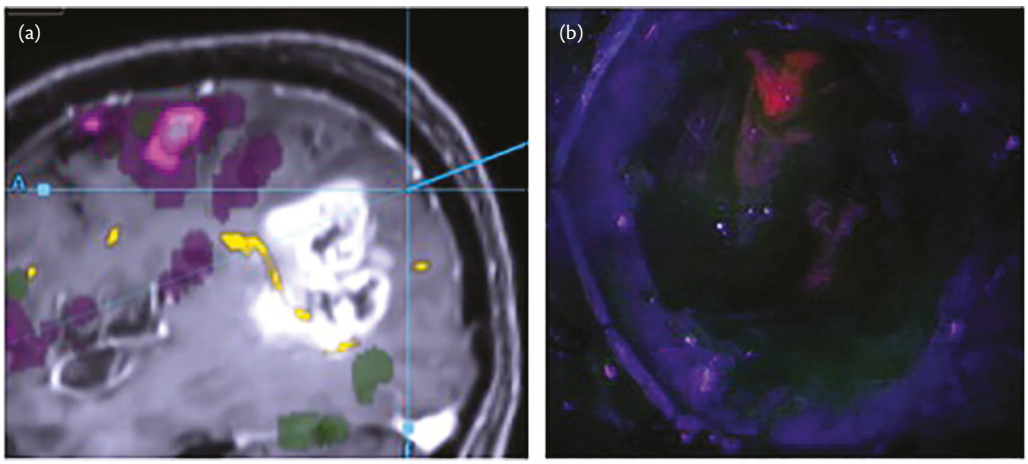

Fig. 13.3 5-ALA administered 2 to 5 hours prior to surgery allows intracellular uptake of fluorescent porphyrins. Functional neuronavigation shows a cortical approach to the tumour (A), which is confirmed under violet-blue light as pink in colour (B).

functional areas. Lesions within the insula, cingulate, and thalamus were previously considered inoperable due to the high risk of perioperative complications. A combination of improved neuroanaesthesia, advanced structural and functional imaging, and microsurgical techniques have allowed greater access to many deep-seated tumours. The surgical approaches and technical considerations for deep-seated tumours within the insula, cingulate, and thalamus will be discussed in greater detail next.

Insular lesions

Insular tumours are among the most challenging neurosurgical lesions to manage. Tumour location and hemisphere of language dominance determines whether a transcortical or trans-Sylvian approach should be considered (Benet et al., 2015). Patients are positioned semi-lateral with the head parallel to the floor (Sanai et al., 2010). For tumours located predominately above or below the Sylvian fissure the vertex of the head is positioned 15 degrees towards the ceiling or floor (respectively). A craniotomy is tailored based on the tumour's location and involvement of the overlying frontal or temporal opercula. Cortical and subcortical sensorimotor and language mapping may be utilized. Once functional areas have been identified transcortical windows superior and inferior to the Sylvian fissure are created through non-functional areas between insular arteries ('cortical windows'). Surgical resection then continues as the vessels of the Sylvian fissure are skeletonized. The resection continues by working under the Sylvian fissure along the uncinate fasciculus. The supra-Sylvian lenticulostriate arteries must be identified and preserved and subcortical motor mapping of the corticospinal tract marks the medial border of the resection. Early identification of the long lenticulostriate perforating branches to the internal capsule and corona radiata and avoidance of excessive manipulation, which may induce vasospasm, minimizes ischaemic complications. The horizontal fibres of the superior longitudinal fasciculus are adjacent to the superior peri-insular sulcus while the uncinate fasciculus is adjacent to the inferior peri-insular sulcus. The IFOF at the level of the external capsule is identified by inducing semantic paraphasia through subcortical stimulations.

Cingulate lesions

The cingulate gyrus covers the corpus callosum and is positioned immediately below the falx cerebri. The cingulate is subdivided into anterior and posterior regions and is covered by the callosomarginal artery, which runs along its medial surface. Due to their location deep within the interhemispheric fissure, tumours within the anterior and posterior cingulate gyrus are difficult to access surgically. Patients are positioned either supine or in a sitting position, for a unilateral or bilateral craniotomy according to the tumour location, size, vascularity, and pathology. Preoperative imaging should be carefully inspected for bridging veins, which may influence the surgical approach. The dura should be opened cautiously to avoid injury to the superior sagittal sinus or proximal draining veins. The surgical approach begins by creating a surgical corridor followed by tumour devascularization, and identification of the callosomarginal and pericallosal arteries. The choice between an interhemispheric approach, superior frontal gyrus resection, or superior parietal lobule resection is made on surrounding functional areas, vascularity, tumour size and location (Talacchi et al., 2010).

Thalamic lesions

Thalamic tumours are relatively rare representing 1–5% of all brain tumours (Sai Kiran et al., 2013). While lesions in this location have historically been treated with stereotactic biopsy and radiotherapy alone, advanced structural imaging and microsurgical techniques have allowed for surgical resection with minimal postoperative morbidity. Surgical resection is reserved for contrast enhancing tumours with clear margins on preoperative imaging. Non-enhancing tumours with poorly defined margins should be managed with a biopsy. Surgical approach is based on tumour location (anterior or posterior within the thalamus) and proximity to the posterior limb of the internal capsule. The majority of deep-seated intrinsic tumours cause anterolateral displacement of posterior limb of the internal capsule making the middle temporal gyrus corridor the common approach. After a temporal corticectomy the tumour is approached through the lateral ventricle along the posterolateral margin of the tumour. Upon reaching the temporal horn of the lateral ventricle the tumour is approached through the choroidal fissure. This approach ensures an entry corridor inferior to the insula and posterior to the internal capsule.

If located anteriorly and presenting into the lateral ventricle especially if the ventricle is enlarged, a transcallosal approach is suitable but is limited by the lateral extension of larger lesions. Care is needed to avoid damage to the crus of the fornix overlying the thalamus or the choriodal fissure in cases where there is medial extension to the third ventricle. A posterior interhemispheric or infratentorial supracerebellar approach may be used to access those lesions located posteriorly in the pulvinar. Visual tract fibres are at risk as a number of these are closely associated with the pulvinar adjacent to the lateral geniculate body.

Postoperative surgical management

In the immediate postoperative period, patients are observed closely in the setting of an intensive care unit, where serial neurological examinations are carried out (Chang et al., 2005). Depending on the tumour location and extent of resection, corticosteroids may be tapered over the days following surgery. Anticonvulsants are continued in patients who have a history of seizures and for tumours in areas known to have a propensity to cause seizures. The long-term use of seizure medications for prophylaxis remains controversial. Given the prognostic significance of the extent of resection for glioma patients and the difficulty in detecting residual tumour during surgery, it is becoming standard practice for surgeons to obtain postoperative MRIs with enhancement to look for residual tumour within 24 hours of resection.

Complications

Surgery for intrinsic brain tumours carries the risk of developing postoperative medical as well as surgical complications. Neurologic complications may produce visual field, motor, sensory, cognitive, or language deficits (Chang et al., 2005). They result from violation of functional cortical and subcortical pathways, cerebral oedema, haematoma, or vascular injury. In most series, the risk of a new neurologic deficit after craniotomy for resection of an intrinsic brain tumour ranges from 10 to 25%. These risks increase with older age,

deeper tumour location, tumour proximity to functional regions, and a low performance score. Neurological complications can be minimized by individualizing the surgical approach planned based on anatomic and functional imaging, cortical mapping techniques, minimizing excessive brain retraction, meticulous haemostasis, and early identification of major vascular structures.

Additional complications are related to the surgical wound and surrounding brain parenchyma. These include surgical wound infections, pneumocephalus, cerebrospinal fluid (CSF) leaks, hydrocephalus, seizure, brain abscess, cerebritis, meningitis, and pseudomeningocele. These complications occur in 1–5% of patients undergoing craniotomy for resection of an intrinsic brain tumour, and happen more readily in elderly patients and those undergoing re-operation. The posterior fossa location and re-operations are associated with a higher rate of pseudomeningocele, CSF fistula, hydrocephalus, and wound infections. Postoperative wound infections and cellulitis occur in 1–2% of patients after supratentorial craniotomy. They typically result from bacterial contamination from the skin by *Staphylococcus aureus* or *Staphylococcus epidermidis*. The risk of postoperative seizures following supratentorial craniotomy is 0.5–5%. Prophylactic antiepileptic drugs can be routinely used in the postoperative period; however, their dose and duration remain controversial.

Systemic complications include adverse events such as deep vein thrombosis (DVT), pulmonary embolus, pneumonia, urinary tract infections, myocardial infarction, and sepsis. These medical complications occur in 5–10% of patients undergoing craniotomy for removal of an intrinsic brain tumour and are more prevalent in older patients and neurologically impaired patients with poor performance status. DVT is the most common complication, occurring in 1–10% of patients within the first month after a craniotomy. Patients with systemic cancer, glioblastoma multiforme, hemiplegia, extended periods of bed rest, and prolonged surgery are at particularly increased risk of developing a DVT or pulmonary embolus. Early postoperative mobilization, intermittent compression devices, and postoperative anticoagulation with low molecular weight heparin may decrease the incidence of postoperative DVT.

Craniotomy for resection of intrinsic brain tumours can be performed safely and most complications can be prevented with careful preoperative planning, meticulous surgical technique, and attentive postoperative care.

Controversy

Awake craniotomy vs. intraoperative MRI (iMRI)

MRI-guided brain tumour surgery has been shown to enhance the extent of glioma resection and patient survival. Numerous studies have attempted to quantify the effect of iMRI on extent of tumour resection (Knauth et al., 1999; Wirtz et al., 2000). Both iMRI and awake craniotomy are tools to maximize the extent of resection while limiting neurological deficits. The main rationale for the use of iMRI combined with conventional neuronavigation-guided resection is the avoidance of brain shift due to CSF loss and tissue oedema (Nimsky et al., 2002). Neuronavigation becomes less reliable as surgery progresses. Intraoperative MRI has been shown to increase both the extent of the resection and survival in patients with low- or high-grade glioma (Black et al., 1999). With no differences in postoperative neurological deficits following surgery, iMRI resulted in a significant improvement in extent of tumour resection. This enhanced extent of resection is supported by a modestly enhanced survival in a number of series involving patients with high-grade glioma (Schneider et al., 2005).

Controversies exist over the use of awake mapping procedures and iMRI-guided procedures. Awake procedures allow real time language and sensorimotor mapping and monitoring, which may be combined with functional and structural imaging (functional neuronavigation). While this is the optimal approach for identification of functional areas, the extent of resection in functional and non-functional areas might be limited. The primary advantage of iMRI is the ability to acquire updated imaging throughout the procedure. Many patients are not ideal candidates for either approach based on their weight and body habitus (awake craniotomy) or cardiac comorbidities (iMRI). It is increasingly acceptable to use awake mapping with MRI-guided surgery within an iMRI suite, which for properly selected patients optimizes the extent of the resection and patient safety.

Meningiomas and haemangiopericytoma (HPC)

Solitary fibrous tumour (SFT)

Harjus S. Birk, Seunggu J. Han, Ramez W. Kirollos, Thomas Santarius, and Michael W. McDermott

Introduction

Meningiomas were first described by Harvey Cushing in 1922 and have since been recognized as the most common intracranial non-glial tumour (Ostrom et al., 2016). These slow-growing tumours arise contiguously to the meninges and originate from arachnoidal cap cells of the leptomeninges. They have the potential of exerting pressure or, less commonly, invade the brain, spinal cord, and cranial and peripheral nerves, resulting in neurological deficits.

Depending on the location, meningiomas can produce a wide array of symptoms. Symptoms and signs can be related directly to compression of adjacent neural structures or secondary to the effects of elevated intracranial pressure. For example, if the tumour is located on the medial part of the sphenoid wing, decreased vision and eye movement paralysis may be commonplace, whereas a tumour at the posterior fossa may result in a different constellation of symptoms including hydrocephalus and dysphonia.

Epidemiology

Meningiomas account for 36.7% of all primary intracranial neoplasms (Ostrom et al., 2016). Taking into account population increases in the United States, 150 000 people currently may have a diagnosis of meningioma, with an incidence rate of 3–3.5 per 100 000 (Claus et al., 2005). Increasing meningioma incidence rates are being reported, with a more pronounced rise in elderly age groups (Klaeboe et al., 2005). This increase can be explained by the introduction of advanced imaging techniques that have allowed for thorough patient examinations, upon which incidental meningiomas are now commonly detected. Incidental findings on brain MRI are common and the prevalence largely increases with age (Morris et al., 2009). This trend is likely to continue in the future.

The risk of developing meningiomas increases with age, with the most affected age range being 40–70 years. There is a predilection for women, with a female-to-male ratio of 1.8:1 for all meningiomas and a slightly higher ratio of 2.3:1 for symptomatic meningiomas (Radhakrishnan et al., 1995). The female-to-male ratio is different for WHO grade 1 versus grade 2 and 3 meningiomas: 2.3, 1.2 and 1.1, respectively (Ostrom et al., 2016). Meningiomas are rather uncommon in children, accounting for only 1.5% of the total, and are extremely rare in infants (Kotecha et al., 2011). Interestingly, childhood meningiomas are slightly more common in males than in females, with a 1.3:1 ratio (Kotecha et al., 2011). Up to 15–25% of childhood meningioma cases are associated with neurofibromatosis type 1 (*NF2*) or type (*NF2*) (Baumgartner and Sorenson, 1996; Kotecha et al., 2011). These cases tend to occur in younger individuals with an equal female-to-male ratio.

Radiation-induced meningiomas

The risk of radiation-induced meningiomas depends upon the radiation dose and field, possible genetic predisposition and, most importantly, the follow-up given the latency period. These meningiomas include different grades and over 10% of these are multiple. The average latency period is 22.9 ± 11.4 years with shorter latency period for those of higher grades (Yamanaka et al., 2017). In one study of childhood cancer survivors receiving cranial radiotherapy, the cumulative incidence of a subsequent meningioma by the age of 40 years was 5.6% with a median interval from primary cancer to meningioma diagnosis of 22 years and increased risk correlating with increased radiation dose (Bowers et al., 2017).

Pathology

Meningiomas are thought to arise from meningothelial cells (also known as arachnoidal cap cells). Meningothelial cells are most abundant on the surface of arachnoid villi around major sinuses,

large cerebral veins, basilar plexus, crista galli, and over the basilar venous plexus, but are also found in the arachnoid membrane in all its locations and other parts of the central nervous system (Haines and Frederickson, 1991). Although frequently repeated, this is, however, only a hypothesis based on observations of striking similarity between meningothelial and meningioma cells, and of the relationship between high concentration of meningothelial cells and common locations of meningiomas (Riemenschneider et al., 2006). Very rare extradural meningiomas are thought to arise either as an entrapment of meningothelial cells or from some other 'stem-like' cell (Lang et al., 2000).

Like other brain tumours, meningiomas are graded based on their histological appearance according to the WHO Classification of the Tumours of the Central Nervous System (WHO Classification), with its last modification published in 2016 (Louis et al., 2016). The histological criteria indicating a more aggressive behaviour and an increase in the malignancy grade include frequent mitoses, regions of hypercellularity, sheet-like growth, high nuclear–cytoplasmic ratio, prominent nucleoli, and spontaneous necrosis.

Meningiomas expand and displace, but generally do not infiltrate adjacent brain or spinal cord. Invasion of the dura and skull does occur and has no significance for malignancy grading. Invasion of the skull may elicit an osteoblastic reaction. Brain invasion can occur in meningiomas of all malignancy grades and indicates a greater likelihood of recurrence, but was not considered a sufficient criterion alone to increase the malignancy grade until the 2016 edition of the WHO Classification (Louis et al., 2016; Jenkinson et al., 2017). Nevertheless, many pathologists classified meningiomas with brain invasion as atypical following the 2007 edition of the WHO Classification.

Prior to the 2000 classification meningioma grade 1 constituted approximately 90% of all meningiomas, while atypical (grade 2) approximately 5% and anaplastic (grade 3) 1–2%. Following the adoption of the 2000 WHO Classification, the proportion of grade 2 meningiomas increased to 15–35% of diagnosed meningiomas (Claus et al., 2005; Riemenschneider et al., 2006; Pearson et al., 2008). In the 2007 Classification, meningiomas with otherwise grade 1 histological features but microscopic brain invasion could be classified as atypical, which led to yet further increased proportion of atypical meningiomas (Backer-Grøndahl et al., 2012). In the population-based study by Kshettry et al., the annual incidence (per 100 000) of atypical meningiomas increased from 26–28% (2004–2006) to 30–32% (2008–2010) (Kshettry et al., 2015). Interestingly, atypical meningiomas are more common in the non-skull base locations (Backer-Grøndahl et al., 2012).

WHO grade 3 meningiomas, also sometimes referred to as malignant meningiomas are defined either by high mitotic index (more than 20 mitoses per 10 high-power fields) or by their histological appearance resembling a carcinoma, sarcoma, or a melanoma. They are the rarest grade of meningiomas, encompassing only 1–2% of newly diagnosed meningiomas (Kshettry et al., 2015). The median overall survival for patients with these tumours averages between 2 and 3 years (Sughrue et al., 2010; Perry, 2013; Champeaux et al., 2015). Even with aggressive management that likely consists of surgery and radiotherapy, local control is often unattainable and extracranial metastases may occur.

The relative frequencies of benign meningioma subtypes (**Fig. 14.1**), as reported by Backer-Grøndahl et al. (2012), are listed in **Table 14.1**. These are similar to other reported series (Perry et al., 1999; Willis et al., 2005). Distinguishing between benign subtypes of meningiomas is of little prognostic importance, however, it is helpful in differentiating meningiomas from other tumours, especially metastases. Secretory subtype can often be predicted from imaging, as these meningiomas are associated with substantial amount of oedema, which can be life-threatening (Regelsberger et al., 2009). Meningiomas may progress to a higher histological grade (approximately 50% anaplastic meningiomas progressed from lower-grade meningiomas) (Champeaux et al., 2015) and should therefore be thoroughly sampled not to miss potential areas with a more aggressive histology.

Diagnosis of atypical (**Fig. 14.2**) and anaplastic meningiomas is made primarily based on mitotic count and other 'softer' criteria listed in **Table 14.2**. However, some rare meningioma subtypes, characterized by particular tumour cell phenotypes, are associated with more frequent recurrence and are automatically (regardless of the presence of aforementioned histological 'features of malignancy') graded as WHO grade 2 (chordoid and clear cell) or WHO grade 3 (papillary and rhabdoid) meningiomas. However, rhabdoid meningiomas are no longer automatically classified as grade 3, but instead those that lack malignant histological features should be classified as any other meningiomas as they seem to be running a course resembling the normal meningioma grades (Louis et al., 2016).

Molecular tumour cell biology

Meningiomas were one of the first solid tumours in humans to be shown to have consistent chromosomal abnormalities and the loss of one copy of chromosome 22 was identified as early as 1972 (Mark et al., 1972). The fact that the second most common tumour in neurofibromatosis type 2 (*NF2*) patients was meningioma, pointed to the *NF2* gene as a target on chromosome 22 (Rouleau et al., 1993; Trofatter et al., 1993). *NF2* is a textbook example of a tumour suppressor gene following Knudson's two-hit hypothesis, where the first hit (loss of one allele) is usually a loss of heterozygosity and second hit is either a loss (deletion) or inactivating (usually a missense) point mutation. *NF2* gene was subsequently found to be mutated in 40–60% of sporadic meningiomas (Ruttledge et al., 1994; Riemenschneider et al., 2006). The *NF2* gene codes for merlin, also known as neurofibromin 2, a membrane cytoskeleton protein. This protein has been shown to be involved in the control of cell growth and motility in culture (Shaw, 2001; Lallemand, 2003). Genetically engineered mice with only one wild-type allele have been shown to develop many tumour forms (McClatchey et al., 1998) while tissue specific inactivation in Schwann cells or leptomeningeal cells resulted in schwannoma or meningioma formation, respectively (Giovannini et al., 2000; Kalamarides et al., 2002).

Numerous reports have been published confirming the important role of *NF2* mutation in meningioma. Using new generation sequencing techniques, three papers published in January 2013 discovered several other genes that are likely important in meningiomas, especially those with wild-type *NF2* (Brastianos et al., 2013; Clark et al., 2013; Reuss et al., 2013). The Clark et al. (2013) and Brastianos et al. (2013) studies have identified mutations in two well-known cancer genes, *SMO* and *AKT1*, both of which were mutually exclusive and exclusive of *NF2* mutations. The frequencies of *SMO* and *AKT1* mutations were, 5% and 10–15%, respectively. Clark et al

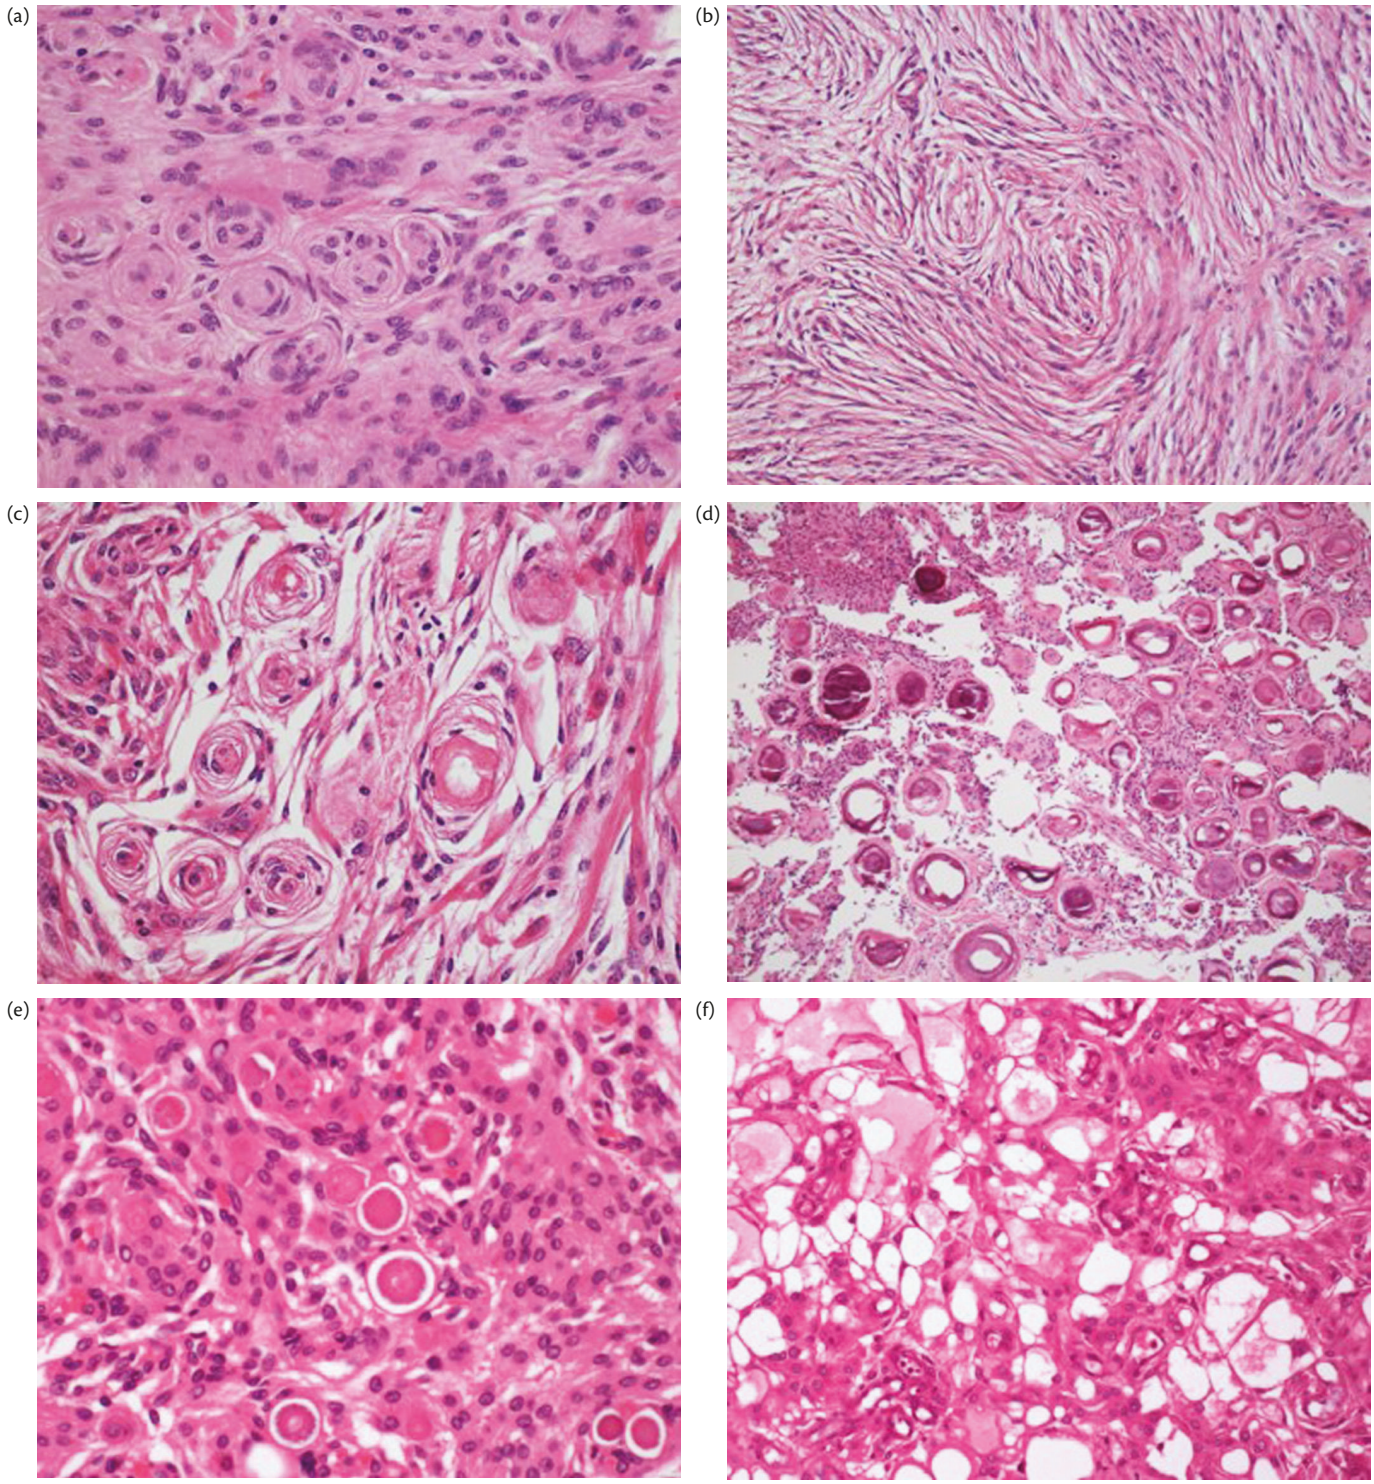

Fig. 14.1 Grade I meningioma–examples of histological subtypes. (A) Meningiotheliomatous meningioma—oval nuclei, a pseudosyncytial cytoplasm, and frequent whorls characterize the meningiotheliomatous meningioma.
(B) Fibroblastic meningioma—spindle-shaped cells arranged in fascicles, often with intervening collagen, are features of fibroblastic meningioma.
(C) Transitional meningioma—perhaps most meningiomas display an admixture of meningothelial and fibroblastic patterns: the so-called transitional meningioma.
(D) Psammamatous meningioma—although present in the vast majority of meningiomas, spherical laminated calcified concretions, known as psammoma bodies, dominate the histology of this subtype that is often encountered in the region of the thoracic spinal cord.
(E) Secretory meningioma—numerous round, eosinophilic 'secretory bodies' characterize this grade I subtype that is often associated with large amounts of cerebral oedema on MRI.
(F) Microcystic meningioma—a cobweb-like, microcystic architecture exemplifies this grade I subtype, which, like the secretory subtype, can be associated with disproportionate cerebral oedema. The glistening cut surface of this subtype gave the entity its old-fashioned name of 'humid meningioma'.

Table 14.1 Relative frequencies of meningioma subtypes

WHO grade	Histological subtype	Approximate proportion (%)
Benign (70–80%)		
	• Meningothelial	17
	• Fibrous (fibroblastic)	7
	• Transitional (mixed)	40
	• Psammomatous	1
	• Angiomatous	1
	• Microcystic	1
	• Secretory	1
	• Lymphoplasmacyte-rich	1
	• Metaplastic	1
Atypical (20–30%)	20–30	
	• Atypical	29
	• Chordoid	
	• Clear Cell	1
Malignant (1–2%)	1–2	
	• Anaplastic	1
	• Papillary	
	• Rhabdoid

also reported mutations of TRAF7, which has previously not been linked to cancers (24% of all tumours), and in 10% of *KLF4*, a gene that promotes reprogramming of pluripotent stem cells from terminally differentiated somatic cells (Clark et al., 2013). These investigators also reported that *AKT1* mutations can co-occur with those of TRAF7, but not with those of *KLF4*. *NF2*-mutated meningiomas were found to have more genomic rearrangement than *NF2*-wild type, suggesting that there is greater genomic instability in tumours with *NF2* mutations.

Mutations in all these genes appear to segregate with different histological subtypes and tumour locations. Reuss et al. have observed *KLF4* mutation in 30/30 and TRAF7 mutation in 29/30 secretory meningiomas (Reuss et al., 2013). While *KLF4* mutations were exclusively seen in secretory meningiomas, TRAF7 mutations were also seen in 8% of non-secretory meningiomas. Meningiomas that occur due to *NF2* mutations tend to be transitional or fibroblastic, while those with SMO and *AKT1* mutations tend to be predominantly of meningothelial subtype (Brastianos et al., 2013; Sahm et al., 2013). Little is known about the genetic bases of meningioma progression to more malignant grades. It seems, however, that higher-grade meningiomas have a greater number of mutations, probably stemming from higher genomic instability (Weber et al., 1997; Brastianos et al., 2013; Clark et al., 2013). When skull base meningiomas were considered, SMO- and *AKT1*/TRAF7-mutated meningiomas were found located in the midline, with KLF/TRAF7 meningiomas, in addition to midline, also occupying more lateral middle cranial fossa. *NF2*-mutated meningiomas were generally more posterior and lateral (Clark et al., 2013). Meningiomas occurring in association with Schwannomatosis disease, which is caused by germline SMARCB1 mutations, are predominantly found in the falx cerebri (van den Munckhof et al., 2012).

Cases with more than one meningioma, but no other clinical features of *NF2* or Schwannomatosis, may arise because of independent sporadic tumours (Butti et al., 1989), mosaic *NF2* with no mutation identified in the blood (Evans et al., 2005), or clonal spread of a single sporadic tumour (Larson et al., 1995; Stangl et al., 1997). The identification of different *NF2* mutations in each tumour indicates that the tumours arose independently. Identical, biallelic *NF2* mutations in each tumour indicates mosaic *NF2* or clonal spread. Identical somatic mutations in other genes or X-inactivation of the same X chromosome (Evans et al., 2005) indicates clonal spread of a single tumour. Rare families also exist with a history of meningiomas, inherited in an autosomal dominant fashion, outside of the context of *NF2* disease (Aavikko et al., 2012; Smith et al., 2013).

Table 14.2 Comparison of World Health Organization (WHO) grade II and III meningioma criteria

Grade 2	Atypical	4–19 mitotic figures/10 HPF or	**Brain invasion or 3 of the following histologic features:** - Increased cellularity - Small cells w/high N/C ratio - Large, prominent nucleoli - Patternless, sheet-like growth - Foci of geographic necrosis
Grade 3	Anaplastic	20 or more mitotic figures/10HPF or	- Frank sarcomatous or carcinomatous histology

Meningioma receptors

Meningioma growth rates are known to be influenced by sex hormones levels such as during pregnancy and with exogenous agents such as the antiandrogen cyproterone acetate. Although progesterone receptors are expressed in up to 70% of meningiomas, attempts of controlling these by antiprogesterone agents, such as mifepristone (RU 486), have not so far proven effective in clinical practice (Cossu et al., 2015; Ji et al., 2015). Currently other agents, such as somatostatin analogues and antiangiogenesis factors, are being investigated to determine their therapeutic role. Octreotide, a somatostatin analogue, targeting the expression of somatostatin receptor subtype 2 (SST2) resulted in decreased proliferation rates in meningiomas *in vitro* but did not induce apoptosis (Graillon et al., 2017).

Simpson grading

An original scheme for grading of the degree of resection of meningiomas was described by Donald Simpson in 1957 (Simpson, 1957). This scale consists of five grades and correlates degree of surgical resection with recurrence of symptoms (Table 14.3). The completeness of surgical removal has consistently been identified as an important prognostic feature (Kallio et al., 1992; Condra et al., 1997; Stafford et al., 1998; Pollock et al., 2012; Heald et al., 2014) although its relevance has been questioned (Sughrue et al., 2010; Rogers et al., 2015). Clearly, the aim of complete resection has to be balanced against the risks of mortality and morbidity and its effects on quality of life of individual patients.

Treatment: Roles of surgery and radiotherapy

When considering treatment for meningiomas, factors to be taken into account include the presence of symptoms, growth pattern, and proximity to sensitive neurovascular structures. Compression, invasion, or oedema of these structures caused or likely to be caused by the tumour and its time frame on one hand and the damage to these structure by the available treatment options on the other are balanced against each other. As recommended by the National Comprehensive Cancer Network guidelines, incidental, asymptomatic meningiomas behave with less aggression and may be managed with observation (Sughrue et al., 2010; Chamoun et al., 2011). With larger, symptomatic meningiomas it is important to consider surgery or other definitive management options, including radiotherapy, once tumour grade is determined. For patients seeking definitive therapy the standard treatment is complete resection, although numerous subsets of patients have not been successfully maintained by surgery alone. In addition, resection by itself is often not feasible if the meningioma is not separable from eloquent anatomy. It is well known that the potential for recurrence exists whether following subtotal resection (STR) or gross-total resection (GTR), and therefore the utilization of multimodal therapy for meningioma treatment has been explored extensively (Stafford et al., 2001; Soyuer et al., 2004).

Table 14.3 Original Simpson grading scheme for meningiomas

Grade 1	GTR, dural attachment excision	9% symptomatic recurrence at 10 years
Grade 2	GTR, dural attachment coagulation	19% symptomatic recurrence at 10 years
Grade 3	GTR, w/o resection or coagulation of dural attachments	29% symptomatic recurrence at 10 years
Grade 4	Partial tumour resection	44% symptomatic recurrence at 10 years
Grade 5	Simple decompression, with or w/o biopsy	100% symptomatic recurrence at 10 years

Among grade 1 meningiomas, gross-total resection remains the surgical objective and has been achieved in one-half to two-thirds of patients in surgical series (Mirimanoff et al., 1985; Pollock et al., 2012). Among benign meningiomas, subtotal resection carries higher rates of progression. For instance, one study revealed that patients who underwent STR alone for benign meningiomas experienced a 15-year survival rate of 51%, much inferior to the 88% for patients who had a GTR (Condra et al., 1997). Radiation therapy for grade 1 meningiomas is commonly supported as an adjunct to STR as a preventative measure against recurrence, specifically in cases in which tumour location is near the optic nerve sheath or cavernous sinus where surgically accessibility may be limited. Reoperation for all but the larger recurrent tumours in these areas can be a difficult, if not an impossible task to complete, with considerable risks and the low likelihood of complete resection. The senior author has abandoned the idea of reoperation for small recurrences around the optic apparatus (anterior clinoid process, tuberculum, diaphragm). Studies revealed that in these cases radiation therapy achieved long-term control in 68% to 100% of WHO grade 1 meningiomas at 5 and 10 years postoperatively (Pollock et al., 2012; Santacroce et al., 2012).

For grade 2 meningiomas, there is consensus among neurosurgeons that STR alone is insufficient treatment. One study reported a 10-year local control rate of only 17% following STR of atypical meningiomas (Goyal et al., 2000). It is recommended that after STR radiotherapy or stereotactic radiosurgery (SRS) be performed to manage residual tumour for grade 2 meningiomas. In a systematic analysis of 619 subtotally resected atypical meningiomas, the 5-year recurrence rate was 53.3% for those receiving adjuvant SRS vs. 89.9% with serial surveillance only, a significant difference suggesting the potential benefit of adjuvant therapy (Lagman et al., 2017). Currently most North American and British neurosurgeons observe atypical meningiomas after Simpson grade 1 and 2 GTR. However, it has to be taken to consideration that the clinical impact of recurrence in grade 2 meningioma is usually more significant than in grade 1 meningiomas (Marcus et al., 2008). Various forms of radiation therapy may be implemented for grade 2 meningiomas following STR, such as SRS and fractionated external beam radiation therapy (EBRT). Studies have indicated that the timing of radiotherapy may play a key role in improving local control. For example, Choi et al. revealed that SRS within 6 months after STR dramatically improved local tumour control (Choi et al., 2010). Multisession SRS is also

recommended for atypical meningiomas, especially for sensitively located tumours (Choi et al., 2010). Kaur et al performed a systematic review examining the role radiotherapy in grade 2 and grade 3 meningiomas (Kaur et al., 2014). Although they have observed the trend towards clinical benefit with adjuvant radiation therapy, the lack of statistical significance is likely a result of small sample sizes, limiting the statistical power to detect any differences between groups. Trials to further clarify the role of radiotherapy in the treatment of meningioma grade 2 meningiomas are being conducted (Jenkinson et al., 2015).

For patients with recurrent meningiomas or newly diagnosed WHO grade 3 (malignant) meningiomas, surgery followed by high-dose EBRT is the first-line therapy. Recurrence has been shown to correspond with extent of resection, and therefore aggressive GTR surgery is often pursued for these malignant tumours when a clear plane between tumour and normal surrounding tissue is identified (Sughrue et al., 2010; Sughrue, Sanai, et al., 2010). A recent paper retrospectively analysed 37 patients who were treated for anaplastic meningiomas and concluded that aggressive GTR conferred an overall survival advantage (Moliterno et al., 2015). Although no randomized trials exist documenting the efficacy of surgery and radiotherapy in malignant meningiomas, retrospective studies have reported measurable benefits of multimodal therapy for grade 3 meningiomas (Moliterno et al., 2015). Furthermore, among these tumour types it has been shown that if radiotherapy is used, higher doses may significantly improve local tumour control (Milosevic et al., 1996; Rogers et al., 2015). Magill et al have reported their experience with ^{125}I brachytherapy treatment of 14 atypical and 28 malignant meningiomas after all other means of treatment were exhausted (Magill et al., 2016). The median survival after the diagnosis was 11.1 and 9.1 years for the respective histological types. Despite associated complications that included radionecrosis (16%), wound breakdown (12%) and infection (6%), these results compare favourably with historical cohorts, and constitute a valid treatment option for patients with high-grade meningiomas.

Special considerations for specific meningiomas

The common locations for meningiomas are parasagittal, sphenoid wing, and the convexity.

Parasagittal meningiomas

Parasagittal meningioma arise from the dura of the superior sagittal sinus (SSS). They are the most prevalent group, making approximately a quarter of all intracranial meningiomas. The middle third of the SSS harbours over 50% of parasagittal meningiomas, while the anterior third somewhat more than the posterior third. The incidence of meningiomas by location most probably reflects the distribution of density of arachnoid cap cells within the body.

The understanding of the anatomy and flow dynamics of SSS, bridging veins, emissary veins, and their collaterals is fundamental to management of and surgery in patients with parasagittal meningiomas. Therefore, not only static structural imaging, but often digital subtraction angiography is required. The consequences of venous compromise caused by surgery range from temporary asymptomatic through symptomatic cerebral oedema, reversible neurological deficit caused by venous infarction, haemorrhagic transformation of venous infarction to malignant brain swelling with the potential of severe permanent neurological deficit and mortality. In some cases, it may be appropriate to treat symptoms and signs associated with obstruction of venous outflow by venous stenting (Higgins et al., 2008; Ganesan et al., 2008).

Similarly to patients with meningiomas in other location, management of patients with parasagittal meningiomas ought to be based on considerations related to the patient (e.g. social functions, occupation, hobbies, age), the tumour (e.g. anatomical location, size, speed of growth, presence of calcifications) and its effect on the surrounding tissues (e.g. brain oedema, SSS narrowing/occlusion, presence of venous collaterals), as well as all other available treatment options (surgery, fractionated radiotherapy, SRS, and venous stenting).

Most commonly Simpson grade 2 is achieved, but in some cases residual tumour invading the wall or lumen of the SSS may have to be left behind. For these, adjuvant radiation treatment either at the outset or after progression on radiological surveillance should be considered on an individual basis. Although opening of the SSS to remove intraluminal meningioma extension followed by suturing or patching is possible, it is liable to failure with thrombosis and has serious consequences, particularly if attempted on the posterior third of the SSS. Most surgeons, including the authors, advocate resection of the SSS only in the presence of completely occluded SSS with well-established collaterals. These may include venous channels in the falx and tentorium as well as emissary veins. Careful preoperative studies of these collaterals and their preservation at surgery is essential. Regrowth or recurrence that results in gradual and eventually total occlusion of the SSS would be amenable to a more radical resection at the second surgery.

Falcine meningiomas

Some 9% of intracranial meningiomas arise from the falx. Unlike parasagittal meningiomas, which tend to have bridging veins running deep to them, some falcine meningiomas extend deep into the hemispheres with compression of the pericallosal arteries and the corpus callosum and have bridging veins running over them. In fact, in the majority of cases upon opening of the dura the tumour is not visible, instead one can see the convexity brain overlying it. Falcine meningiomas can be unilateral or bilateral with varying proportions of tumour bulk on respective sides. For complete surgical removal, when indicated, resection of the falcine origin is recommended, but preservation of important dural venous channels needs to be ensured, especially if the SSS is also compromised. Given that these tumours tend to grow 'into the brain', it may, in some unilateral cases, be advantageous to approach them from the contralateral side to avoid excessive brain retraction and manipulations, disturb the overlying bridging veins and gain early control of the falcine blood supply. Patients with tumours adjacent to the supplementary motor cortex may suffer transient postoperative hemiparesis and mutism.

Convexity meningiomas

Fifteen per cent of intracranial meningiomas arise from the convexity. They compress adjacent brain and their blood supply comes primarily via meningeal arteries. Like in other locations, large, rapidly growing, grade II and III and secretory type meningiomas

are usually associated with perilesional oedema, which usually indicates disruption of the pial surface. These tumours tend to recruit additional cortical blood supply (Alvernia and Sindou, 1994). Venous flow obstruction by stretching adjacent cortical veins can, in its own right, be the cause of, or contribute to the surrounding oedema.

On postcontrast imaging, the majority of meningiomas are seen to have a 'dural tail', a tapered extension of contrast along the meninges away from their attachment. Clusters of meningiotheliomatous cell aggregates were shown to extend onto the surrounding dura at varying distances from the main meningioma attachment (Borovich and Doron, 1986). As recurrences tend to appear at the resection margins, Kinjo et al. advocated grade 0 resection where an additional cuff of 2 cm of circumferential dura is excised around the tumour (Kinjo et al., 1993). Given the relative ease of achieving Simpson grade 1 or even grade 0 resection in the high proportion of convexity meningiomas, surgical cure is more likely in this group of meningiomas than those in other locations. However, this does not mean that each convexity meningioma ought to be treated surgically at first presentation. For example, small incidental meningiomas in older people frequently become static and non-progressive and do not require treatment.

Sphenoid wing meningiomas

Sphenoid wing meningiomas (SWM) make up 10–20% of intracranial meningiomas. They are often discussed as either lateral (LSWM) or medial sphenoid wing meningiomas (MSWM) and there are quite different considerations associated with each group, especially as surgery and prognosis is concerned. A special group of meningiomas with predominantly intraosseous component involving the greater sphenoid wing, called spheno-orbital meningiomas (SOM), will be discussed separately.

Lateral sphenoid wing meningiomas

Management and surgery of meningiomas arising from the lateral sphenoid wing are similar to that of convexity meningiomas. Bone involvement and *en plaque* tumours seem to be relatively common in this group of meningiomas and require special considerations. Some have wide *en plaque* extension along the middle fossa which can be challenging to excise, especially in the proximity of the skull base neural exit foramina. Underlying hyperostotic bone has been shown in most cases to contain tumour cells within the bone lamellae and to achieve complete resection the inner table or the entire bone width, of if the outer table is also affected, should be drilled extradurally at the beginning of the resection. To minimize the risk of recurrence very large craniotomy flaps are required and affected meninges ought to be resected.

Medial sphenoid wing and clinoidal meningiomas

As a group, medial SWMs are more challenging to manage, especially because of their proximity and potential involvement with neurovascular structures as well as invasion of the cavernous sinus. Extension into the middle cranial fossa can sometimes continue extracranially to the infratemporal fossa through the neural foraminae and skull base. Cavernous sinus involvement varies from being in the lateral wall to being extensively within the sinus ('holocavernous'). To avoid surgical morbidity these residual extensions are best dealt with SRS, if indicated (i.e. to ameliorate symptoms or to progressive growth). In some cases a more extensive skull base approaches, such as the fronto-temporal-orbitozygomatic approach, are needed. (See also Chapters 21 and 27 for operative approaches.)

Meningiomas with predominant origin at the anterior clinoid process (ACP) termed clinoidal meningiomas may extend to the suprasellar region and/or through the anterior tentorial hiatus to the prepontine and ambient cisterns. They have a tendency to encase the origin of the internal carotid artery. In most cases an arachnoidal plane is present between the tumour and surrounding neurovascular structures, but some meningiomas are adherent to the adventitia and some residual tumour may have to be left behind. Similarly, other structures, such as the internal carotid artery (ICA) branches, proximal A1 and M1 segments of the anterior and middle cerebral arteries, optic nerve, and chiasm, oculomotor nerve, and the pituitary stalk can be fused with the meningioma and, rarely, even course within the tumour. In these cases identification of the distal middle cerebral artery branches at the superior pole of the meningioma by widely splitting of the Sylvian fissure would safely identify in a retrograde fashion the course of the arteries. It is important to consider and spare the lenticulostriate branches as these are the most vulnerable. Frequently there is extension into the superolateral segment of the optic canal which should be explored in cases with visual compromise even if not readily visible on preoperative imaging. If the ipsilateral optic nerve and chiasm is surrounded by tumour, a subfrontal trajectory to identify the contralateral optic nerve, again, helps decompression of the chiasm and optic nerve in a retrograde fashion thus facilitating the preservation of its blood supply which is predominantly via the superior hypophyseal arteries.

Spheno-orbital meningiomas

SOMs make up around 5% of intracranial meningiomas, but the numbers published in the literature are very much dependent on the exact definition of this group. SOMs are frequently indolent and do not require intervention if vision is preserved, are not growing, or severe visual compromise with optic atrophy has already been established. The major indications for surgery are potential or incipient optic nerve compromise, proptosis, or for cosmetic reasons.

Although the extent of the tumour varies widely, they tend to be confined to the sphenoid bone with its greater wing forming a large part of the lateral orbital wall and extend to the floor of the middle fossa and its foraminae (rotundum, ovale, and spinosum) as well as the superior orbital fissure. This is located between the lesser and greater wing and is separated medially from the optic canal by the optic strut linking the ACP to the body of the sphenoid bone. The squamous temporal bone can also be involved. The soft tissue component can involve the intracranial compartment as well as the orbit and can grow down to the infratemporal fossa or deep to the temporalis muscle. The intracranial component is variable, ranging from an *en plaque* extension to a distinct intracranial mass. Image-guidance on bone window settings facilitates radical resection of involved bone (Marcus et al., 2013). The stages of resection are extradural followed by intradural excision. The aim is to decompress the optic canal and orbit whenever involved and this may require a 'tailored' clinoidectomy. Residual tumours in the orbital apex or involving the cavernous sinus may require radiation treatment if progressive.

Anterior cranial fossa meningiomas

Olfactory groove meningiomas

10–15% of intracranial meningiomas are classified as olfactory groove meningiomas (OGM). They originate in the midline between the crista galli and the fronto-sphenoid suture behind which the anterior fossa floor continues as planum sphenoidale. OGMs can reach large sizes at the time of diagnosis with the majority of patients being anosmic and exhibiting varying degrees of cognitive dysfunction. Occasionally they may present with a classic Foster–Kennedy syndrome consisting of anosmia, optic atrophy in one eye and papilloedema in the other. For large lesions, a frontal transbasal approach with a supraorbital osteotomy or its modifications allows early control of its blood supply which is predominantly from the anterior ethmoidal artery and the placement of a pericranial flap to repair the skull base after cranialization of the frontal sinus and drilling of the hyperostotic bone at their origin. Frontolateral approaches allow early identification and protection of posterior neurovascular structures, such as anterior cerebral arteries and optic nerves. (See also Chapters 21 and 27 for operative approaches.)

Planum sphenoidale and tuberculum sellae meningiomas

Between 5 and 10% of intracranial meningiomas are classified as planum sphenoidale (PSM) or tuberculum sellae meningiomas (TSM). Arbitrarily, the tumours originating anteriorly to the limbus sphenoidale are termed PSMs, whereas those originating posteriorly to the limbus are called TSMs. The origin of TSM may be at the tuberculum sellae itself, the chiasmatic sulcus, or the diaphragma sellae, the latter sometimes referred to separately as diaphragma sellae meningiomas. The exact origin of large meningiomas in this region cannot always be established, but given the relationship between their site of origin and the optic apparatus, TSMs tend to elevate, while PSMs depress the optic chiasm. The location of hyperostosis on the computed tomography (CT) scan can also hint the site of origin.

The main indication for surgery is visual preservation. Despite the close proximity to the pituitary gland and stalk, pituitary function is almost always preserved preoperatively, which is in contrast to other lesions in that region. It is important to appreciate the frequency of extension into the optic canals regardless of the preoperative radiological appearance (Sughrue et al., 2015; Nimmannitya et al., 2016). Lesions that are small or extending into the sphenoid sinus with absence of vascular encasement on MRI and not extending laterally to the carotid may be considered for extended endoscopic endonasal approaches, especially if they are of soft consistency. This may, to an extent, be predicted by a bright signal on T2-weighted MRI sequence. The pterional approach allows to deal with further extensions into the interpeduncular cistern and around the internal carotid artery, but will likely involve a degree of manipulation of the ipsilateral optic nerve and the area medial to the nerve could be a blind spot. The anterior interhemispheric approach rather than subfrontal can preserve olfaction more readily and avoid manipulations of the optic nerves, but a retroclival extension, especially with a prefixed chiasm, is a blind spot. (See also operative approaches in Chapters 21 and 27.)

Tentorial meningiomas

Different surgical approaches are required based on the wide-ranging locations and extensions of meningiomas arising from the tentorium. Resection of the tentorial attachment is desirable whenever possible to achieve complete resection, but one has to bear in mind potentially vital venous drainage from the deep brain structures and its variability.

This is especially important around the falcotentorial junction and the torcular (see next). Anteriorly located supratentorial meningiomas are approached via the trans-Sylvian or subtemporal approaches trying to minimize brain retraction. Early opening of the cisterns and cerebrospinal fluid egress is desirable, but it may not be readily achievable at the very start of the exposure. Insertion of a lumbar drain is generally not safe, especially for large lesions with brain oedema. Particular attention should be given to preserving the integrity of the trochlear nerve at the tentorial hiatus.

The occipital interhemispheric approach exposes falcotentorial tumours and the occipital transtentorial approach is used for those extending to the pineal region and posterior central tentorial hiatus. (See also Chapter 37 for operative approaches.) Large lesions may require a combined supra- and infratentorial approaches with preservation of the transverse sinus whenever possible. Preservation of patent straight sinus and the deep veins is most important and may necessitate leaving residual tumour. Posterior fossa lesions which are supracerebellar and may extend to the cerebellopontine angle as well as petrotentorial meningiomas are approached via a suboccipital craniotomy. They tend to displace rather than directly involve the cranial nerves.

Petroclival meningiomas

Albeit relatively rare (approximately 2% of intracranial meningiomas) these are one of the most challenging lesions to manage. Several of these meningiomas are static or demonstrate slow growth rate, especially in older age, and most of those with no or minimal symptoms are best observed, with surgery advocated only if progressive. The origin of the petroclival meningiomas is centred at the petroclival junction medial to the internal auditory meatus and posteriorly to the Meckel's cave. True clival meningiomas arise from medial to the sixth nerve and may extend to the cavernous sinus.

Both clival and petroclival meningiomas can grow into a substantial volume before becoming symptomatic. At this stage they often extend to the cavernous sinus and tentorium with invasion of the Meckel's cave. The morbidity of radical resection is related to cranial nerve dysfunction with the sixth nerve being particularly vulnerable. A signal change in the brainstem on FLAIR sequences of preoperative MRI indicates disruption of the pial surface. In these cases adhesion to the brainstem and its vascular supply is to be expected, and subtotal resection is advised. The serious nature of the neurological deficits that may arise from the cranial nerves, vessels and brainstem has shifted the practice towards more conservative surgery aiming to minimize neurological deficit and maintaining quality of life. (See also Chapter 24 for operative approaches.)

Foramen magnum meningiomas

Foramen magnum meningiomas (FMM) are rare and constitute only some 2% of all intracranial meningiomas. The most popular definition places their origin from meninges between the upper border of the arch of C2 and the junction of the lower and the middle

third of clivus, laterally extending to the jugular tubercle. Early presentation with neurological deficits from neural compression is usual, although diagnosis is commonly delayed. This is mostly because of similarity with symptoms of commoner conditions affecting musculoskeletal and nervous system in this region. Cruciate paresis, also known as hemiplegia cruciata, is often mentioned in the context of more anteriorly placed FMMs, but in practice it is rarely encountered.

The location of the meningioma, circumferentially (posterior *vs.* posterolateral *vs.* anterolateral *vs.* anterior) as well cranio-caudally (intracranial extension *vs.* spinal extension), dictates the surgical approach. For the more anterior locations a far lateral approach is ideal. However, the need and degree of the condylar resection (transcondylar approach) should be tailored to the location and size of the lesion. Even modestly sized meningiomas often create a sufficient surgical corridor by displacing the medulla and spinal cord thus obviating the need for condylar resection. However, transcondylar approach may be necessary for a small anterior lesion. For those extending mainly to the upper cervical canal and foramen magnum at the level of the C1 tubercle, condylar resection is not needed. Tumours with superior extension up to the jugular foramen often have the jugular tubercle obscuring the view of the tumour. The attachment just medial to the dural entry of the vertebral artery (VA) poses another difficulty with the VA obscuring this attachment. Releasing the first denticulate ligament which separates the spinal accessory nerve from VA as it enters the intradural space, opens the surgical window wider onto the anteriorly placed meningiomas. In many cases where the dural origin is not resected a persistent enhancing dural base on postoperative MRIs tend to be stable in the long term. *(see also Chapter 31 for operative approaches).*

Intraventricular meningiomas

Intraventricular meningiomas are very rare, constituting 1–3% of all intracranial meningiomas. They are thought to originate from meningeal cell rests within the choroid plexus. Many of the rarely reported paediatric meningiomas are intraventricular. They are discussed in Chapter 35.

Calvarial meningiomas

Although these meningiomas can be purely intraosseous, many have intracranial extensions as minor durally based lesions. The indications for surgery are usually cosmetic and diagnostic (to differentiate from other pathologies, such as metastases). An intraoperatively tailored or a preformed image-guided cranioplasty is usually completed at the time of resection. Calvarial meningiomas located over the sinuses, such as the superior sagittal sinus, could be challenging.

Multiple meningiomas

These can be seen in 1–9% of meningiomas, occurring more frequently in females and do not necessarily indicate association with *NF2* syndrome (Terrier and François, 2016). They can arise at different times. Multiple lesions may be seen with radiation-induced meningiomas.

Case for and against preoperative embolization of meningiomas

During the past few decades, rapid technological advancements in microcatheters and embolization treatments have led to the adoption of these techniques for preoperative management of meningiomas with the goal of a safer resection. Currently this is a controversial issue, and analysis of the published literature makes the case for and against preoperative embolization of meningiomas.

The first-line treatment for symptomatic meningiomas growing over time is surgical resection. However, resection may be hindered by tumour location if proximal to eloquent brain regions or structures as well as limited accessibility. Other factors that may prevent adequate tumour removal include tumour hypervascularity and dural venous sinus involvement. Embolization can reduce the tumour blood supply and ease resection by curtailing operative time and intraoperative blood loss (Gruber et al., 2000; Dowd et al., 2003). However, some surgeons believe that the benefits of preoperative embolization do not outweigh the risks. For instance, reports exist of excessive blood loss, subarachnoid haemorrhage, and retinal emboli following embolization of meningiomas (Hayashi et al., 1987; Raper et al., 2014). Other potential complications include inadvertent embolization of cerebral arteries through anastomoses of the ECA branches to the ICA (Raper et al., 2014). In 2000 a group compared two groups of 30 patients each, one who underwent preoperative embolization and the second group who did not (Bendszus et al., 2000). It was concluded that there was no effect on blood loss nor haemostasis during resection, and there was one permanent neurological deficit caused by the embolization.

Limited consensus has been reached defining the role of preoperative embolization for intracranial meningiomas. A recent systematic review in 2013 analysed 36 studies comprising 459 patients who had undergone this procedure prior to meningioma resection. Among these patients, 4.6% (21/459) had reported complications that were a direct result of the embolization. Incidence of major complications among these 21 patients was 4.8% (1/21), with the mortality rate double that at 9.5% (2/21). Therefore, it can be stated that preoperative embolization for meningiomas carries risks of significant morbidity and mortality. However, these risks can be limited with meticulous selection of patients in whom this procedure would be of the most benefit. Further prospective studies that analyse the role of preoperative embolization will likely elucidate the benefits and risks of this procedure among certain meningioma types.

Prognosis

Residual tumour, histological grade and, likely, biological (genome, transcriptome and methylome) factors determine the risk of recurrence. When considering prognosis of meningiomas, it is crucial to analyse the WHO grade of the tumour as well as what mode of therapy was undertaken, and whether surgery alone was performed or also radiotherapy. Benign meningiomas are slow-growing and have a 5% 5-year recurrence rate following gross-total resection

(Riemenschneider et al., 2006). Atypical meningiomas have a 5-year recurrence rate of 40%. Anaplastic WHO grade 3 meningiomas have a recurrence rate of 80%, double that of grade 2 and 16-fold greater than that of grade 1 meningiomas (Choy et al., 2011). Among patients who underwent multimodal treatment, the 5- and 10-year survival rates for atypical and anaplastic meningiomas were 95% and 79%, and 64% and 35%, respectively (Palma, 1997). A major clinical factor in recurrence is extent of resection. Patient age, location, and other tumour factors will influence the decisions related to the degree of resection. Again, depending on age and a number of other factors the decision between radiological surveillance or adjuvant radiation, including SRS for localized residual or recurrence, is made on individual basis.

Controversy: Management and follow-up of incidental meningiomas

Decision-making in the management of incidental meningiomas depends on multiple factors such as age, size, location, potential morbidity of the treatment and its effectiveness at the time of discovery and later on, as well as the psychological impact of knowledge of the diagnosis on the patient. The indications ought to be considered on an individual basis and guidelines, despite of good intentions, may be a step backwards by offering coarse treatment packages rather than bespoke, refined, and flexible personal treatment plans. For example, the proximity of the tumour to important structures, such as cranial nerves, may an important factor to indicate treatment prior to the onset of potentially irreversible deficit in one patient, but it may be a reason to adopt conservative management in another patient to whom the potential morbidity from surgery is not acceptable at that time. The growth rate is variable and on many occasions is non-linear. Therefore, for those managed with radiological follow-up a robust, ideally, volumetric assessment over time should be adopted.

Haemangiopericytoma (HPC)-solitary fibrous tumour (SFT)

Although not a meningioma, haemangiopericytoma-solitary fibrous tumour (HPC-SFT) is discussed in this chapter as these tumours resemble meningiomas and for that reason, in the past, some of them were classified as meningiomas and haemangiopericytomas (HPCs). In fact, HPCs were generally classified as angioblastic meningiomas until 1954 when Begg and Garret reported the first meningeal HPC (Begg and Garret, 1954). In other parts of the body HPCs were increasingly classified as solitary fibrous tumours (SFTs), however until recently in the CNS they were kept separate, not least because different prognosis. Since 2013 edition of the WHO Classification of Tumours of Soft Tissue and Bone (Fletcher et al., 2013), HPC and SFTs are considered one entity. The term HPC has been abandoned and both entities are now called SFT. This is because they share the same *NAB2-STAT6* fusion gene. Molecular studies on HPCs of the dura/meninges have found similar genetic aberrations and the most recent WHO Classification of Tumours of the CNS (Louis et al., 2016) also considers haemangiopericytoma-solitary fibrous tumour as the same entity (Fig. 14.3).

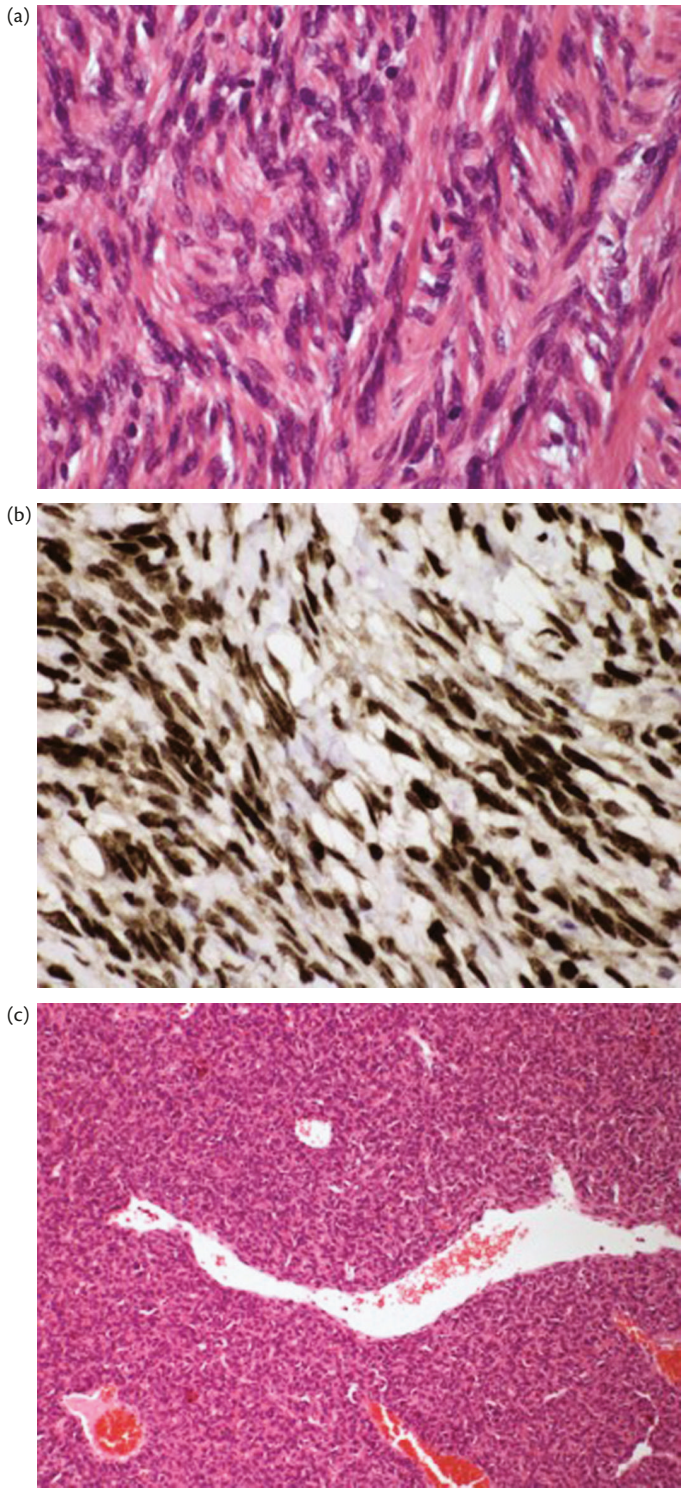

Fig. 14.3 (A) Solitary fibrous tumour—fascicles of spindle cells characterize this tumour that often mimics meningioma radiologically. The histology of this neoplasm can be mistaken for fibroblastic meningioma or schwannoma. Immunohistochemistry will resolve this differential.
(B) Solitary fibrous tumour *STAT6* immunoreactivity—the central and (to date) specific genetic abnormality in SFT and the related tumour, haemangiopericytoma, is a fusion between the *NAB2* and *STAT6* genes. This results in the nuclear localization of *STAT6* which is well-demonstrated by immunohistochemistry.
(C) Haemangiopericytoma—a highly cellular tumour composed of patternless sheets of spindle cells with characteristic dilated, thin-walled vessels. As with the related solitary fibrous tumour, nuclear expression of *STAT6* would be expected immunohistochemically.
Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

SFTs commonly affects the pleura, peritoneum, meninges, and lower extremities, but they can be found in any body site. Approximately 12–22% are found to be malignant (DeVito et al., 2015). Meningeal SFTs are nearly always benign, but very rare malignant variant exists. HPCs are generally of WHO grade 2 and grade 3. Although meningeal HPCs and SFTs are generally distinct from each other, an overlap exists. Overall, it is probably most practical to think of meningeal HPCs and SFTs as a part of the same disease spectrum. Although the ultimate diagnostic test is identification of the *NAB2-STAT6* fusion gene, this is not practical as the first step. Instead, identification of nuclear staining of STAT6 using immunohistochemistry is a good surrogate test (Schweizer et al., 2013).

The radiological appearances are similar to those of meningioma, both in terms of location and signal characteristics. The features that make the diagnosis of SFT/HPC more likely include: heterogeneous signal intensity on T2-weighted images; the presence of areas of low T2 signal intensity that strongly enhance after gadolinium injection; the absence of dural tail adjacent to the tumour; the absence of skull bone thickening; and, on MR spectroscopy, an elevated myo-inositol peak (Clarençon et al., 2011). Few have no dural attachment with intraparenchymal or rarely intraventricular (Bisceglia et al., 2011).

The initial management of HPC-SFT is pretty much the same as treatment of meningiomas, with resection and tissue diagnosis. If the diagnosis is of HPC, body staging is done as the frequency of systemic metastases is high (25–50%). The main potential difficulty at surgery can be excessive bleeding as many HPCs are very vascular.

The recurrence of HPC after surgery is 60–75% and 5-year overall survival probabilities vary between 65 and 95% with median overall survival between 7 and 16 years (Guthrie et al., 1989; Kim et al., 2003; Rutkowski et al., 2012; Melone et al., 2014). Malignant transformation may occur with further recurrences (Apra et al., 2017). Despite the latest WHO Classification unification of SFTs and HPCs, there is a clear distinction between the clinical outcomes of these historically distinct conditions. Champeaux et al have analysed SFTs and HPCs together, but in a multivariate analysis histological type (SFT vs. HCP) came out as one of the independent prognostic factors (Champeaux et al., 2017). Other significant prognostic factors in the same analysis included venous sinus invasion and completeness of resection. The impact of radiotherapy on overall survival is unclear (Trifiletti et al., 2017). Given the high recurrence rate and metastatic potential, postoperative radiotherapy is uniformly used in HCPs.

Conclusions

Meningiomas are the most common form of primary brain tumour over the age of 30 and continue to challenge modern surgical and medical techniques in achieving cure or long-lasting tumour control. While the natural history of benign meningiomas is one of slow growth, and understanding that every intervention carries risk, patients should be aware of the risks associated with observation and their likely distribution over time. Many tumours that ultimately grow may have been amenable to surgical cure with lower perioperative medical and neurological morbidity if operated at an earlier age when the tumour was at its smallest size. Physical forms of treatment with surgery and radiotherapy have probably reached their peak and we look forward to advances in targeted medical therapies and immunotherapy to help us prolong and improve the lives of patients, especially those with recurrent meningiomas.

Haemangiopericytomas (HPC) are now considered one entity with solitary fibrous tumours (SFT). HPC-SFT thus form a pathological entity with a range of behaviour from benign to malignant with tendency to recur and forming distant metastases.

Chordomas and chondrosarcomas of the skull base

Rami O. Almefty and Ossama Al-Mefty

Introduction

Chordomas and chondrosarcomas are often paired together because of their similarities in anatomical location, clinical presentation, and radiographic findings. However, they represent two distinct pathologies with starkly different clinical outcomes. This chapter reviews both entities and highlights the key distinctions between them.

Epidemiology

Chordomas and chondrosarcomas of the skull base are rare tumours. Together, they make up 0.1% of all brain tumours and have a combined incidence of 0.02 per 100 000 (CBTRUS, 2012). Chondrosarcomas are even more rare than chordomas.

Chordomas are located in the skull base, mobile spine, or sacrum. McMaster and others used the Surveillance, Epidemiology, and End Results (SEER) programme of the National Cancer Institute to calculate a population-based incidence of 0.8 per 100 000. In their study chordomas occurred nearly equally among the skull base (32%), spine (33%) and sacrum (29%) (McMaster et al., 2001). Heffelfinger et al. published the Mayo Clinic's experience of 155 chordomas, 76 (49%) occurred in the sacrum, 55 (35%) in the skull base, and 24 (15%) in the mobile spine (Heffelfinger et al., 1973). Since this study is based on an institutional experience rather than population based, it may be affected by the institutions' expertise and referral patterns.

Chordomas in general have a male predominance, perhaps as high as 2:1 (Heffelfinger et al., 1973; McMaster et al., 2001), however; this does not hold true for cranial chordomas where there is a near equal incidence (McMaster et al., 2001; Almefty et al., 2007). Cranial chordomas also present at an earlier age than chordomas at other sites. According to McMaster et al., the median age at presentation for cranial tumours is 49 years with a quarter of patients presenting prior to 35 years of age (McMaster et al., 2001). In the senior author's (OA) published series of 89 cranial chordomas, the mean age was 37.7 years (Almefty et al., 2007). Chordomas are even rarer in the paediatric population and especially rare in those younger than five years old. In a cross-sectional national database analysis, Chambers et al. reported that of 594 cranial chordomas, 30 cases occurred in patients 10–19 years old and 26 in those less than ten years old (Chambers et al., 2014). At the time of their report, Borba et al. found 21 of the 76 reported paediatric cases to be in those younger than five years old (Borba et al., 1996). Chordomas are exceedingly rare in African-Americans (McMaster et al., 2001; Almefty et al., 2007).

Pathology

Chordomas arise from primitive notochord remnants at the sphenooccipital synchondrosis (**Fig. 15.1**). They are typically described as slow growing but this belies their malignant and invasive behaviour (**Fig. 15.2**). They form a grey, gelatinous, lobulated mass with an encapsulated soft tissue component but with infiltrative bone involvement. Microscopically, they contain uniform physaliferous cells which are small, oval cells with eccentric nuclei with dense chromatin and numerous cytoplasmic vacuoles. A pseudocapsule appearance is created by fibrous strands forming thick hyalinized septae or lobules with thin septations. The lobules can have the appearance of sheets of physaliferous cells or a pool of mucin. The sheets of cells contain a varying degree of intracytoplasmic mucin (Heffelfinger et al., 1973). Heffelfinger et al. described the chondroid variant of chordoma which also has a cartilaginous component (Heffelfinger et al., 1973). The distinction between chondroid chordoma and chondrosarcoma can be difficult histologically, highlighting the need for immunohistochemistry in differentiating the two, as chondroid chordoma behaves the same as non-variant chordomas and must be treated as such (Rosenberg et al., 1994; Almefty et al., 2007). In addition to the classic and chondroid types, the final subtype of chordoma is the de-differentiated or atypical type. Atypical chordoma is rare, even among chordomas, and has a more aggressive cytology and clinical course.

Chondrosarcomas originate from primitive mesenchymal cells or from embryologic rests in the cranium of the cartilaginous matrix. They typically occur in the long bones and pelvis and are rare in the cranium. Grossly, they are composed of multiple, interconnecting globules of chondroid or myxoid consistency. These tumours can be

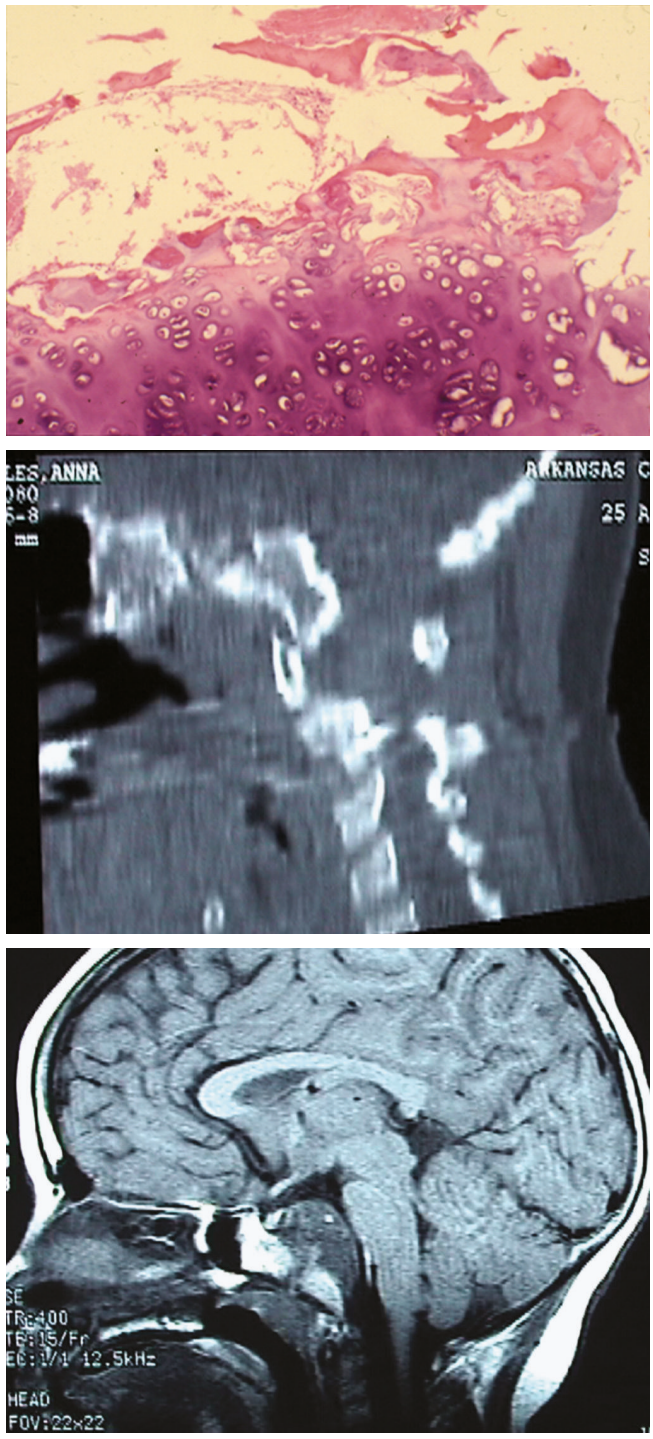

Fig. 15.1 H and E stain (A), bone window sagital CT scan (B), and sagital MRI (C) showing the origin of chordoma from the sphenooccipital synchondrosis.

grouped into classic, mesenchymal, and myxoid. The classic form is most common and contains large cells with single or multiple nuclei in a variable chondroid matrix. Classic chondrosarcomas are divided into grades I, II, or III depending on mitotic rates, cellularity, and nuclear size. The chondroid matrix in higher grade tumours have increased mitosis and less chondroid matrix (Evans et al., 1977). The mesenchymal type contains areas of relatively well differentiated cartilage and undifferentiated round or spindle shaped cells, whereas the myxoid type has a myxoid matrix with strings of round cells (Korten et al., 1998).

The key pathological distinction between the two entities that must be studied is their immunohistochemical profile (see Fig. 15.3). Chordomas are positive for cytokeratin, EMA, S-100, and vimentin, including the chondroid variant. Chondrosarcomas, however, are negative for cytokeratin and EMA but are positive for S-100 and vimentin (Rosenberg et al., 1994). Brachyury is a nuclear transcription factor additionally helpful in the diagnosis of chordoma and distinction from chondrosarcoma. Brachyury staining is rare outside of chordoma and not present in the lesions typically considered in the differential diagnosis. When included with an immunohistochemical panel of S-100 and epithelial markers a sensitivity of 100% can be achieved (Oakley et al., 2008; Jo et al., 2014).

Genetics

The sum results of studies to date have characterized chordoma as a genetically heterogenous tumour with frequent imbalances of large chromosomal regions without recurrent structural rearrangements (Hallor et al., 2008). Scheil-Bertram et al. demonstrated the genetic heterogeneity when they found 166 unique aberrations in a study of 33 cases (Scheil-Bertram et al., 2014). When chordoma karyotypes are abnormal, whole or partial loss of chromosomes 1, 3, 4, 9, 10, 13, 18 gains in chromosomes 7 and 20 and the formation of isochromosome 1q have been shown (DeBoer et al., 1992; Bridge et al., 1994; Sawyer et al., 2001; Scheil et al., 2001; Tallini et al., 2002; Sandberg and Bridge, 2003; Kuzniacka et al., 2004; Brandal et al., 2005; Bayrakli et al., 2007). 1p36 has been purported as a tumour suppressor gene locus in sporadic chordomas (Dalpra et al., 1999; Miozzo et al., 2000; Riva et al., 2003) as 7q33 has for familial cases (Kelley et al., 2001). Hallor et al. used array comparative genomic hybridization (aCGH) to show the absence of CDKN2A and CDKN2B in 70% of cases (Hallor et al., 2008). More advanced techniques such as aCHG and whole-genome single—nucleotide polymorphism microarray analysis (SNP) have revealed chromosal abnormalities in 91–100% of chordomas (Scheil et al., 2001; Hallor et al., 2008; Le et al., 2011; Kitamura et al., 2013; Scheil-Bertram et al., 2014).

Al-Mefty et al. were able to define the clinical significance of cytogenetic abnormalities in chordomas. Chordomas with normal karyotypes were found to have a recurrence rate of 3% in *de novo* cases. *De novo* tumours with an abnormal karyotype, on the other hand, had a recurrence rate of 45%. They found an abnormal karyotype in 75% of recurrent cases in comparison to 24% of *de novo* cases. Tumours with aberrant chromosomes 3, 4, 12, 13, and 14 showed frequent recurrences and decreased survival. Abnormalities in chromosome 13 had the highest odds ratio for progression (OR 24), and a median recurrence-free survival rate of only 4.5 months, significantly shorter than tumours with aberrant karyotypes not involving chromosome 13. It should be noted that karyotyping was done using the G banding technique and comparative genomic hybridization may reveal abnormalities not detected with the G banding technique (Almefty et al., 2009). Other authors have found gain of 2p (Kitamura et al., 2013), deletion of 9p21 (Horbinski et al., 2010), and p53 overexpression (Naka et al., 1996) to be associated with poorer prognosis. Loss of the SMARCB1 locus has been associated with

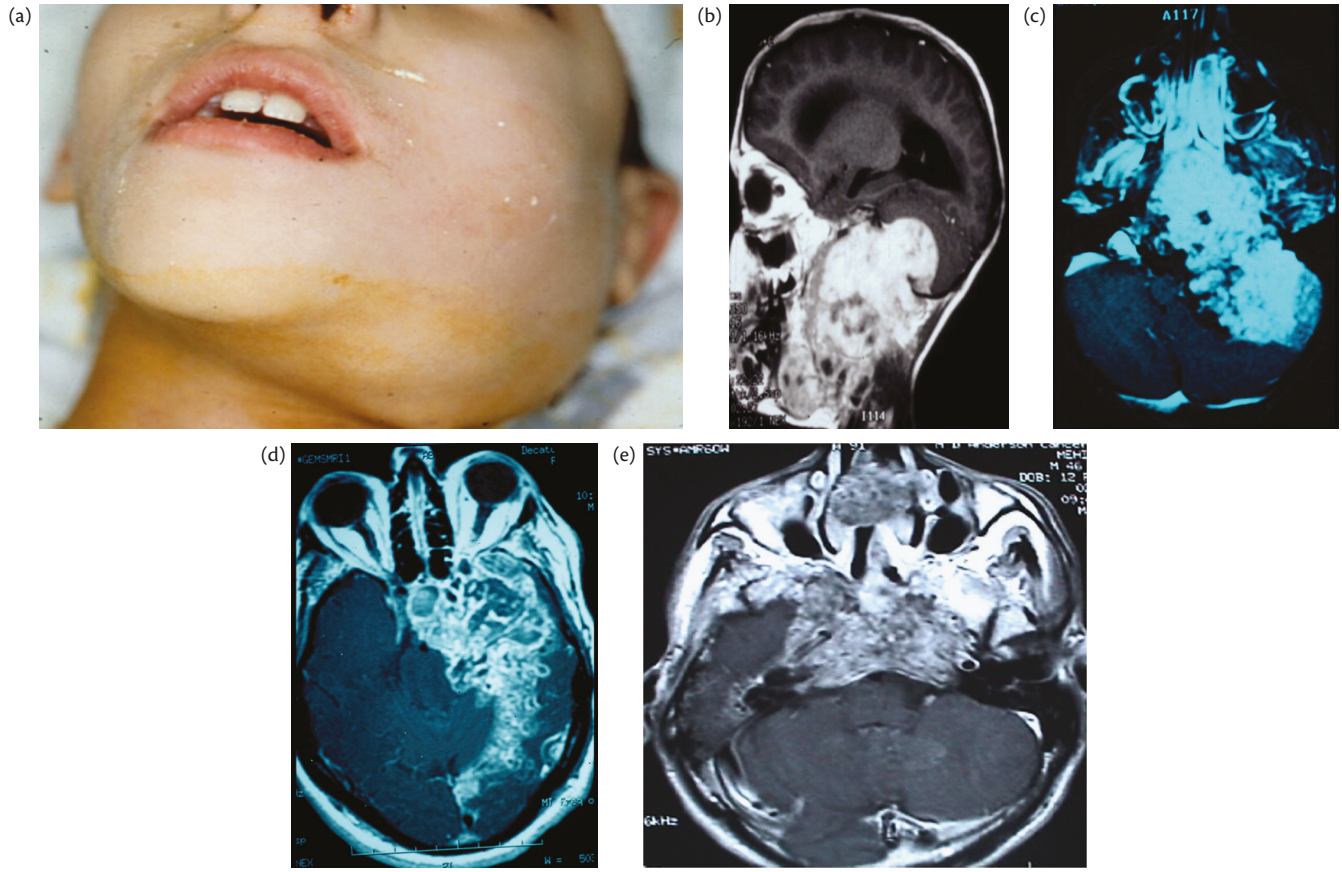

Fig. 15.2 (A, B) Axial enhanced MRI scan and patient photograph showing a chordoma extensively invading the skull base and neck. (C, D, E) Additional examples of axial enhanced MRI scans showing the invasive nature of chordomas.

poorly differentiated cases (Mobley et al., 2010) and homozygous loss of CDKN2A and CDKN2B has been linked to metastatic cases (Hallor et al., 2008). Chordomas demonstrate the classic theory of tumour progression where the accumulation of additional genetic mutations correlates with more aggressive clinical behaviour.

Preoperative work-up and planning

The preoperative assessment of patients with chordoma should include MRI, CT, and vascular imaging. A thorough review of all available imaging is critical in understanding the tumours extension and relationship to critical neurovascular structures and to best plan radical resection and postoperative radiotherapy. On CT imaging, chordoma appears as a centrally located, well circumscribed, primarily hyperdense mass arising from the clivus. CT is most valuable in showing the extensive lytic bone involvement that can spread throughout the skull base and must be removed for a truly radical resection. Intratumoural calcification that most likely represents sequestered bone may be present. Chordoma enhances with iodinated contrast. MRI is complimentary to CT as it better delineates the soft tissue tumour extent with excellent anatomical detail. Typically chordoma appears as low to intermediate

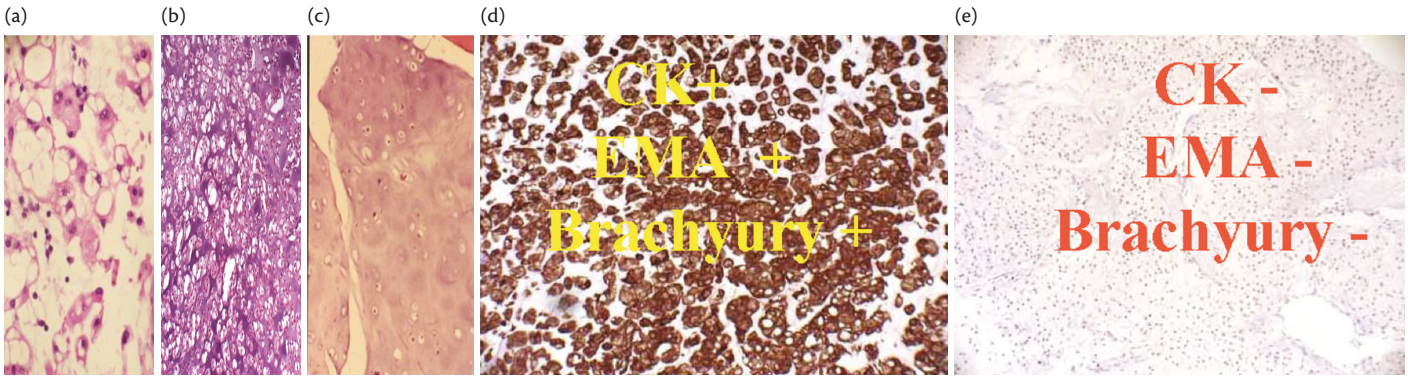

Fig. 15.3 H&E stain of chordoma, chondroid chordoma, and chondrosarcoma; and immunohistochemical staining of chordoma and chondrosarcoma.

intensity on T1-weighted imaging, hyperintense on T2-weighted imaging, and is moderate to markedly enhancing. In the event of necrosis or a large amount of mucinous material, the enhancement may be diminished or absent. Vascular imaging is also obtained to delineate tumoural encasement or displacement of cerebral vessels and to study the venous anatomy for approach planning (Erdem et al., 2003). This can typically be accomplished with non-invasive imaging and we have found dynamic CT angiography to be particularly helpful (Bi et al., 2015). On occasion, catheter angiography is needed if vessel narrowing is severe, to assess collateral flow, or in the event of prior radiation to assess for radiation induced angiopathy, which can make any dissection around the artery hazardous.

Additional studies beneficial in the preoperative assessment are pituitary function testing and neuro-ophthalmological testing. As chordomas frequently involve the sellar area, hypopituitarism can occur and should be diagnosed and corrected. Many patients with chordomas present with visual complaints and the tumours often spread to involve the optic apparatus. Baseline testing is important in following these patients.

Treatment

It is critical to understand chordoma behaviour and natural history in order to optimally manage a patient's disease. Though they are histologically benign, their natural history and aggressive behaviour is *malignant*. They have a short life expectancy without treatment, a high recurrence rate (Forsyth et al., 1993; Gay et al., 1995; Al-Mefty and Borba, 1997; Ammirati and Bernardo, 1999), and a propensity to metastasize (Markwalder et al., 1979; Fagundes et al., 1995), and surgically implant (Arnautovic and Al-Mefty, 2001; Fagundes et al., 1995). Considering the malignant behaviour of chordoma, the need for early, aggressive treatment is unambiguous. Chordomas must be treated at the time of diagnosis without a period of observation.

Long-term survival has been reported where treatment has consisted of radical removal followed by high-dose radiation to the tumour bed at the onset of diagnosis (Al-Mefty and Borba, 1997; Almefty et al., 2007). Anything less is doomed to recur. Following recurrence, chordoma has a dismal prognosis with 3- and 5-year survival rates of 43 and 7% (Fagundes et al., 1995). To this end, everything must be done to control chordoma at the time of initial treatment.

The extent of surgical removal to recurrence-free survival has been well-established (Forsyth et al., 1993; Fagundes et al., 1995; Gay et al., 1995; Al-Mefty and Borba, 1997; Colli and Al-Mefty, 2001; Tamura et al., 2015). The advancements in skull base and microsurgery have made radical removal of skull base chordomas safe. Several considerations must be made when discussing the surgical removal of chordomas. Key among them is the fact that chordoma exists as islands in the surrounding bone and not just the clearly visible soft tissue mass. Therefore, to achieve radical resection, extensive drilling of the surrounding bone must be performed in addition to complete removal of the soft tissue mass. Preoperative CT imaging must be thoroughly reviewed to understand the bony involvement and plan surgery accordingly, as chordoma has a tendency to spread throughout the skull base.

We have characterized this phenomenon by dividing chordomas into three types based on their extension into skull base compartments. Type 1 tumours are rare cases limited to one compartment confined to a single anatomical area. Type II tumours extend to two or more contiguous areas that can be radically resected through a single approach, and Type III tumours extend to several compartments and require multiple approaches. We have found 60% of tumours to involve the cavernous sinus, 50% the petrous apex, 25% the occipital condyle and 50% to have extended intradurally (al-Mefty and Borba, 1997). These extensions must be anticipated, studied, and planned for in the operative approach or approaches. Indeed, multiple skull base approaches are often needed to achieve radical removal of chordomas and provide the best chance of long-term control.

All approaches to chordomas should be planned to allow for the fact that chordomas begin as extradural tumours, so extradural approaches should be used in the first instance. If the tumour has not yet spread intradurally, then every effort should be made to keep the operation extradural. If the tumour has extended intradurally then it can be followed intradurally from an extradural approach.

Since most chordomas extensively involve the clivus, an anterior midline approach is typically needed. We have found the sublabial transmaxillary, transphenoidal and anterior clivectomy approach to provide an excellent exposure (Al-Mefty et al., 2008). The entire length of the clivus can be exposed and it offers a wide working area suitable for both microscopic and endoscopic techniques. We prefer to use the microscope for the drilling of the clivus as it offers critical three-dimensional vision. The endoscope is an extremely valuable adjunct that allows visualization of areas hidden from the microscopic view. The combined use of the microscope and endoscope is an excellent strategy that we have found useful for all tumour types (Abolfotoh et al., 2015). All skull base surgeons should have expertise in both techniques as they are complementary.

Given the frequent involvement of the cavernous sinus, radical resection of chordomas includes removal of the cavernous sinus component and this can be done safely from the middle fossa approach (Al-Mefty, 1998). When the occipital condyle is involved as frequently occurs, a transcondylar approach is needed and this may necessitate occipito-cervical fusion, which can be accomplished during the same exposure (Al-Mefty, 1998). Since the radical resection of chordomas involves extensive skull base removal and the tumours often extend intradurally, cerebrospinal leak is a concern that must be planned for, in advance, with preparation of a vascularized flap of temporalis muscle or pericranium.

Given the extreme importance of radical resection, we do everything possible to ensure the maximal possible resection has been achieved. As a part of this strategy, we feel intraoperative imaging is essential. We prefer to perform all chordoma resections in the Advanced Multimodality Image Guided Operating (AMIGO) suite. The suite is equipped with intraoperative MRI, CT scan, PET CT, ultrasound, and angiography allowing one to leave the operating room knowing all possible tumour has been resected (**Figs. 15.4A–C**).

Another operative consideration in the treatment of chordomas is their propensity for surgical implantation (Figs. 15.5A–C). All efforts must be taken intraoperatively to avoid potential seeding. First, preoperative planning of all clival lesions should allow for the possibility of a chordoma. If chordoma is considered, approaches and techniques must be employed that minimize the risk of seeding. An approach that provides a contained surgical field is optimal. After the approach is completed but before the tumour resection commences, the field and operative tunnel are coated with fibrin glue and cotton patties. Following complete removal of the tumour, the glue and patties are removed prior to introducing clean grafts. Prior to initiating the closure, all contaminated drapes and towels are

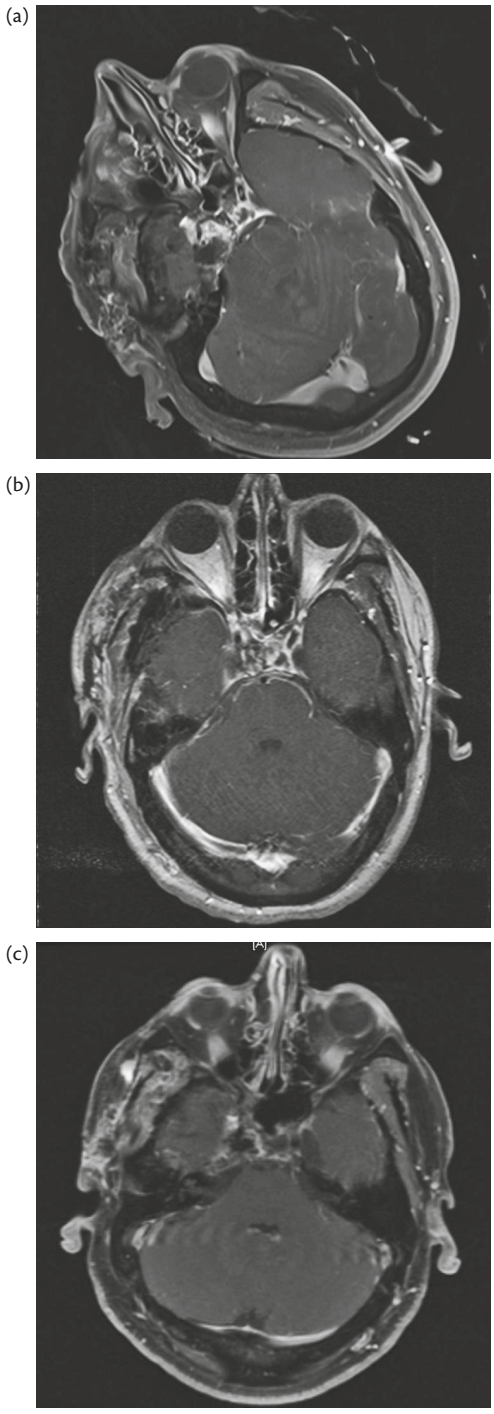

Fig. 15.4 (A) Intraoperative MRI showing residual chordoma; (B) postoperative MRI showing no residual chordoma after additional resection; (C) 3-month follow-up MRI showing no residual chordoma.

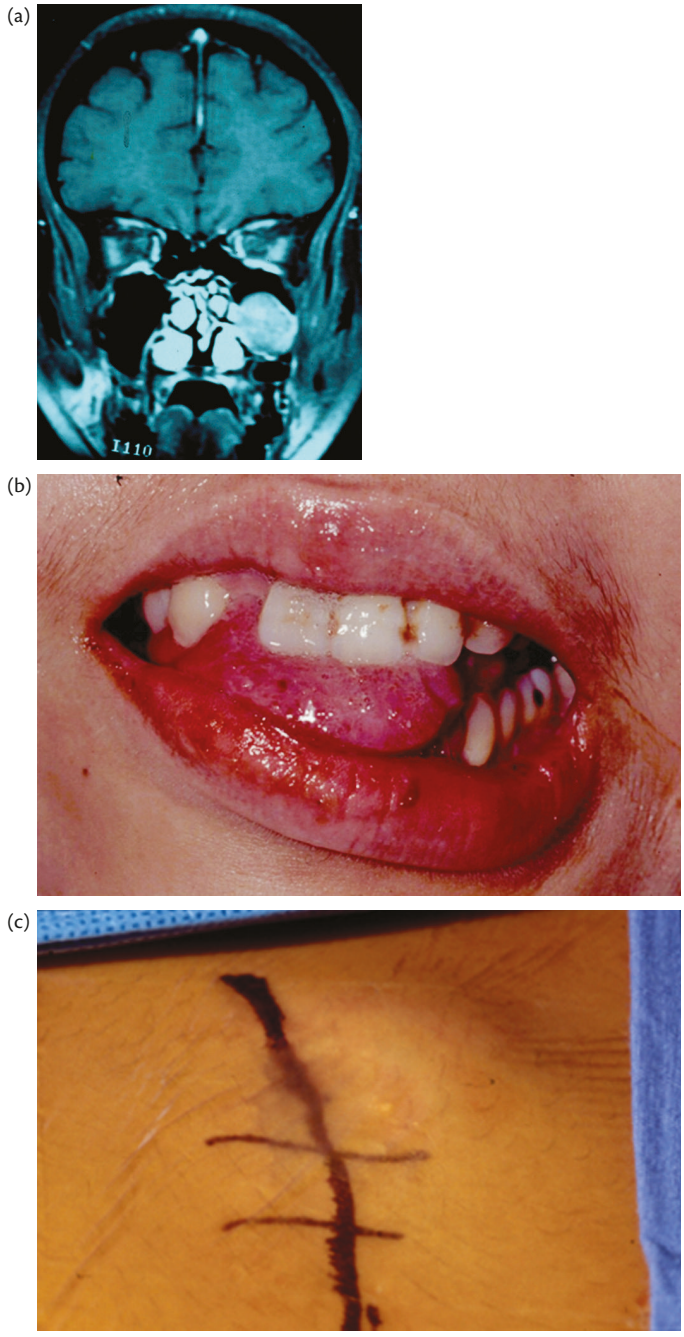

Fig. 15.5 Examples of surgical seeding of chordoma. (A) Coronal MRI showing chordoma seeding of the maxilla following a transmaxillary approach. (B) Patient photograph demonstrating chordoma seeding the gingiva following a sublabial exposure. (C) Patient photograph showing seeding of the abdomen at the site of the abdominal fat graft.

replaced, and clean instruments and gloves are used. If fat or fascia is harvested from other sites, clean instruments and gloves are used and a clean field recreated (Arnautovic and Al-Mefty, 2001).

In keeping with the idea that chordomas act malignantly and given the dismal prognosis following recurrence, the best chance for long-term control is maximal treatment at presentation. Therefore, radical resection should be followed with high-dose radiotherapy. Chordomas are relatively radiation resistant tumours, however, high-dose radiation such as is possible with particle-based therapy has been shown to offer improved local control and survival (Hug et al., 1999; Munzenrider and Liebsch, 1999; Igaki et al., 2004; Noel et al., 2005; Weber et al., 2005). Due to the high rate of local recurrence and infiltrative nature of chordoma and propensity for seeding, it is important that the radiation field includes the entire operative bed, surgical corridor, and anatomical compartment.

In contrast to chordoma, chondrosarcoma has an excellent prognosis. Radical removal of chondrosacromas offers the potential for long-term control and possible cure and should be pursued with zeal. Radiation therapy has been proven to be effective in providing

long-term control, but this may reflect the less aggressive nature of this tumour and may not, therefore, be necessary after complete resection. We advocate radical removal without adjuvant radiation therapy and radiological surveillance of any small residual.

Prognosis

Several factors affect the prognosis of chordomas including age, histologic subtype, and treatment received. The impact of gender will not be discussed in detail, other than to say conflicting results have been reported. Unfortunately, due to their rarity, the frequent mixing with chondrosarcomas, and the lack of uniform treatment, the true prognosis of patients with chordomas is difficult to determine. However, we will address how each of these factors affect prognosis and emphasize that the best chance for long-term control is with radical resection including the involved bony islands followed by high-dose radiation at the time of initial diagnosis.

The effect of age on prognosis has revealed conflicting results with the exception of the particularly aggressive course of chordomas in those less than five years old. In children less than five years old, 65% of tumours are atypical and those with the classical subtype are more cellular. Furthermore, nearly 60% of patients less than five years old suffer from metastases (Borba et al., 1996). However, in general with the paediatric population, we have been pleased to see a number of long-term disease-free survivors using the strategy of radical resection and high-dose radiation (unpublished data).

Atypical chordomas have a worse prognosis than the classic or chondroid type (Ouyang et al., 2014; Yakkioui et al., 2014). In their seminal work on chordoma and chondrosarcoma in which they introduced the chondroid subtype, Heffelfinger et al. suggested that the chrondroid variant had a more benign course and other authors have supported that claim (Heffelfinger et al., 1973; Rich et al., 1985). Debate over the prognostic significance of this type has ensued, however, we have convincingly shown in a study of 109 patients all with pathology confirmed with immunohistochemical staining that chondroid tumour is indeed a subtype of chordoma with no difference in outcome and that both chordoma subtypes have a significantly worse outcome than chondrosarcoma (Almefty et al., 2007). Other studies have supported this finding (Forsyth et al., 1993; Colli and Al-Mefty, 2001; Bohman et al., 2014). These findings highlight the importance of confirming the pathologic diagnosis with immunohistochemical staining.

The combination of radical surgical resection and high-dose radiation treatment has proven to be the optimal treatment strategy for patients with skull base chordoma. However, this management path is not uniformly followed, so the survival of patients with chordoma may be underestimated in some publications. Two critical points are evident, firstly that treatment with anything less than an aggressive approach is doomed to recurrence and short life expectancy following recurrence. Secondly, that radical resection with up-front high-dose radiotherapy offers a chance for prolonged control. Indeed, when complete tumour removal is achieved and adjuvant proton beam therapy utilized, we have seen a recurrence-free survival rate of 74%, whereas, this falls to 40% when residual tumour is present (Almefty et al., 2007).

Although, often grouped together, chondrosarcomas have been repeatedly shown to have a much better prognosis than chordoma. In our study of 20 patients with chondrosarcoma, none suffered a recurrence or died from their disease. Half of these patients received proton beam therapy (Almefty et al., 2007). Proton beam therapy has been proven to have excellent control rates with five- and ten-year survival rates in the 90–100% range (Hug et al., 1999; Munzenrider and Liebsch, 1999; Ares et al., 2009). However, it is quite likely that these excellent control rates are more indicative of the tumours favourable biology. Therefore, it is our practice to attempt complete resection of chondrosarcomas and avoid radiation therapy. Small residual chondrosarcomas can be followed.

Controversies

Optimal radiation modality for chordomas

We have stated throughout this chapter the benefit of high-dose radiation for chordomas. Particle-based therapy, in which the largest experience is with protons, has been shown superior to conventional photon based treatment (Cummings et al., 1983; Fuller and Bloom, 1988; Catton et al., 1996; Hug et al., 1999; Munzenrider and Liebsch, 1999; Zorlu et al., 2000; Igaki et al., 2004; Noel et al., 2005; Weber et al., 2005; Ares et al., 2009). The radiation treatment of chordomas must consider that chordomas are intimately associated with vital structures, are relatively radioresistant, and require high radiation doses, have a high rate of local recurrence, have a high rate of surgical seeding, disperse as islands of microscopic tumour throughout the skull base, and local control is a critical part in overall survival. Given these features, proton-based therapy offers many advantages that are ideally suited for skull base chordomas. Key among the advantages in proton-based therapy is that it does not have an exit dose, making the volume of normal tissue receiving radiation smaller than with photons. The properties of chordoma also create a clear advantage for fractionated proton therapy over single-fraction radiosurgery. Single-fraction radiosurgery typically targets gross tumour volume and only limited microscopic volume. Any microscopic tumour beyond the target will receive a sharp fall-off in the dose. In contrast, as Hug et al. describe, proton irradiation for chordomas uses the concept of a clinical target volume defined as 'any area of risk for microscopic disease, in general including the entire operative bed and anatomical compartment of initial extension' (Hug, 2001). The clinical target volume has a distinctly different shape and size than the gross tumour volume and for chordoma is one that is not ideally suited for single-fraction radiotherapy.

The use of carbon ions as particle therapy radiation is a developing technology that has garnered enthusiasm from some authors (Schulz-Ertner et al., 2007; Takahashi et al., 2009). Carbon ions offer some of the same advantages as proton therapy in that they have a steep dose fall-off but are said to have a higher biological equivalent dose. The higher biological equivalent dose and ability for intensity modulation may allow the same tumour effect at lower dose potentially reducing the toxicity. Schulz-Ertner et al. reported 3- and 5-year local control rates of 80% and 70% and overall survival of 92% and 89% treated with surgery plus carbon ion therapy (Schulz-Ertner et al., 2007). Takahashi et al. reported 3- and 5-year recurrence-free survival rates of 70% and 70%, although only nine patients were included (Takahashi et al., 2009). Carbon ion therapy has the potential to be an attractive option for the adjuvant treatment of chordomas

but additional studies with more patients and longer follow-up are needed.

Endonasal resection of chordomas

With the development and growing popularity of endonasal approaches to the anterior skull base, this technique is being increasingly used in the treatment of chordomas. We have already mentioned the virtues of the endoscopic techniques and the importance of surgeons learning this skill. The controversy regarding the endonasal approach for resection of chordomas is not its utilization but rather its use as the sole surgical modality. Given that chordomas are extradural tumours arising from the clivus, anterior midline approaches are typically needed. However, chordoma is not limited to the visible soft tissue mass but exists as islands in the surrounding bone. Therefore, radical resection of chordomas requires removal of this bone. Frequently, to accomplish this goal, multiple approaches are needed and an endonasal approach alone in these cases will not achieve the sought-after radical removal. Additionally, the clivus is typically widely involved and extensive drilling is required. In order to drill in such a critical area, the three-dimensional view provided by an operative microscope is preferable. Finally, chordomas have a propensity for surgical seeding and the endoscope may increase the risk of implantation because to maintain a sense of depth of field constant movement with the endoscope is necessary and instruments are constantly passed through an uncontained field.

Dermoid and epidermoid cysts

Andrew McEvoy

Introduction

Dermoid and epidermoid cysts are important intracranial developmental lesions. They are commonly derived from retained surface ectoderm trapped by two fusing neuroectodermal surfaces during neural tube closure, and are also termed congenital ectodermal inclusion cysts. There is some debate as to whether they arise from a primary failure of neural tube closure in the third to fifth week of embryogenesis, or an earlier primary failure of gastrulation that would explain the associated mesodermal abnormalities (Dias and Walker, 1992). Occasionally epidermoid cysts are acquired lesions derived from iatrogenic implantation of surface ectoderm (termed implantation dermoids).

Epidemiology

Dermoid cysts are rare, making up 0.3% of intracranial tumours, while intracranial epidermoid cysts are approximately four times as common, making up 0.5–1.5% of intracranial tumours (MacCarty et al., 1959; Gormley et al., 1994). Both exhibit slow, linear growth, but dermoid cysts typically present at an earlier age with a shorter duration of symptoms.

Pathology

Dermoid cysts have a tendency to occur near the midline. The most common intracranial sites are near the anterior fontanelle extradurally, and in the sellar, parasellar, and intraventricular regions intradurally. The most common intraspinal site is near the cauda equina, and can be associated with a dermal sinus tract and subsequent increased risk of bacterial infection.

Dermoid cysts are composed of epithelial cell debris and keratin, and also include elements of dermis such as hair follicles, sebaceous glands and sweat glands (**Fig. 16.1**). The active secretion of glandular fluid and subsequent growth and rupture is postulated as a possible cause for their earlier presentation (Osborn and Preece, 2006).

Macroscopically dermoid cysts are well-defined, lobulated, pearly masses with thick partially calcifiesd capsules. The contents of the cyst may include the yellow, odious fluid that results from glandular secretion, and may also contain hair and teeth. Histologically dermoid cysts exhibit both dermal and epidermal elements, although the epithelial cell lining may be less well differentiated compared with epidermoid cysts.

Epidermoid cysts are mainly intracranial, and are found away from the midline. The most common location is the cerebellopontine angle (40–50%), where they make up the third most common lesion in adults after vestibular schwannomas and meningiomas. They are also found in the fourth ventricle, the sellar and parasellar regions, the cerebral hemispheres, and the brainstem. Epidermoid cysts are less common but do occur in the spine, with a predilection for the thoracic spine.

Epidermoid cysts are composed of only epithelial cell debris, including cholesterol and keratin, with no dermal involvement, that is laid down in a lamellar pattern (**Fig. 16.1**). This gives rise to a more irregular and lobulated mass, with a sheeny surface that grows to encase surrounding nerves and vessels along cleavage planes. The cyst contains soft keratohyalin material that results from progressive epithelial desquamation, and is often described as having a classic 'candle wax' appearance intraoperatively.

Epidermoid and dermoid cysts can broadly present in two ways. Firstly there is local mass effect, which is dependent on tumour location and insidious by nature on account of the slow, linear growth rate. Cysts in the middle cranial fossa are often asymptomatic, and can grow relatively large before detection, with atypical presentations such as trigeminal numbness.

Secondly there is a more acute presentation, secondary to cyst rupture (**Fig. 16.2**). Aetiology may be traumatic, iatrogenic, or spontaneous, with a consequent leakage of cyst contents into the subarachnoid space and associated chemical meningitis. This should be distinguished from the septic meningitis seen in intraspinal dermoid cysts, caused by the presence of a dermal sinus tract. Cyst rupture can lead to several neurological sequelae, including headache, seizures, vasospasm, neurological deficit, and death.

Finally, dermoid cysts can be associated with other congenital abnormalities that may account for the initial presentation. An association with Klippel-Feil syndrome has been reported for both intraspinal (McLaughlin et al., 2013) and intracranial (Pai et al., 2007) dermoid cysts. The presence of associated mesenchymal abnormalities supports the notion put forward by Dias and Walker that the key embryological event for the development of dermoid cysts occurs prior to neural tube closure, around the time of the formation

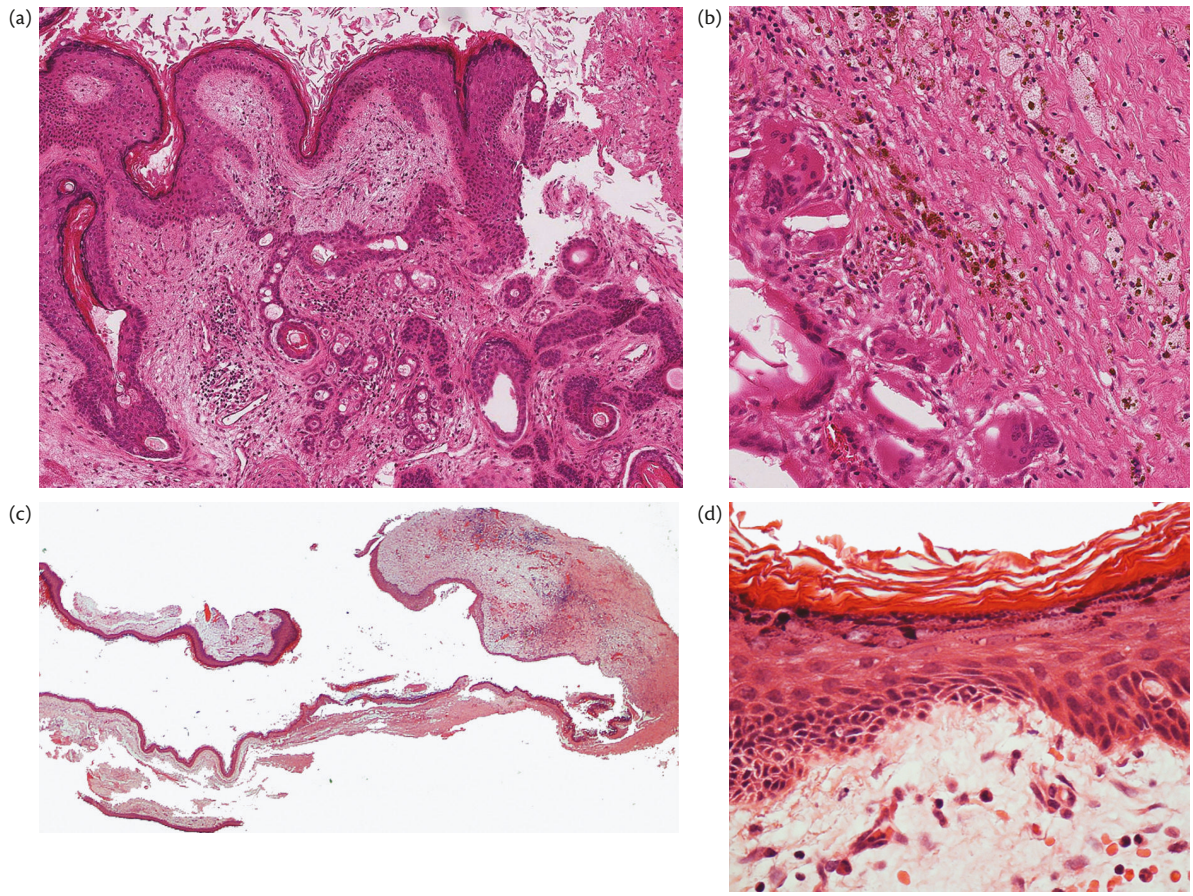

Fig. 16.1 Histopathology of dermoid and epidermoid cysts
(A) Wall of a dermoid cyst with a lining of stratified squamous epithelium with prominent surface keratinization. The wall of the cyst shows mature adnexal structures including pilosebaceous glands, which classify this as a dermoid. (B) A focal foreign body giant cell reaction with macrophages and haemosiderin pigment is seen indicative of previous cyst rupture. (C) Epidermoid cyst at low power magnification showing a simple unilocular cyst with a squamous epithelial lining and fibrocollagenous wall but no adnexal structures. (D) The epithelial lining is simple stratified squamous epithelium with keratinization.

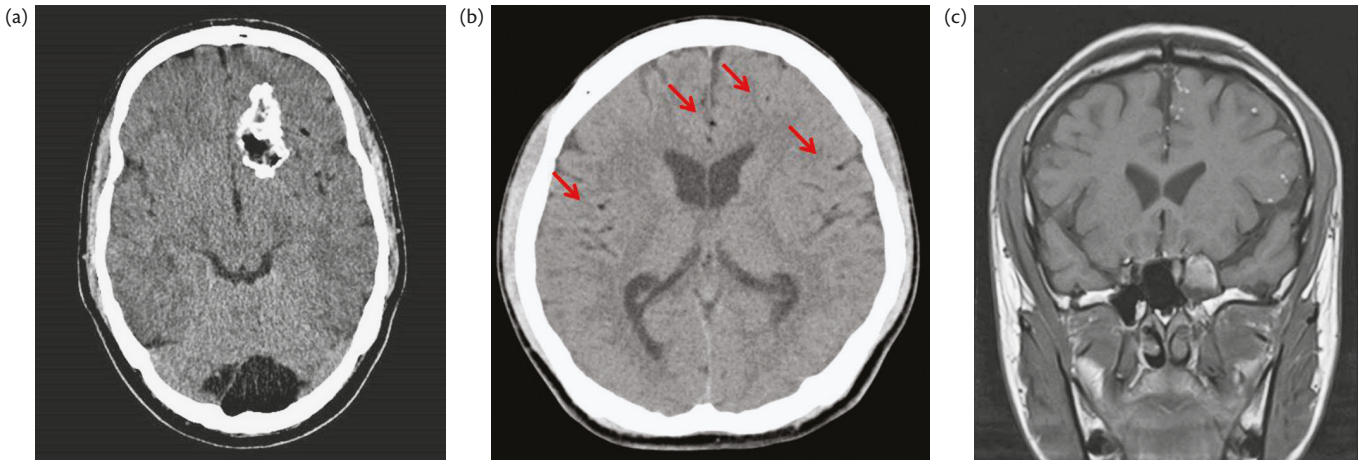

Fig. 16.2 Ruptured dermoid cyst. (A) CT showing ruptured left frontal calcified dermoid cyst. (B) CT showing disseminated locules of fat in the subarachnoid space. (C) Coronal T1W MRI showing ruptured left parasellar dermoid cyst.

Table 16.1 Features of dermoid and epidermoid cysts

	Dermoid	Epidermoid
Frequency	Rare	More common
Location	Midline	Off midline
Presentation	Earlier	Later
Contents	Dermal elements	No dermal elements
Rupture	More common	Less common
Associated abnormalities	May be present	Absent
Surgical resection	Less difficult	Difficult

of the trilaminar plate (Dias and Walker, 1992). Table 16.1 presents the features of dermoid and epidermoid cysts.

Radiological features

The typical radiological findings of epidermoid and dermoid cysts are shown in Table 16.2.

Fluid attenuated inversion recovery (FLAIR) and diffusion MRI (DWI) are useful to distinguish epidermoid cysts from arachnoid cysts. In contrast to epidermoid cysts, arachnoid cysts exhibit signal drop-out with FLAIR and free diffusion with DWI (Fig. 16.4).

Dermoid cysts (Fig. 16.5) can have a variable appearance on MRI, dependent on the balance of their contents which may include fat, hair, sebum, and teeth. They differ from lipomas by not consistently following fat densities on all sequences. Haemorrhage within the cyst can lead to hyperdensity on CT, and can occasionally mask the underlying lesion (Sanchez-Mejia et al., 2006).

Surgery

Indications

The aim of resective surgery for any space-occupying lesion is threefold, diagnostic, treatment of symptoms, and improvement in outcome. With the range of MRI sequences outlined surgery is rarely indicated to make a diagnosis in these cases. Therefore, the main indication for surgery is to treat current symptomatology, which is usually secondary to the mass effect. The risk of future morbidity can be difficult to predict, and a broader discussion on the advantages and disadvantages of conservative management follows in a later section.

Preoperative

Patients should undergo comprehensive MR diagnostic imaging, with the input of an experienced neuroradiologist. For posterior fossa cysts, particular attention should be paid to the presence of associated abnormalities at the craniocervical junction, including occipitalization of C1, basilar invagination, atlantoaxial subluxation, Klippel-Feil syndrome and Chiari malformations (Chandra et al., 2005).

All patients should be examined for signs of a dermal sinus tract, which may predispose to bacterial infection. In these cases, excision of the tract should be incorporated with the surgical resection of the cyst.

The slow, linear growth of these cysts means there is little surrounding vasogenic oedema, and a preoperative course of corticosteroids is rarely necessary. However, corticosteroids are indicated following cyst rupture or postoperatively when cyst contents are spilled, when they are thought to reduce the severity and duration of chemical meningitis.

Surgical rationale

The ideal goal of surgery is complete resection of the cyst including the epithelial lining, providing curative treatment and removing the risk of recurrence. However, surgery can be technically demanding on account of the deep, critical location of the tumours and the relationship of the tumours to surrounding neurovascular structures. Since this is a benign condition, a form of subtotal resection with functional preservation is always preferable to gross total resection when there is a high risk of causing neurological deficits.

There are few large case series on account of the rarity of the tumours. In Yasargil's series of 43 patients treated at a single centre (consisting of 35 epidermoid and eight dermoid cysts), compete resection was achieved in 41 cases (34 epidermoid cysts and seven dermoid cysts) with excellent results, using strict microsurgical

Table 16.2 Radiological features of dermoid and epidermoid cysts

Imaging modality	Dermoid	Epidermoid
CT	Hypodense, very similar to CSF Lobulated margins Fine linear strands No enhancement	Hypodense, slightly greater than CSF Bone erosion in 33% No enhancement
T1W MRI	Typically hyperintense, same as fat No enhancement	Isointense, same as CSF Occasionally hyperintense around periphery, No enhancement
T2W MRI	Variable	Isointense or hyperintense, same as CSF
FLAIR	Variable	Hyperintense to CSF
DWI	Restricted diffusion, hyperintense to CSF	Restricted diffusion, hyperintense to CSF
Fat saturation sequence	High signal drops out	Unchanged
Local findings	More mass effect Associated abnormalities (i.e. Klippel-Feil, dermal sinus tract)	Insinuates between neurovascular structures

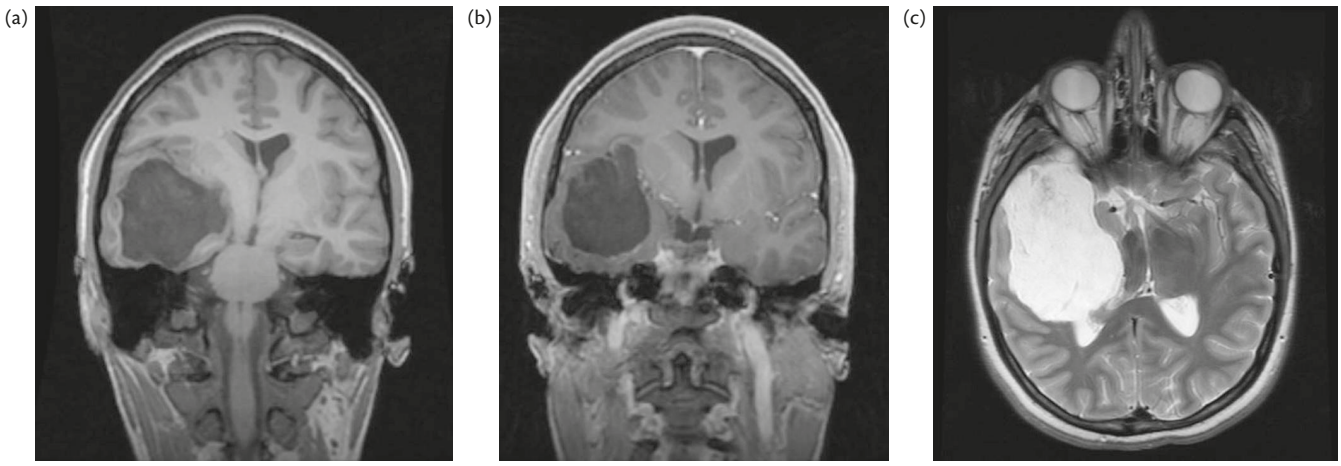

Fig. 16.3 Epidermoid cyst. (A and B) Coronal T1W MRI without and with gadolinium showing right perisylvian epidermoid cyst. (C) Axial T2W MRI showing right perisylvian epidermoid cyst.

skull base surgery approaches (Yasargil et al., 1989). In this series total resection was defined as complete removal of cyst contents and capsule. Most other series report lower rates of total resection ranging from 0% to 75% (Lynch et al., 2014). This reflects the technical difficulties of surgery and emphasizes the need to avoid causing functional deficits. The development of minimally invasive skull base techniques may change the way these tumours are approached (Chivukula et al., 2013), although it remains to be seen whether this will improve the rates of gross total resection.

Independent of the surgical approach resection can be technically demanding for several reasons. Tumour adhesions to adjacent structures on the skull base and also to surrounding brain

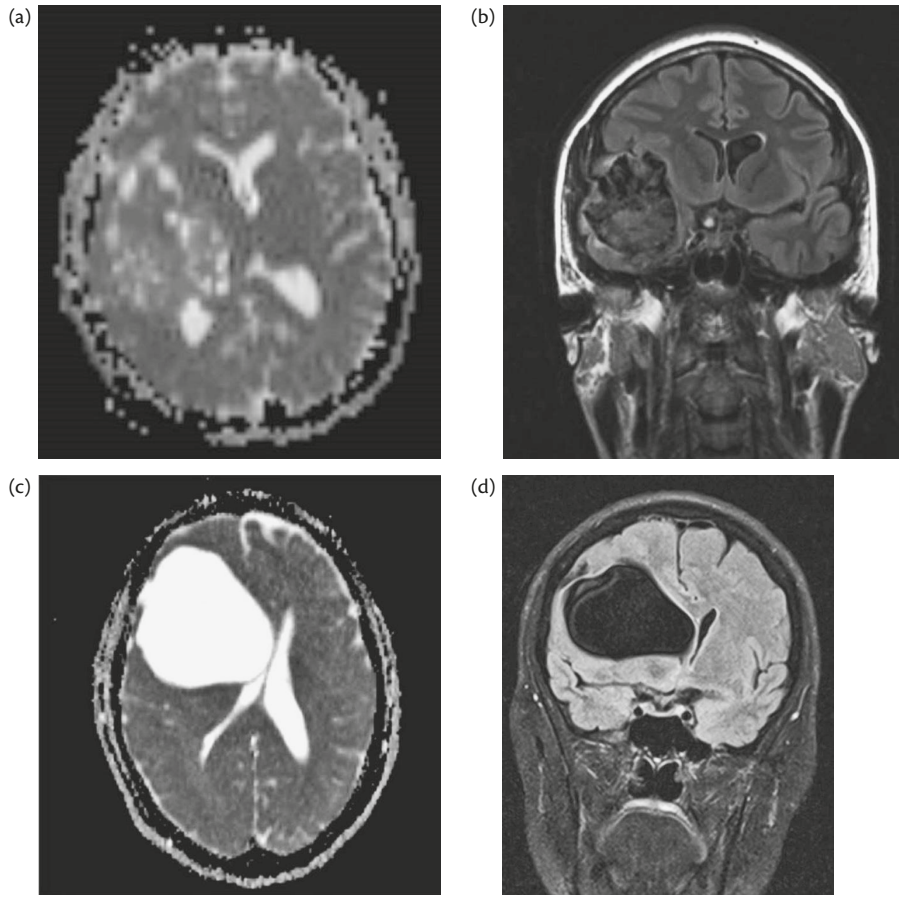

Fig. 16.4 Differentiating epidermoid (A and B) from arachnoid cyst (C and D).

parenchyma are common. This is most pronounced with dermoid cysts, which tend to cause a greater granulomatous reaction with the arachnoid mater and occasionally the pia mater. Additionally, the cyst can extend between different anatomical compartments. This is most pronounced with epidermoid cysts, which are soft and pliable and have a tendency to 'flow' into the available subarachnoid space. Finally, prolonged linear growth of tumours can lead to substantial distortion of the surrounding anatomy, such as displacement of the basilar artery from the ventral surface of the brainstem. A strict microsurgical technique should be employed at all times, with wide exposure, minimal retraction, preservation of surrounding arachnoid planes and meticulous haemostasis. The principles of resection involve using the ultrasonic aspirator to achieve a primary intracapsular debulking followed by removal of the capsule by the development of a plane between capsule and overlying arachnoid. The cyst contents should not be allowed to spill into the subarachnoid space as they are intensely irritant and can cause a chemical meningitis. This requires meticulous layering of the surrounding normal structures with linteens before the cyst is opened and the contents accessed. In cases where the capsule is adherent to the brain or important neurovascular structures, it may be necessary to leave residual capsule behind. This carries the risk of tumour recurrence in the future, and possibly commits the patient to long-term surveillance imaging and follow-up. However, this approach avoids damage to neurovascular structures that may be disastrous for the patient.

Most series that report surgical outcomes group epidermoid and dermoid cysts together, making it difficult to discern differences between groups. There is no evidence that outcomes are worse for epidermoid cysts compared with dermoid cysts. Dermoid cysts may present more of a challenge in the development of a plane between capsule and arachnoid in areas of granulomatous reaction, while epidermoid cysts may be more challenging in their anatomical location and extension.

There is currently no role for radiotherapy or chemotherapy in the treatment of dermoid or epidermoid cysts with the exception of malignant transformation.

Complications

A well-recognized complication from surgical resection of both dermoid and epidermoid cysts is the 'spilling' of the contents of the cyst into the surrounding CSF, which can occur with intraoperative handling. This results in the dissemination of fat droplets throughout the subarachnoid and intraventricular space, setting up a chemical inflammation of the meninges (Fig. 16.2). The clinical sequelae are variable, and include no adverse effects (Carvalho et al., 2000), headaches, seizures, and hydrocephalus (Liu et al., 2008). The risk of intraoperative spillage can be reduced by sharp dissection of the

capsule, copious irrigation in the surgical field and protection of the surrounding brain with cotton pads. Treatment is largely conservative, although steroids are indicated for chemical meningitis, and hydrocephalus should be treated with appropriate CSF diversion.

Recurrence

Complete tumour resection is desirable to minimize the risk of future morbidity from tumour recurrence, and the first resection is usually the best opportunity to achieve this. The recurrence rate for dermoid and epidermoid cysts is likely to be dependent on the volume of residual tumour left following subtotal resection. However, growth is linear, leading to long periods of patients being asymptomatic. In one series of 29 patients who underwent resection of epidermoid cysts with long-term follow-up, primary recurrence occurred in seven patients after a mean period of 8 years and 10 months, and secondary recurrence (recurrence following re-do surgery) occurred after a mean period of 12 years 6 months from their first resection (Yamakawa et al., 1989). Re-do resections present new difficulties, with the added presence of intradural adhesions as a result of previous surgery. However, in symptomatic patients with tumour recurrence re-operation is often indicated.

Risk of malignant transformation

Malignant transformation of dermoid and epidermoid cysts is a rare but recognized cause of intracranial squamous cell carcinoma, after metastases and extension from the cranial base. A review found 52 cases of malignant transformation of cysts in the literature, with a median survival of 9 months (Hamlat et al., 2005). Radiotherapy is considered to confer a modest survival benefit (median survival 26 vs. 3 months, $P = 0.077$). Leptomeningeal carcinomatosis has only been seen with malignant transformation of epidermoid cysts and is associated with a particularly poor prognosis. Although extremely rare, malignant transformation should be considered in any patient who does not recover as expected from surgery and who deteriorates in the absence of hydrocephalus with rapid recurrence of the tumour or where imaging shows enhancement at the tumour site.

Controversies with follow-up imaging: The case for and against

Routine surveillance imaging may follow initial diagnosis as part of a conservative strategy, and may also follow a subtotal or gross total resection.

The benefits of surveillance imaging are that tumour growth and recurrence may be closely monitored so that both patient and surgeon will have a good understanding of the tumour's behaviour. This may be especially important if the tumour begins to encroach on vital structures or straddle anatomical compartments, making total resection more difficult to achieve. There is also a theoretical advantage of improving detection of malignant transformation, although this is a very rare event with few documented cases in the literature (Hamlat et al., 2005).

The main disadvantage for the patient is that follow-up imaging may add to the psychological burden. Radiological progression in the absence of symptoms is rarely an indication for surgery. A pragmatic approach would therefore be to repeat imaging when the patient presents with new symptoms or signs.

There are currently no clear guidelines on how this patient group should be followed up. From the surgeon's point of view, an immediate postoperative MRI is essential to establish a baseline of residual tumour, and some staged follow-up imaging can prove useful in providing patient information on the risk of future morbidity or surgery. Occasionally patients with no new symptoms may be suitable for surgery if there is clear radiological progression with impending neurological deficit. However, in all cases the frequency of follow-up imaging should be discussed with the patient, and tailored to fit their own expectations and practical circumstances.

Esthesioneuroblastoma

Georgios Klironomos, Lior Gonen, and Fred Gentili

Introduction

Esthesioneuroblastoma (ENB) is a rare, malignant tumour of neuroectodermal origin, arising in the upper nasal cavity. First described in 1924 by Berger and Richard, several names have subsequently been assigned to this tumour but currently the most common terms are 'esthesioneuroblastoma' and 'olfactory neuroblastoma'. Histological and molecular studies indicate that the most likely cells of origin are the basal cells of the olfactory epithelium located at the area of cribriform plate, the upper third of the nasal septum and the superior nasal turbinate. In humans the olfactory epithelium retains the capacity to regenerate through division and differentiation of the basal cells. ENB is an aggressive tumour with a variable tendency to metastasize. It can extend or recur intracranially by local extension through the cribriform plate. It may be difficult to differentiate this tumor from other neoplasms arising in the nasal cavity and paranasal sinuses.

Epidemiology and clinical presentation

ENB represents 0.3% of all cancers of the upper digestive tract and approximately 3–6% of all intranasal malignant tumours of the nasal cavity (Broich et al., 1997). There is a slight male predominance (male 55%, female 45%), and it affects several ethnicities. In the literature a bimodal age distribution has been suggested with one peak around 20 years of age and a second peak in the fifth decade (Klepin et al., 2005). However recent reviews indicate that the incidence of ENB has a unimodal distribution with a peak in the fifth and sixth decade (Platek et al., 2011). No predisposing factors have been described for ENB.

The clinical presentation of patients with ENB is insidious, nonspecific, and mimics benign processes and other nasal malignancies. A large number of patients with small tumours may be asymptomatic and diagnosed incidentally. Nasal obstruction followed by unilateral epistaxis are the most common presenting symptoms and may be present from 6 to 12 months before the ENB diagnosis is made. Other symptoms may be present depending on the tumour's size and the presence of extension to adjacent structures. Symptoms may include headache, facial pain, sinusitis, anosmia/hyposmia, visual changes, diplopia, and proptosis if orbital involvement occurs. Neurological symptoms may be present in cases of intracranial extension including nausea and vomiting due to intracranial hypertension, hormonal disturbances secondary to pituitary gland and hypothalamic involvement and visual changes due to the involvement of the visual apparatus. Paraneoplastic syndromes related to ENB have been reported, most commonly related to antidiuretic hormone (SIADH) and adrenocorticotrophic hormone secretion (Gabbay et al., 2013). Ectopic ENBs have been described in the sphenoid sinus, the oral cavity, maxillary sinus and intracranially (Purochit et al., 2015). Symptoms of ENB are in most cases non-specific and may mimic benign sinonasal pathologies. For this reason, a high index of suspicion is very important for the early detection of these lesions.

Diagnostic evaluation

Any patient with persistent nasal symptomatology should have a thorough evaluation from an ear, nose, and throat (ENT) specialist. Apart from detailed physical and cranial nerves examination, nasal examination with a flexible endoscope permits a thorough inspection of the nasal cavity and nasopharynx. ENB may appear as a fleshy, reddish-yellow mass filling the nasal cavity to a varying extent, covered by mucosa with possible ulceration.

After tumour identification radiological evaluation should be undertaken including a high resolution (3 mm section) computed tomography (CT) scan of the skull base, paranasal sinus, and neck with and without contrast. The tumour appears hyperintense on non-contrast CT because of the high cellularity and it heterogeneously enhances with contrast administration. The major advantage of a CT scan is the evaluation of bony structures. Thin coronal and sagittal sections can reveal destruction of the cribriform plate, lamina papyracea and sphenoid sinus walls (**Fig. 17.1**). A neck CT scan should be obtained in all patients with ENB in order to evaluate possible regional lymph node spread.

MRI is another imaging modality that is recommended for the evaluation of tumour extension as it has a better resolution in soft tissue imaging. The tumour typically displays lower signal compared with grey matter on T1 and enhances heterogeneously after gadolinium administration. On T2-weighted images, the ENB appears slightly hyperintense. T2 sequences demonstrate the cystic components of the tumour better and are useful in differentiating

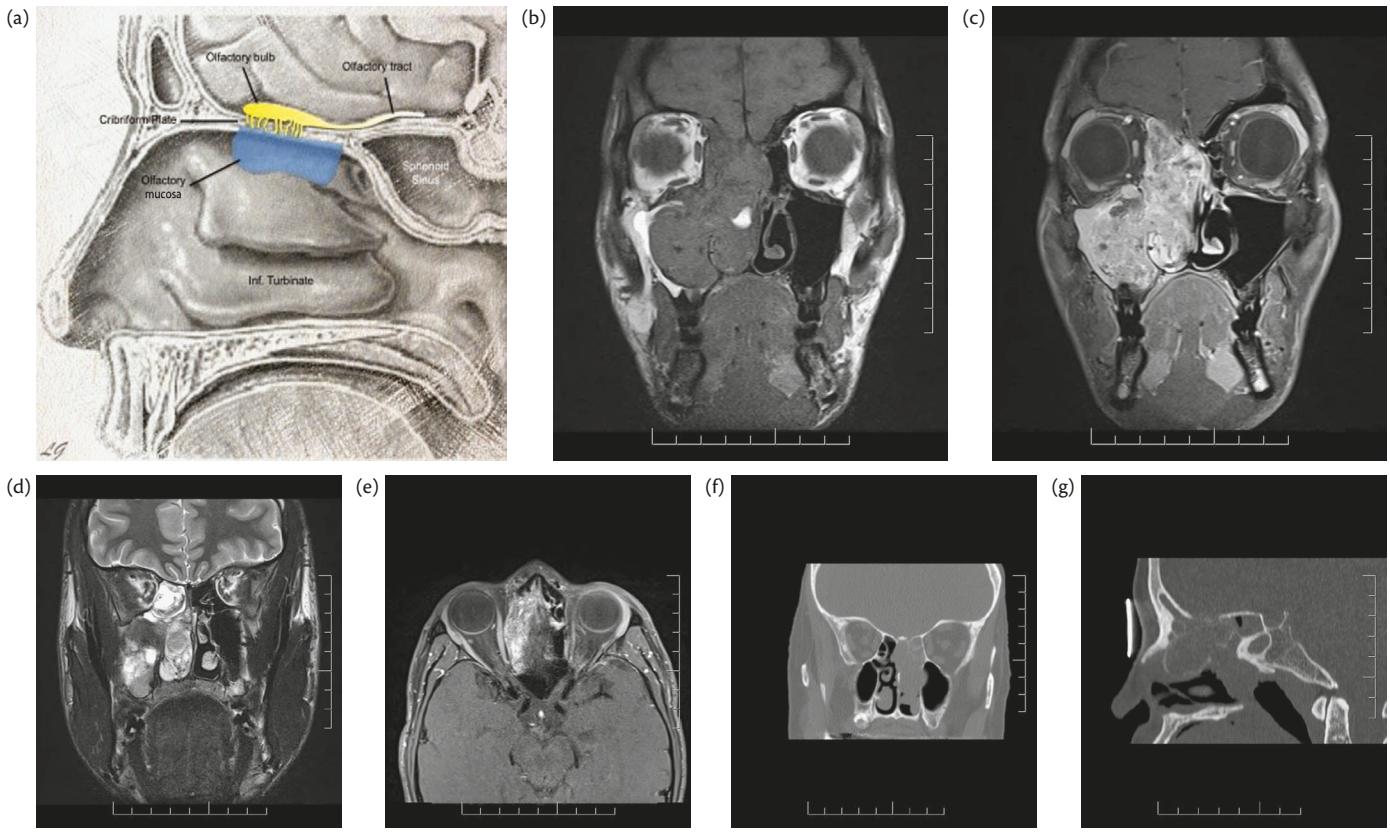

Fig. 17.1 (A) The olfactory mucosa at the upper part of nasal cavity is the area of ENB development. (B) Coronal T1 MRI without gadolinium of a 21-year-old male who presented with nasal obstruction and epistaxis for 6 months. (C) Heterogeneous enhancement after gadolinium administration. (D) Coronal T2 reveals a high signal lesion and intact dura of the frontal base. (E) Axial T1 with gadolinium showing compression of the lamina papyracea. (F) Coronal thin cut CT showing that the lamina papyracea and the cribriform plate are intact. (G) Cribriform plate erosion in another case of ENB in a 55-year-old female with anosmia and nasal blockage.

mucus retention inside the sinuses from true tumour invasion. MRI is the best modality for evaluation of periorbital invasion as well as for dural involvement and intracranial extension. ENBs, especially those of higher grade, appear restricted on diffusion-weighted imaging (DWI) due to increased cellularity.

Angiography is not routinely recommended as a diagnostic modality for ENB. However, in some cases it may be useful to delineate the relationship of the tumour to the carotid artery as well as the vascularity of the tumour. In cases of significant tumour vascularity preoperative embolization may be useful.

The next step in the diagnostic workup for ENB after radiographic evaluation is biopsy of the lesion. We recommend biopsy inside the operative room under general anaesthetic because of the high vascularity of the tumour.

If metastatic disease is suspected a neck CT is recommended as well as PET CT.

Staging

ENB may appear as a purely intranasal mass originating from the olfactory mucosa (Fig. 17.1) at the time of diagnosis or more commonly can invade the paranasal sinuses or extend towards the orbit or intracranial space. Cervical lymph node metastases have been reported in about 10% of the patients at the time of diagnosis. Remote, haematogenous metastases are rare at the first presentation but may occur at recurrence. The usual locations for metastases are the lungs, bones, and brain while rare delayed distal dural metastasis have also been reported. Defining the exact extent of the tumour is very important for choosing the appropriate treatment modality and for the overall prognostic evaluation. Several staging systems have been proposed for ENB. The first and most commonly used, was described by Kadish et al. in 1976 (Kadish et al., 1976). According to the Kadish staging system tumours that involve only the nasal cavity are classified as Kadish A, tumours that extend to the paranasal sinuses are classified as Kadish B and those that extend outside the paranasal sinus are classified as Kadish C. This system does not classify regional and remote metastases. Morita, in 1993 modified the Kadish staging system by designating D tumours with nodal and remote metastases (Morita et al., 1993).

The second most common grading system used for ENB is that proposed by Dulguerov (Dulguerov and Calcaterra, 1992) (Table 17.1). The Dulguerov staging system is a more detailed classification that differentiates between involvement of the nasal cavity, sinuses, and cribriform plate, as well as extension of disease to the anterior fossa, dura, and brain. Moreover, it provides information concerning regional and distant involvement and separates disease extent by the traditional T, N, and M categories.

It remains unclear which staging system is the most accurate and useful for evaluation of treatment efficacy and patient outcome.

Table 17.1 Dulguerov and Biller staging systems

	Dulguerov staging system	Biller staging system
T1	Tumour inside nasal cavity and/or paranasal sinuses but spares sphenoid sinus and superior ethmoid cells	Tumour inside nasal cavity/paranasal sinuses but not the sphenoid
T2	Tumour involves sphenoid and/or cribriform plate	Tumour extents into the orbit and/or cranial cavity
T3	Tumour extents into the orbit or into the anterior cranial fossa without dural invasion	Tumour involves the brain but deemed resectable
T4	Tumour involves the brain	Tumour involves the brain extensively and deemed unresectable
N0	No lymph nodes involvement	No lymph nodes involvement
N1	Lymph nodes involvement	Lymph nodes involvement
M0	No distant metastasis	No distant metastasis
M1	Distant metastasis	Distant metastasis

Source data from Pavel Dulguerov, Thomas Calcaterra, Esthesioneuroblastoma: The UCLA experience 1970–1990, *The Laryngoscope*, volume 102, issue 8, pp. 843–9, 1992 and Hugh F. Biller, William Lawson, Ved P. Sachdev, et al. Esthesioneuroblastoma: Surgical treatment without radiation, *The Laryngoscope*, volume 100, issue 3, pp. 1199–201, 1990.

A retrospective study of 261 patients with ENB performed by Jethanam et al. showed significant differences in patient outcome in the four different stages of the modified Kadish system. Patients with lymph nodes and remote metastases displayed a poor outcome. It is obvious that the presence of regional and distal metastatic disease negatively affects a patient's outcome and this needs to be considered when choosing a staging system.

Gross appearance, histology, and grading system

The tumour appears grossly as a nasal mass covered by intact or occasionally, in undifferentiated tumours, ulcerated respiratory mucosa. A cut surface will appear fleshy and reddish because of the abundant vascularized stroma.

Histologically ENB displays cells with nesting or sheet-like appearances in the submucosa. The tumour nests are separated by abundant hyalinized, fibrous, highly vascularized, or inflammatory stroma. In some cases, focal or complete sheet-like appearances of tumour cells and minimal stroma may be seen. The sheet-like formation is more common but not exclusive to higher grade tumours. The nuclei of ENB cells are usually small, round and with 'salt and pepper' appearance and small nucleoli. Nuclear pleomorphism is usually mild but occasionally larger cells with a prominent nucleolus resembling a ganglion cell may be seen. The cytoplasm may be minimal like in 'small round blue cell tumours' or lightly eosinophilic or amphiphilic like carcinoid or pituitary adenoma cells. Mitotic activity is generally low, but high-grade undifferentiated tumours are characterized by high mitotic rate, excessive nuclear pleomorphism, little stroma, and necrotic areas. The tumour stroma is mostly made of interdigitating cellular processes that appear eosinophilic and fibrillary (neuropil) and a vascular bed of plexiform or glomeruloid capillaries. Tumour cells may surround stroma areas creating a palisade structure forming pseudorosettes of Homer-Wright type which are characteristic of well differentiated tumours.

Pseudorosettes are almost pathognomonic for ENB when they surround true neuropil and are encountered in biopsies of intranasal lesions. True rosettes of Flexner-Wintersteiner type, where the tumour cells form gland like structures, may be apparent in low-differentiated tumours. Perivascular rosettes also may be seen. Some ENB cases may display calcifications, necrosis in higher grade tumours, cysts, and areas of squamous or glandular epithelium surrounded by tumour cells. Rarely ENB may exhibit divergent differentiation to melanocytes, myogenic cells, or display focal glandular configuration making the differential diagnosis challenging.

The most commonly used grading system for ENB was developed by Hyams (Hyams et al., 1998). This system is based on the architecture of tumour development, amount of neuropil, frequency and type of rosettes, mitotic activity, the presence of necrosis, and the extent of nuclear pleomorphism (Table 17.2). There are several studies

Table 17.2 Hyams grading system

Grade	Lobular architecture	Mitotic index	Nuclear pleomorphism	Necrosis	Rosettes	Fibrillary stroma
I	+	none	–	–	HW	++
II	+	low	+/–	–	HW	+
III	+/-	moderate	+	rare	FW	+/-
IV	+/-	high	++	common	none	-

showing a good correlation of the Hyam grading system with outcome (Miyamoto et al., 2000; Dulguerov et al., 2001).

Immunohistochemical characteristics

Immunohistochemistry is performed in all cases of suspected ENB. The differential diagnosis is very critical as it can direct the therapeutic strategy and also determine the patient's prognosis. Care should be taken when dealing with recurrent tumours as the immunohistochemical profile may have changed. ENBs often express non-specific enolase, chromogranin, and synaptophysin. The diagnosis of ENB requires that either synaptophysin or chromogranin be positive in a high percentage of cells. Other neuroendocrine or neuronal markers such as CD56 and CD57 are also positive. S-100 staining can be seen at the periphery of tumour cell nests in the sustentacular cells which have a supportive role to the olfactory cells in normal epithelium and have a Schwann-like ultrastructure. Their presence as s-100 positive cells is very helpful for an ENB diagnosis and this tumour should not be confused with a melanoma. These cells are not found in high-grade lesions. Very rarely tumour cells can be s-100 positive. Glial fibrillary acidic protein (GFAP), b-tubulin, and microtubule-associated protein staining is variable. About 30–40% of ENBs display regional staining for keratins and low molecular weight keratins. Epithelial markers are typically negative in ENBs, although in some cases diffuse positive staining may be seen. Staining for mesenchymal markers such as desmin, myogenin, vimentin, and actin is negative as well. Melanocytic markers such as HMB-45 are negative despite some reports of melanocytic differentiation and melanin pigmentation. Ewing's sarcoma and PNET markers such as MIC2 (CD99), FLI1 are negative. Common leukocyte antigen and other haemopoietic markers are negative as well. See **Figure 17.2**.

Differential diagnosis

The differential diagnosis of ENB is broad and must be considered in all cases presenting with a sinonasal mass. ENB must be differentiated from other tumours of neuroectodermal origin with epithelial differentiation (neuroendocrine tumours) such as poorly differentiated small cell or non-small cell tumours (sinonasal undifferentiated carcinoma, or SNUC). Tumours of neuroectodermal origin with neural differentiation such as paraganglioma, malignant melanoma, Ewing sarcoma/PNET, neurofibroma, and schwannoma must also be in the differential diagnosis. Other pathologies that must be considered are lymphoma, rhabdomyosarcoma, adenocarcinoma, adenoid cyst carcinoma, sinonasal squamous carcinoma, nasopharyngeal carcinoma, osteosarcoma, and chondrosarcoma. Benign neoplasms that may develop in this area include inverted papilloma and pituitary adenoma.

The differential diagnosis is critical for the appropriate treatment modality, the follow-up schedule of the patient and the overall prognosis. Neuroendocrine tumours tend to behave more aggressively with higher risk of local and distal failure. High-grade ENB may be difficult to differentiate from neuroendocrine tumours. Typically, SNUC have a higher mitotic index. Cytokeratin staining is positive for neuroendocrine carcinoma but typically negative for ENB. S-100 staining is absent in neuroendocrine carcinoma but has a characteristic pattern in ENB.

Treatment

Surgery, radiation, and chemotherapy alone or in different combinations are the treatment modalities that have been used in the treatment of ENB. The most common treatment strategy is a combination of surgery with postoperative radiation for resectable tumours and the addition of chemotherapy for more advanced, metastatic, or non-operative cases.

The main goal of surgery is the achievement of gross total resection with clear resection margins. The traditional surgical approach is the anterior craniofacial resection using a bifrontal craniotomy and lateral rhinotomy, Weber-Ferguson fascial flap, or fascial degloving approach. The transglabellar subcranial approach is an alternative traditional approach. Tumours that reach the dura require resection of the dura and olfactory tracts. In cases of brain invasion safe brain resection may be necessary in order to achieve clear margins. The resection through the facial approach can involve partial or extensive maxillectomies with or without orbital exenteration.

Endoscopic endonasal approaches have advanced significantly in the last two decades and have been used alone and in combination with open transcranial approaches for the treatment of ENBs. Tumours of Kadish stage A or B and stage C without significant lateral extension are the best candidates for a purely endoscopic resection where clear margins can be achieved. Published studies describe satisfactory results with pure endoscopic resection of ENB (Hanna et al., 2009). The accumulating experience and the increasing sophistication of endoscopic skull base reconstruction techniques has decreased the complication rates. In carefully selected patients the endoscopic approach is an excellent, less invasive surgical alternative for ENB treatment.

Radiation is an important treatment modality for ENB. It can be used alone, accompany surgery in a preoperative or postoperative manner or be used in combination with chemotherapy. Radiation as a monotherapy or in combination with chemotherapy may be used for cases with local or regional involvement where complete resection is impossible or surgery is not an option. Several studies have shown that surgical resection followed by radiation has better results than either surgery or radiation alone (Jethanamest et al., 2007). The goal of postoperative radiation is to treat microscopic residual diseases and is usually given as intensity modulated radiation treatment (IMRT) in a schedule of 1.8–2 Gys up to total dose of 70 Gys. The option of preoperative radiation has been evaluated in several studies. The goal of preoperative radiation is to reduce the tumour volume and increase the tumour resectability. The report of Bachar et al. showed that there is no difference in patient survival and recurrence between groups receiving preoperative versus postoperative radiation (Bachar et al., 2008).

There is limited data supporting the role of chemotherapy in ENB and its use is based on the experience reported from treating other head and neck malignancies. Generally, chemotherapy is used either preoperatively or postoperatively together with radiation. The use of chemotherapy has been proposed in locally or distantly advanced disease.

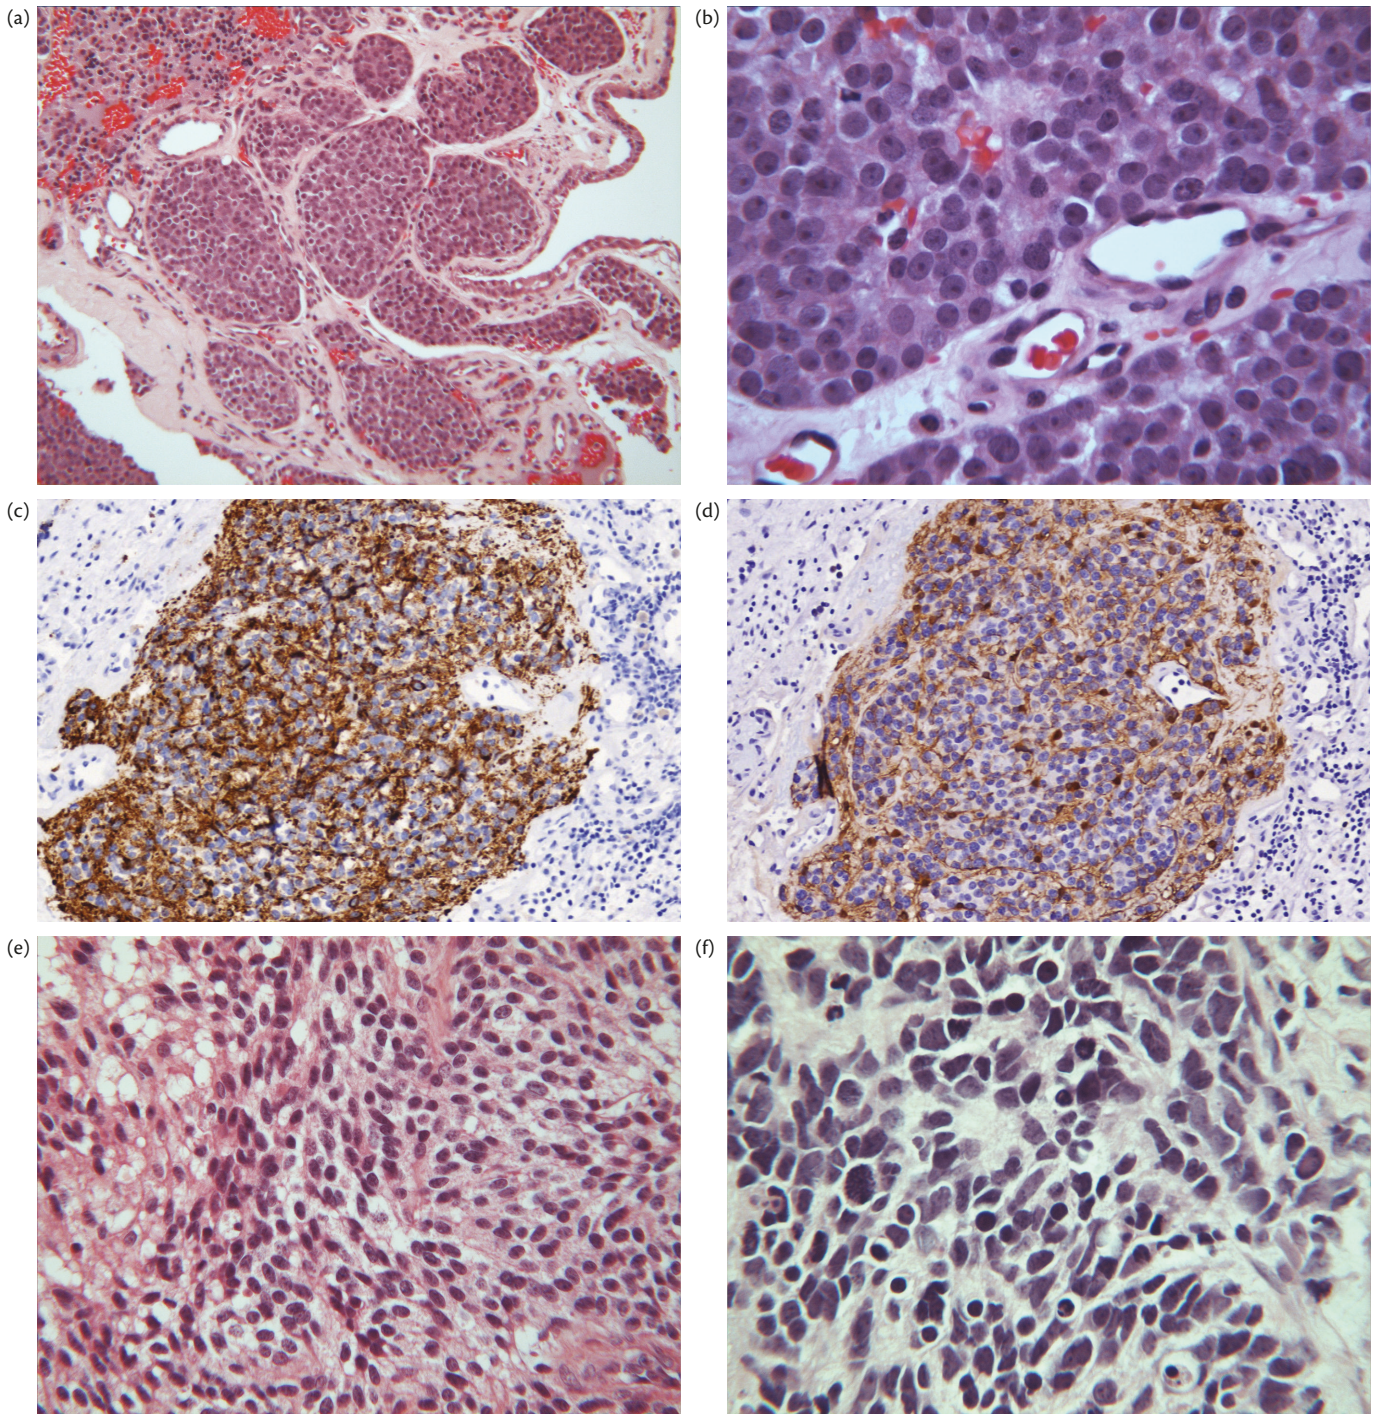

Fig. 17.2 (A) H&E stain, lower magnification view showing the typical lobular growth of a grade I ENB. Note the intact covering nasal mucosa. (B) H&E, high magnification of a grade I ENB showing the neoplastic cells with relatively uniform, round-to-oval nuclei, and finely granular cytoplasm surrounded by neurofibrillary matrix. Homer Wright pseudorosettes are seen. (C) ENB positive for chromogranin. (D) s-100 staining of the sustentacular cells. This is the characteristic pattern in ENB. (E, F) Grade IV ENB, H&E staining. Note the high nuclear pleomorphism and mitotic figures.

Prognosis and recurrent disease

The rate of local recurrence of ENB depends on the primary treatment. The study of Demiroz et al. (2011) showed that the rate of local recurrence was 71% in 5 years for patients treated with surgery alone and 17% in 6 years for patients treated with surgery followed by radiation. The success of salvage treatments to control the recurrent disease depends on the extent of recurrence and for this reason close follow-up with nasal endoscopy and MRI is important. Local recurrence is usually manageable, with further surgery, endoscopic or open, plus salvage radiation if possible. A metanalysis of 33 articles revealed that 20.2% of patients developed neck metastasis

and in 61.7% of those, metastases occurred 6 months after initial treatment. Salvage rates for these recurrences (defined as 1 year of disease-free survival) was 31.2% and this was higher with combined surgery and radiation compare with either treatment alone (Gore and Zanation, 2009). Distant metastases developed in up to 10% of patients and indicate a poor prognosis. Despite the poor prognosis salvage treatment can offer palliation of symptoms and extend survival. Cisplatin based treatment was shown to be active in advanced disease in a report of McElroy et al. (1998).

Conclusion

Esthesioneuroblastoma is a rare and aggressive tumour that continues to pose challenging management problem. The use of uniform staging systems has helped correlate survival and recurrence. A multimodality, multidisciplinary treatment approach is the preferred treatment for most lesions. While very small tumours located below the cribriform plate can be considered for resection without additional radiotherapy the great majority of patients require surgery with adjuvant radiation. Recurrent metastatic lesions may require chemotherapy. Recurrence in ENB is frequent and can occur many years after initial treatment thus necessitating close long-term follow-up of patients.

The introduction of endoscopy for the treatment of esthesioneuroblastomas, in either a purely endonasal or combined cranionasal approach has been a very positive addition to the surgical management and early results are favourable demonstrating outcomes in selected patients that are better than with standard approaches.

Controversies

The management of neck lymph node metastatic disease in ENB is not well established. Published data suggest that the incidence of lymph node involvement at presentation may be around 10% but eventually 20–30% of patients will develop lymph node metastasis. Patients with clinical or radiographic lymph node metastases at presentation or during the follow-up period are candidates for neck dissection and postoperative neck radiation. The extent of neck dissection is usually guided by the level of lymph node involvement. Elective or prophylactic neck dissection is not standard and there are no reports showing clear benefit. Elective neck irradiation has not been shown to reduce the incidence of lymph node recurrence (Noh et al., 2011) despite other data supporting the elective irradiation of neck lymph nodes (Monroe et al., 2003). Despite this the neck area is commonly included prophylactically in the radiation field for patients who receive radiation as an adjuvant treatment.

Malignant skull base tumours

Benedict Panizza and Adel Helmy

Introduction

The majority of tumours encountered in skull base neurosurgery are histologically benign. The philosophy for treating those tumours is based around choosing an appropriate surgical corridor (e.g. endoscopic endonasal, anterior, lateral, midline posterior), protecting surrounding neurovascular structures, internal debulking, and extracapsular dissection. Malignant skull base tumours (MSBT) however, are a much rarer and more histologically diverse group of tumours that are more complex to treat and require a distinct set of management principles. For this reason they are grouped together despite a wide variation in pathology, outcome, and prognosis. In order to deliver the highest standards of care a truly multidisciplinary approach is required that bridges the surgical specialties (neurosurgery, head and neck, otology, plastic and reconstructive), radiology, and oncology. Several of the more common MSBT, such as chordoma, chondrosarcoma, and esthesioneuroblastoma, are considered in separate chapters and will not be discussed in detail here.

A remarkable range of histological entities can be found at the skull base, that reflect the anatomical complexity of the boundary between the head and neck and the intracranial cavity. These tumours can arise from skin, mucous membranes, salivary gland, cartilage, bone, or muscle. The most useful clinical distinction is into anterior skull base and lateral skull base tumours (**Table 18.1**). Alternatively, one can classify tumours from the pathological perspective as primarily arising at the skull base, invading from surrounding tissues (e.g. from nasal cavity or infratemporal fossa, and distant metastasis).

There is little definitive epidemiological data on these tumour types when the subset that involve the skull base is considered. However, they are all rare entities with even the commonest histological subtype, squamous cell carcinoma (SCC), rare at 0.5–1/1 000 000 per annum usually arising in the sinonasal cavity and spreading to the anterior skull base. These tumours are more common in Japan, Indonesia, and some parts of Asia. Primary temporal SCCs are estimated to occur in 6/1 000 000 per annum, although in 90% cases where temporal bone resection is carried out, the original pathology is cutaneous malignancy with secondary spread to the temporal bone.

In principle, the optimal treatment for MSBT is extensive resection *en bloc* with histologically negative tumour margins. Piecemeal resection of tumours risks seeding of tumour cells within the surgical cavity and compromising clearance at the surgical margin. In some cases, *en bloc* resection is not possible, for example, large tumours that occlude access to the deep margin or those adjacent to critical structures, such as the jugular foramen or in the region of the internal carotid artery, where *en bloc* resections would carry high morbidity. In these cases, piecemeal resection with macroscopic clearance is utilized. This often requires extensive craniofacial resections with the associated challenges of dural repair, to avoid CSF leak and pneumocephalus, and plastic surgical input to ensure soft tissue coverage.

Adjuvant treatment most commonly includes radiotherapy to involved tumour margins, although in specific pathologies, chemotherapy is taking an increasing role.

The American Joint Committee of Cancer Staging (AJCC) have published specific staging systems for several extracranial tumours that encompass three domains: T (tumour extent); N (regional lymph node involvement); and M (metastasis remote to regional lymph nodes). Although not all tumour types have the full range of values, the outline of the system is described in **Table 18.2**. The TNM system is used as a method for prognostication as well as determining treatment paradigms related to curative versus palliative surgery, and the need for coexistent management of the head and neck lymph node basin. The National Comprehensive Cancer Network (NCCN) provides detailed algorithms for treatment of head and neck malignancies based on the TNM staging system (Network, 2019).

Anterior skull base

Clinical assessment

Anterior skull base malignancies most commonly present to the ear nose throat (ENT) surgeon with combinations of anosmia, ageusia (loss of taste), pain, nasal blockage, nasal discharge, and epistaxis. In more locally advanced tumours, ocular symptoms from cavernous sinus involvement precipitating diplopia or ophthalmoplegia, direct involvement of the orbit causing proptosis, chemosis, or pain and direct compression of the optic nerve pathway causing visual field or acuity deficits. Seizure from direct invasion of the frontal lobes and

Table 18.1 Common histological subtypes malignant skull base tumours

Anterior skull base	Lateral skull base
Squamous cell carcinoma	
Salivary gland malignancies (adenocarcinoma, adenoid cystic, acinic)	
Sarcoma (e.g. osteosarcoma, fibrosarcoma, rhabdomyosarcoma, liposarcoma, Ewing's)	
Malignant melanoma	Basal cell carcinoma
Sinonasal undifferentiated carcinoma	
Olfactory neuroblastoma	

headache from raised intracranial pressure (ICP) are rarely the first presentation.

Clinical examination in the outpatient clinic, combined with nasal endoscopy, can sometimes identify the tumour within the nasal cavity; however, MRI with gadolinium contrast is regarded as the first line investigation for diagnosis and to determine the anatomical extent of the tumour. A concomitant fine-cut (<1 mm cuts) bony computed tomography (CT) scan with multiplanar reconstruction provides detailed information on the bony extent of tumour invasion and is critical in surgical planning, especially to determine the extent and need for skull base reconstruction.

Any newly diagnosed, presumed malignant, skull base tumour requires staging in line with the TNM system, with clinical examination of the cervical lymph nodes and systemic imaging to assess lymph node dissemination and metastatic disease, as necessary.

Depending on the size and extent of the lesion, formal ophthalmological or dental assessments may also be needed alongside those from the head and neck surgeon.

Following the necessary clinical assessments, determining a histological diagnosis is a key determinant of the management paradigm and will require transnasal biopsy before definitive treatment planning, except for vascular tumours such as suspected juvenile nasopharyngeal angiofibroma.

Location and histology

Although there are a wide range of histological entities, the degree of aggressiveness of the tumour and the extent of invasion determine the management plan. Intermediate grade malignancies such as low-grade adenoid cystic carcinoma, chondrosarcoma, and olfactory neuroblastoma can be managed with less aggressive resections to avoid neurological morbidity on the understanding that adjuvant radiotherapy can control residual disease. For more aggressive histological entities such as squamous cell carcinoma, melanoma, or high-grade sarcomas that have not spread systemically, a more extensive resection with macroscopic excision should be considered to achieve potential cure. These are difficult decisions to make and depend on the patient's wishes, comorbidities, and the treating surgical team's expertise.

Table 18.2 Outline of TNM system for extracranial tumours

T: Tumour extent	N: Lymph node involvement	M: Metastasis
Tx: Cannot be evaluated	Nx Cannot be evaluated	
Tis: Carcinoma *in situ*	N0: No regional nodes	M0: No distant metastasis
T0: No sign of primary tumour	N1: Proximate regional nodes	M1: Distant metastasis
T1–4: Size and or extension tumour	N2–3: Progressive involvement of more numerous or distant nodes	

Source data from *AJCC Cancer Staging Manual*.

Surgical management

Over the past 10 years, there has been a dramatic increase in endonasal endoscopic techniques for the full range of anterior skull base pathology. However, other than in the case of esthesioneuroblastoma, the current evidence base does not support the use of endoscopic techniques for definitive treatment of MSBT (Rawal et al., 2012). The endoscope is simply a tool for delivering surgical goals and if equivalence in oncological control can be demonstrated, it is envisaged that combined and independent endoscopic approaches will become more popular as they have significantly less morbidity than traditional craniofacial approaches (Castelnuovo et al., 2014).

Radiotherapy

Postoperative radiotherapy is an essential adjunct to surgical resections with both palliative and curative intent. In practice, the location of these tumours ensures that surgical margins are always close and patients should be routinely counselled as to the need for postoperative radiotherapy. This is typically delivered by LINAC-based systems rather than radiosurgery as a large treatment volume is required in the region of critical neurovascular structures. Fractionation is used to minimize dosage to normal structures, for example, 60 Gy in 30 fractions.

Other adjuvant therapy

Adjuvant chemotherapy also has a role in MSBT when postoperative margins are histologically involved or there is extranodal tumour spread. However, there are exceptions to this. On one hand, sinonasal undifferentiated carcinoma is treated definitively in many head and neck cancer units with chemotherapy and radiotherapy without surgical intervention with equivalent results. Alternatively, there is currently no evidence for chemotherapy in the treatment of perineural spread of cutaneous malignancies.

Outcomes

There is a wide spectrum of malignant tumours that present at the skull base, however, overall the outcome for craniofacial resection at 5 years is 60% disease-specific survival and 53% recurrence specific survival. One-third of patients will have a postoperative complication with wound problems being the most common. Perioperative mortality is in the order of 4% (Patel et al., 2003). Specifically, in melanoma, perioperative complication rates are similar, but the longer-term prognosis is poorer with a 3-year disease-specific survival of 30% and recurrence-free survival of 26% (Ganly et al., 2006). Endoscopic techniques are able to provide similar disease control with reduced perioperative morbidity. As for all head and neck malignancies, clear margins confer a survival advantage.

Lateral skull base

Clinical assessment

Lateral skull base pathology most commonly involves the temporal bone, however, tumours can also extend into the middle fossa from the infratemporal fossa. Clinical presentations are diverse but most commonly arise from cutaneous primaries either as a first presentation or following partial treatment. As tumours spread deeply a wide range of symptoms can develop including hearing loss, otalgia, facial weakness, and imbalance from temporal bone involvement, diplopia and facial numbness from cavernous sinus/petrous apex involvement, lower cranial nerve, and brainstem symptoms, as well as trismus from temporomandibular joint involvement.

The primary site of the tumour should be identified in the first instance, as either from the skin or, more rarely, from infratemporal fossa pathologies such as salivary gland malignancy or a primary mesenchymal tumour. Clinical assessment must include examination of the relevant lymph node basins. MR and CT imaging is essential in defining the site and extent of the tumour as for anterior skull base malignancies.

Location and histology

The commonest pathology to require neurosurgical involvement is a squamous cell carcinoma invading the temporal bone. These are aggressive malignancies that initially arise in the skin of the external auditory meatus or, in 5% of cases, from the middle ear lining. In addition, it is common to require a temporal bone excision to enable clear margins with tumours extending to the temporal bone usually from cutaneous malignancy and involving the preauricular temporomandibular sulcus region. In one series, T4 tumours (invading medial petrous structures or extensive soft tissue involvement) were most commonly located in the preauricular region and this region carried a worse prognosis (Essig et al., 2013). Other histological subtypes of tumour include basal cell carcinoma (most common tumour on the pinna), salivary gland malignancies (adeno, adenoid cystic, acinic carcinomas from the parotid gland) and sarcomas. The complexity of temporal bone anatomy allows several potential routes for tumour spread once the middle ear is breached including anteriorly to the carotid canal and Eustachian tube, medially into the vestibule, cochlea, and internal auditory meatus, inferiorly to the jugular bulb and lower cranial nerves and finally superiorly through the tegmen tympani into the middle fossa.

Several staging systems have been described for SCC of the temporal bone with some variations however whichever system is used the following factors are recognized as conferring a poor prognosis: bone invasion, middle ear invasion, facial paralysis, dural involvement, perineural spread of tumour, and regional lymphadenopathy.

Surgical management

Lateral skull base malignancies mandate *en bloc* resection to attain optimal outcomes even more so than in the anterior skull base. Biopsy or resection in the nasal cavity is at an air/tumour interface and intact mucosa over normal tissue provides a barrier to seeding of the malignant cells. However, in lateral skull base pathology the deep resection margin provides a well vascularized bed that can accommodate tumour implantation especially as a result of use of a high-speed drill.

Figure 18.1 shows imaging and operative photographs from a patient with an invasive temporal bone SCC presenting with a House-Brackmann 6 facial palsy. Several methods of temporal bone resection (TBR) have been described for SCC, that all incorporate a superficial parotidectomy. Lateral TBR incorporates resection of the external auditory meatus with its bony margin as far as the tympanic annulus, leaving the facial nerve intact. Subtotal TBR additionally includes resection of the mesotympanum and internal auditory meatus nerves leaving only the petrous apex and carotid intact. Total TBR also includes resection of the carotid artery and petrous apex risking additional damage to the cavernous sinus and is rarely used. In this case, a radical parotidectomy, mandibulectomy, and lateral TBR was combined with a temporal craniotomy and resection of the radiologically involved dura. Resection of dura potentially increases the risk of seeding of malignant cells into the CSF space and should be avoided unless it is demonstrably involved and the tumour can be completely removed. Leaving the dura intact not only acts as a barrier to spread but also allows for a more focussed radiotherapy field.

Various methods have been suggested to minimize the risk of carotid sacrifice, however, these still carry significant morbidity. Preoperative test balloon occlusion (TBO) is used in many settings to predict ischaemic complications following occlusion of the carotid artery but the predictive accuracy varies with a 2–16% risk of stroke (van Rooij et al., 2005; Whisenant et al., 2015) and with thrombo-embolism and hypoperfusion both contributing to morbidity. For this reason, the senior author recommends preservation of the carotid artery in most cases (e.g. **Figs. 18.2** and **18.3**) as the morbidity of total TBR cannot be justified given the option of adjuvant radiotherapy.

Following surgery for invasive tumours where the adventitia of the carotid has been used as a margin, angiographic follow-up is carried out at 2–3 days and 2–3 weeks postoperatively to exclude vascular injury, dissection, or pseudoaneurysm formation. Similarly, involvement of the jugular foramen implies a poor prognosis and the morbidity of jugular bulb resection and lower cranial nerve palsy is regarded as unacceptable. In these cases, near total resection combined with adjuvant therapy is preferred.

Temporal bone resections require involvement of plastic and reconstructive surgeons in order to provide soft tissue coverage. This most commonly requires a free flap reconstruction with vascular supply from the external carotid. This has implications for planning concomitant cervical lymph node dissection.

Radiotherapy

Postoperative radiotherapy combined with histologically clear margins provide the best outcomes. With positive margins, postoperative radiotherapy is also recommended to deal with residual disease. In select cases with advanced disease such as jugular or carotid involvement, a decision may be made to avoid the morbidity of extensive surgery and carry out a palliative resection with adjuvant radiotherapy.

Other adjuvant therapy

Immunotherapeutic agents such as PD-1 and PDL-1 inhibitors may lead to dramatic changes in how we deal with advanced cutaneous malignancy. Early impressive and short term sustainable (1-2 years) results have been obtained in residual and recurrent cases of advanced cutaneous SCC. How these novel agents fit in to current treatments will require ongoing clinical trials.

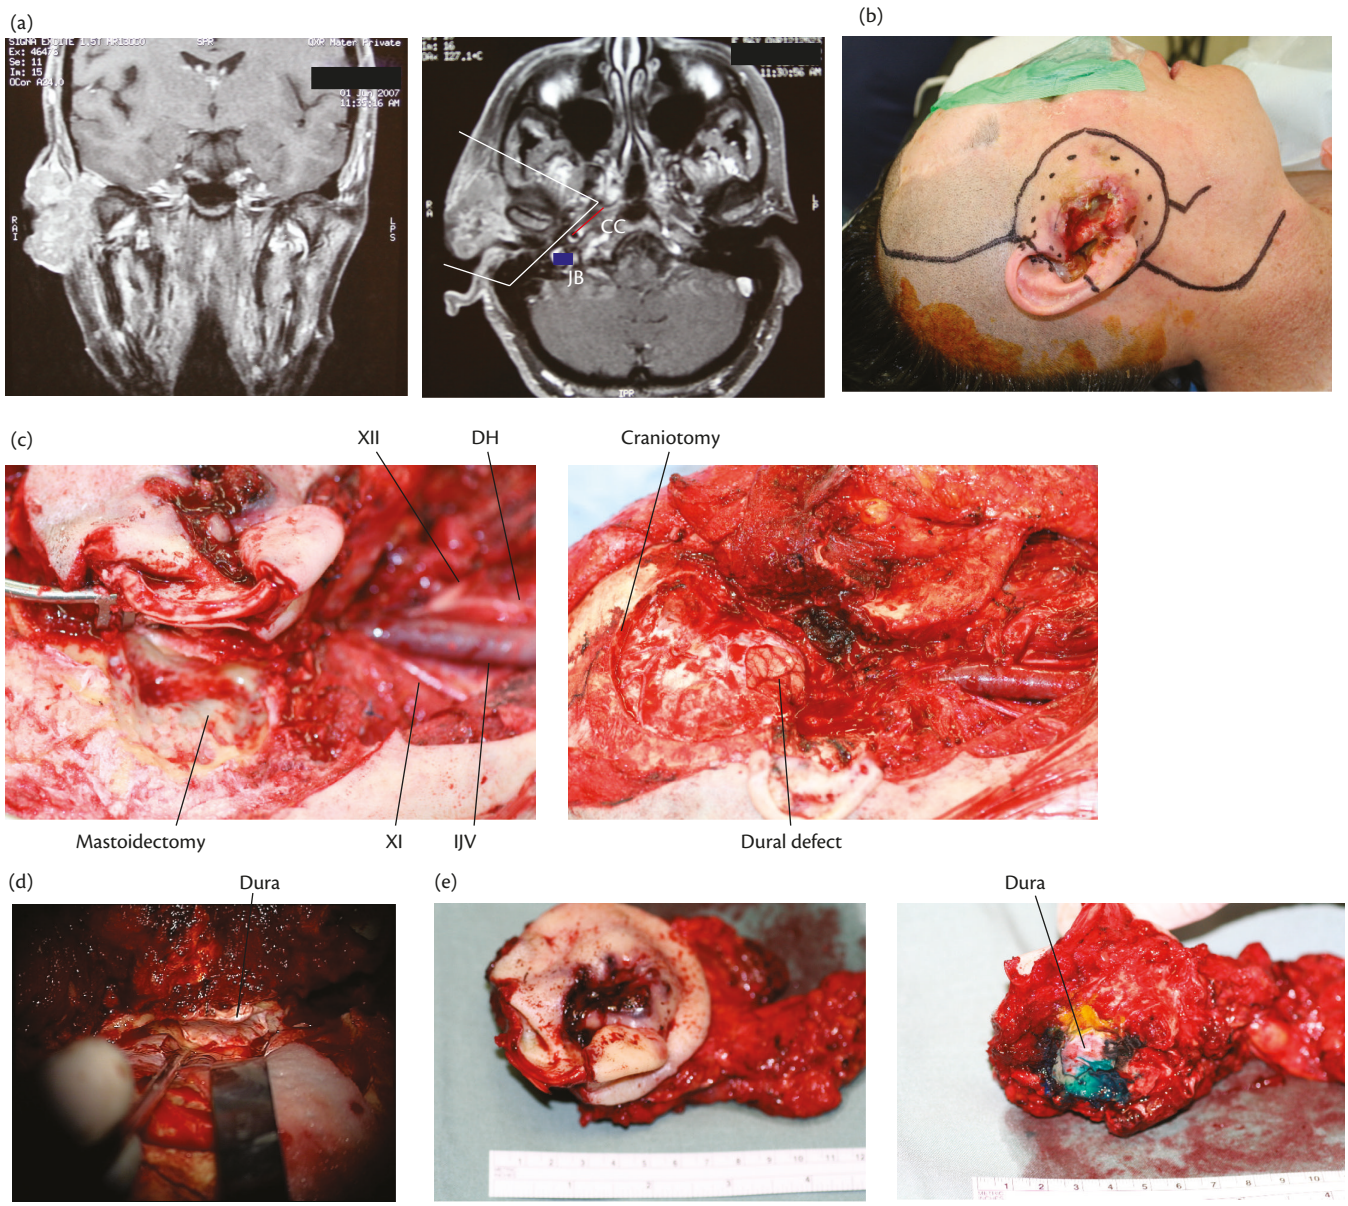

Fig. 18.1 Temporal bone squamous cell carcinoma. This patient presented with an ulcerating lesion anterior to the pinna. (A) Preoperative T1 weighted MRI with gadolinium contrast in sagittal and axial planes. The limits of the surgical resection are demonstrated on the axial image in white alongside the position of the carotid canal (CC) and jugular bulb (JB). (B) Operative planning incorporating part of pinna with extension of excision to allow access for craniotomy, infratemporal fossa, and neck dissection. (C) Macroscopic operative stills showing mobilization of tumour from the infratemporal fossa, temporal craniotomy, disconnection of deep margin of tumour and removal of the affected dura. (D) Intraoperative microscope views of disconnection of the deep margin of the specimen, craniotomy, and attachment of middle fossa dura to the bone which is circumferentially drilled to allow an en bloc removal. (E) Superficial and deep (inked dura) margins of tumour. (XI, spinal accessory nerve; XII, hypoglossal nerve; IJV, internal jugular vein; DH, descendens hypoglossi.)

Outcomes

For lateral temporal bone resection, the senior author's outcomes are 5-year disease-specific survival 62% and disease-free survival 59%.

Controversies

Perineural involvement of cutaneous malignancies are a particularly complex surgical problem. A subset of tumours has an aggressive neurotropic phenotype that involves divisions of the trigeminal or facial nerves (Panizza et al., 2014; Warren et al., 2016b). These patients present with numbness or formication in a trigeminal nerve branch or weakness in a facial nerve branch. Tumour can extend centrally towards the brainstem and, via branch points, into adjacent nerves. As tumour spread is extensive on presentation surgical management requires extensive resection. The alternative approach is radiotherapy to the involved nerves with palliative intent, but avoiding the risks of surgery. However high-volume centres have described good outcomes (70% curative resection) in patients without brainstem involvement (Warren et al., 2016a).

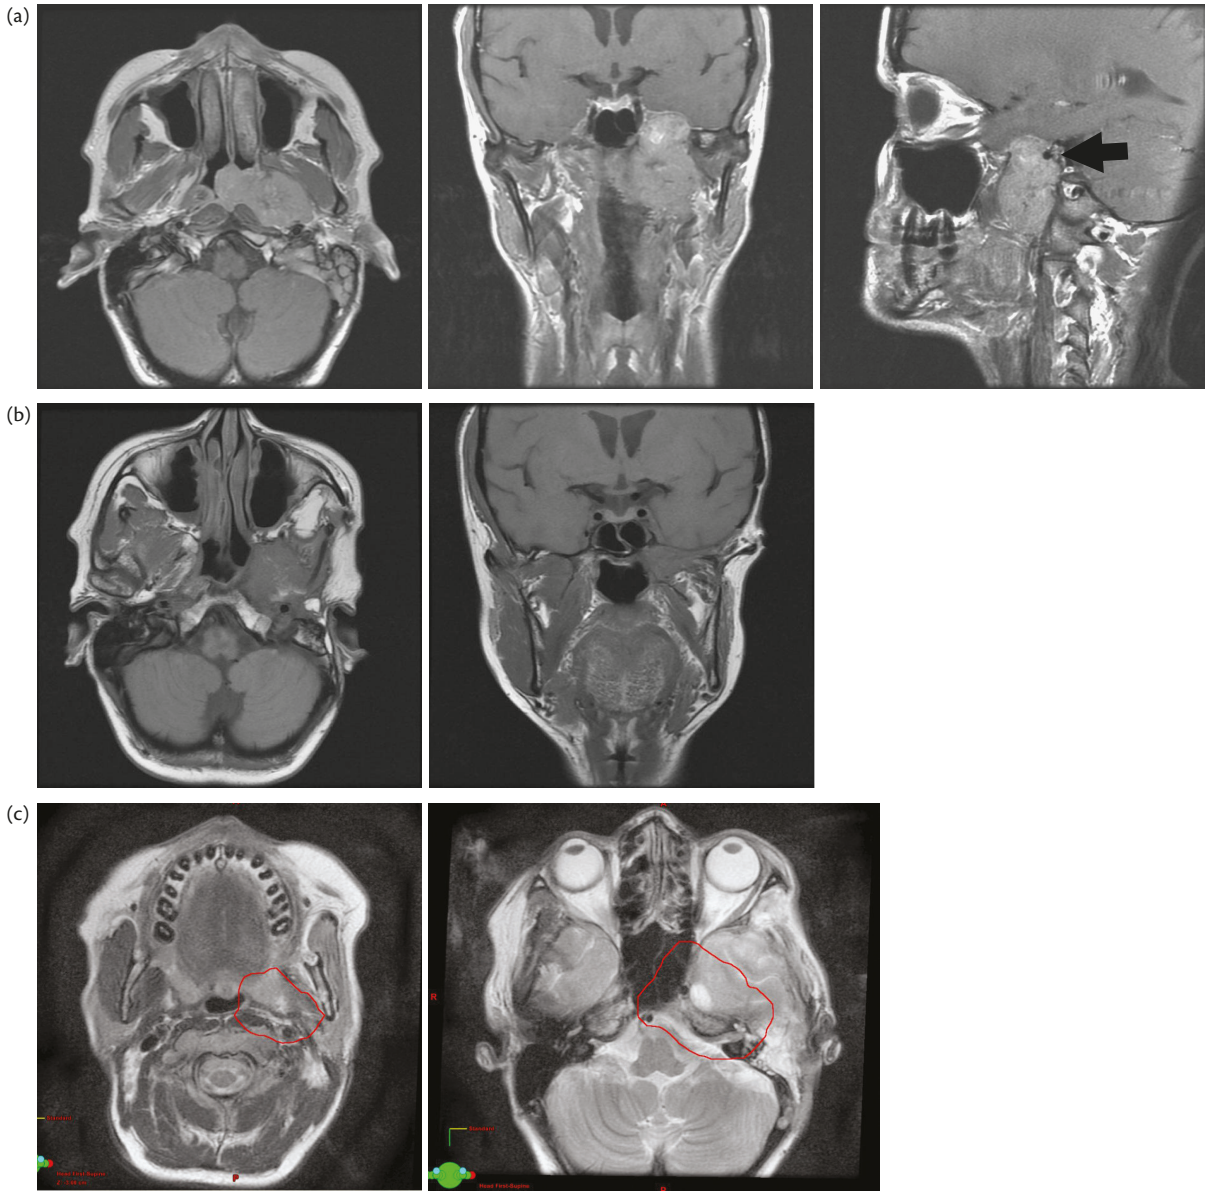

Fig. 18.2 Low-grade adenocarcinoma. This 52-year-old woman presented with deafness from a left middle ear effusion with a smooth vascular swelling identified in the posterior nasal space on endoscopy. Biopsy revealed a low-grade adenocarcinoma. The patient underwent an infratemporal fossa clearance and a middle fossa craniotomy in order to clear disease. Postoperative radiotherapy consisted of 60 Gy in 30 fractions. (A) Preoperative T1-weighted imaging with gadolinium contrast in axial, coronal, and sagittal planes. Carotid encasement by tumour is seen on the sagittal cut (arrowed) (B) Corresponding postoperative axial and sagittal cuts on T1-weighted MRI. (C) Illustrative radiotherapy plans encompassing the previous extent of the tumour.

Figure 18.4 shows pre- and postoperative imaging for a 55-year-old patient presenting with pain and sensory loss in the mandibular division (V3) of the trigeminal nerve. Biopsy confirmed adenoid cystic carcinoma and preoperative T1 weighted MRI with gadolinium contrast demonstrated contiguous extension of the tumour mass through the foramen ovale into the Gasserian ganglion. When confronted with an extensive tumour of this sort, the first consideration is whether the tumour is wholly resectable and whether a macroscopic clearance would provide acceptable tumour control if combined with postoperative radiation. If an extensive resection is considered the potential benefits to the patient will only be accrued if the tumour can be wholly excised and this would need to encompass resection of the proximal portion of V3 at the Gasserian ganglion as well as the peripheral branches of the nerve in the infratemporal fossa. The details of surgical management are outside the scope of this chapter, but the interested reader can find additional details in the literature (Redmond and Panizza, 2016; Solares et al., 2016).

The potential morbidity from an *en bloc* resection of the infratemporal fossa and hemi-mandible in addition to ocular morbidity from denervation of the ophthalmic division of the trigeminal nerve at the Gasserian ganglion must be balanced against the survival advantage of complete surgical resection with the potential for curative resection.

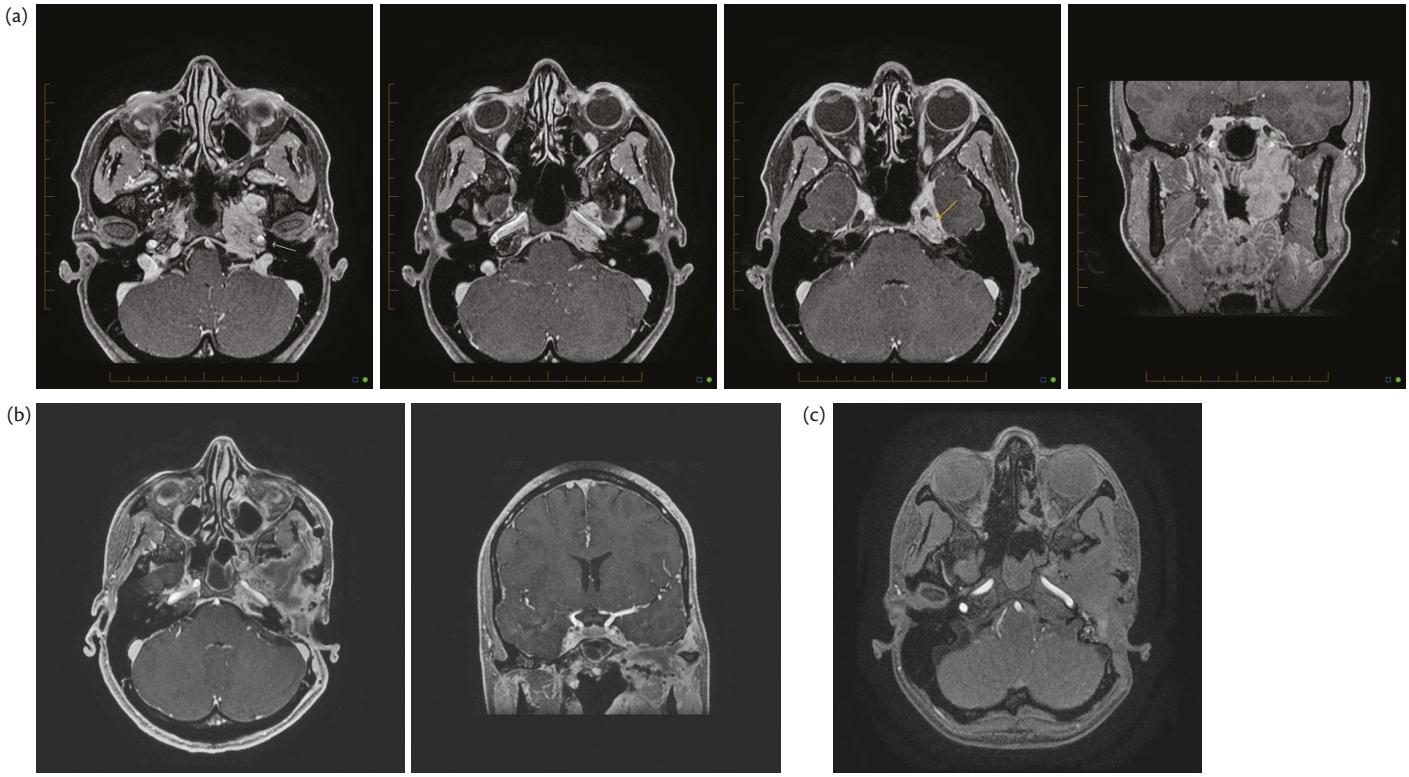

Fig. 18.3 Adenoid cystic carcinoma. This 37-year-old lady presented with 18 months of left-sided earache and Eustachian tube dysfunction. Biopsy demonstrated adenoid cystic carcinoma. The patient underwent a nasoendoscopic mobilization of the nasopharyngeal margin, transoral approach to the inferior oropharyngeal margin, an infratemporal fossa approach, and middle and posterior cranial fossa craniotomies. (A) Axial and coronal preoperative T1-weighted MRI with gadolinium contrast. The tumour is seen abutting the cavernous sinus and surrounding the petrous carotid artery (arrowed). (B) Postoperative T1 weighted MRI with gadolinium contrast. (C) Postoperative time of flight MRI angiogram to confirm carotid patency.

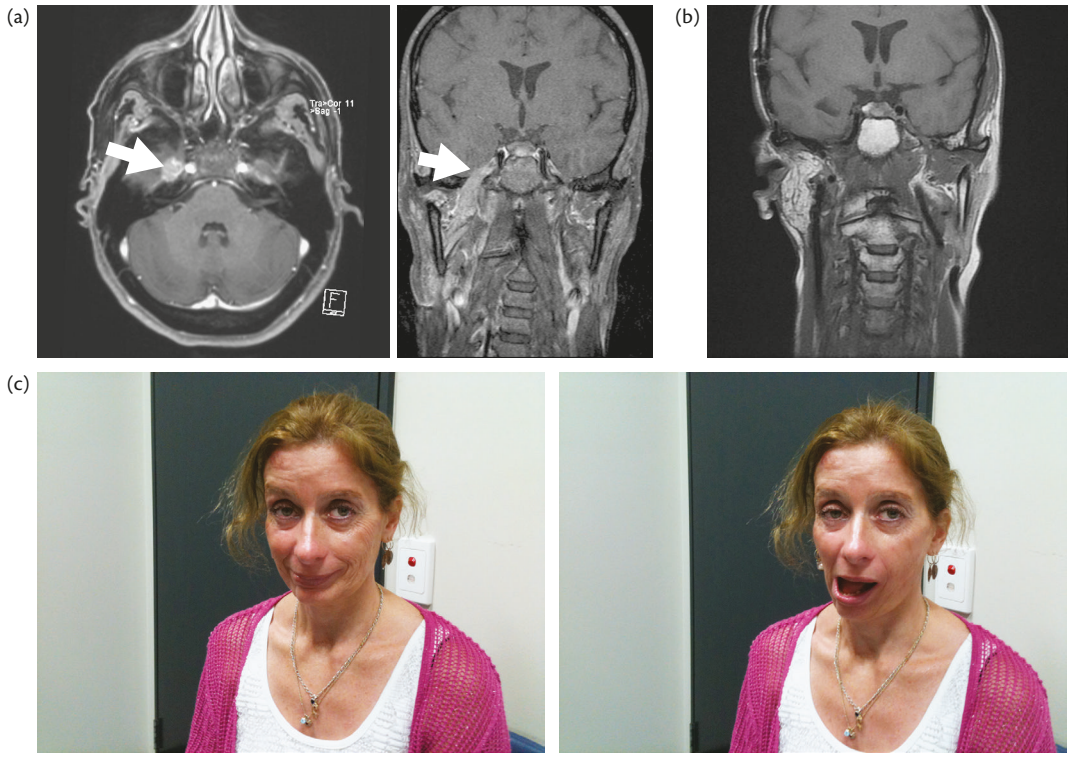

Fig. 18.4 Adenoid cystic carcinoma with perineural spread. This patient presented with formication and paraesthesia in the mandibular division of the trigeminal nerve. (A) Axial and coronal preoperative T1-weighted MRI with gadolinium contrast demonstrating infratemporal fossa mass with bulky contiguous enhancing extension into the cavernous sinus via the foramen ovale (arrowed). (B) Coronal 7-year postoperative T1-weighted MRI with gadolinium contrast demonstrating removal of the mandibular division of the trigeminal nerve. (C) Postoperative examination. In the left image the patient has been asked to 'smile' and 'raise their eyebrows' demonstrating intact facial nerve function. In the right image the patient has been asked to protrude the jaw with jaw deviation to the affected side from infratemporal fossa and mandibular bone resection.

Given the good premorbid state of the patient, and following discussion of the treatment options, the patient elected to have macroscopic resection of the tumour. A subtemporal preauricular approach was taken to the infratemporal fossa and combined with a hemimandibulectomy in order to remove the inferior alveolar nerve in its entirety within its bony canal. This was performed deep to the masseter muscle in order to preserve the facial nerve and combined with a subtemporal craniotomy and extradural approach to the Gasserian ganglion. The foramen rotundum and ovale were first exposed from the inferior aspect before a subtemporal craniotomy was performed to allow extradural access from within the intracranial cavity allowing retraction of the temporal lobe and incision and splitting of the two dural leaves between V2 and V3. Progressive dissection of this plane exposed the cavernous sinus, analogous to the Dolenc approach. It is key to preserve V1 to prevent the morbidity of an insensate cornea and the upper portion of V2 is used to delineate the upper border of the Gasserian ganglion resection. Once the nerve fibres are divided a frozen section was sent from the foramen rotundum portion of V2 to confirm a clear margin and allowing it to be safely divided and dissected out with V3 thus permitting the intradural dissection to be removed *en bloc* with the infratemporal fossa specimen. Positive margins at V2 would necessitate further drilling of the more distal portion of the nerve into the pterygopalatine fossa. Preoperative planning based on the radiological appearance minimizes the chances of encountering unexpectedly positive margins.

Figure 18.4C shows the patient's postoperative outcome with preserved facial nerve function and loss of mandibular nerve function. The patient remains alive and well 7 years postresection. Careful planning and a combination of skull base and neurosurgical expertise can deliver good outcomes even in these challenging tumours.

Surgical management of tumours of the orbit

Joseph D. Chabot, S. Tonya Stefko, and Paul Gardner

Introduction

The orbit can harbour a variety of lesions and their approach and treatment should be dictated by anatomical location and pathology. The proximity of the orbit to the sinonasal cavity and anterior and middle cranial fossae make it an ideal location for collaboration among neurosurgeons, otolaryngologists, and ophthalmologists.

Traditional orbitotomy, microsurgical transcranial, and endoscopic endonasal approaches (EEA) provide 360-degree access for biopsy or resection of both primary intraorbital lesions and those involving the structures surrounding the orbits.

This chapter outlines the anatomy, clinical presentation, and techniques that guide surgeons in management of these lesions.

Anatomy

In his description of orbital anatomy, Dr Albert Rhoton describes a 'rule of sevens', seven nerves, and seven muscles inside a pyramid made of seven bones (Martins et al., 2011). The base of the pyramid is the anterior surface of the eye and lids, the space tapers posteromedially to the orbital apex. The volume of this pyramid is approximately 30 cc, consisting of fat, muscle, nerves, blood vessels, glands, connective tissue, and the globe (approximately 7 cc).

The seven bones that make up the orbit are the frontal, ethmoid, lacrimal, palatine, sphenoid, maxilla, and zygoma. The orbital roof consists mostly of the frontal bone separating the orbit from the frontal lobe anteriorly, and the lesser wing of the sphenoid demarcating the parasellar regions posteriorly.

The frontal bone joins inferiorly and medially with the ethmoid bone which forms the mass of the medial wall. The body of the sphenoid posteriorly and the lacrimal bones and maxilla anteriorly join the ethmoid and frontal bones to form the medial wall of the orbit, which separate the orbit from the nasal cavity.

Inferiorly, the orbital process of the palatine bone and the orbital surface of the maxillary bone create the triangular orbital floor, which ends laterally at the inferior orbital fissure. This wall separates the orbit from the pterygopalatine fissure and the maxillary sinus.

As the zygoma sweeps superiorly, it meets with the greater wing of the sphenoid creating the lateral wall of the orbit. This separates the orbit from the temporalis muscle and temporal lobe.

Seven nerves pass through two openings in the orbital apex. Medially, the optic canal (OC), a 4.5 mm wide, 5–10 mm long, bony channel through the lesser wing of the sphenoid, transmits the optic nerve (ON) and ophthalmic artery. A fold of dura called the falciform ligament covers its proximal opening. The intracranial dura passes through the OC and splits into two layers, the optic nerve sheath and the periorbita. The artery enters the OC lateral and inferior to the ON and terminates intraorbitally as the central retinal artery. It is the main blood supply to the retina, while perforators from the ICA perfuse the prechiasmatic and intracanalicular optic nerve (Hendrix et al., 2014).

The other six nerves, oculomotor, trochlear, abducens and the lacrimal, frontal, and nasociliary branches of the ophthalmic division of the trigeminal nerve, pass through the superior orbital fissure (SOF), which is separated from the optic canal by the optic strut.

At the exit of the optic canal, the four rectus muscles originate from the Annulus of Zinn and form a cone, topped by the globe, with the ON in the centre (**Fig. 19.1**). The superior oblique muscle originates high and posterior on the medial wall. The levator palpebrae arises from the roof of the orbit, and the inferior oblique from the anteromedial floor of the orbit.

The superior ophthalmic vein (SOV), the dominant drainage pathway, forms from several medial tributaries, while the inferior orbital vein forms from lateral tributaries. These veins anastomose with the facial and angular veins at the anterior orbit (base of the pyramid), and the SOV continues posteriorly via the SOF to join the cavernous sinus.

Clinical presentation

Symptoms of orbital lesions correspond to their relationship to the 'cone' of extraocular muscles and ON. Extraconal lesions may be outside (extraorbital) or inside (intraorbital) the periorbita. Proptosis and diplopia occur early, while visual impairment is a later finding as the lesion deforms the globe and optic nerve. Intraconal lesions lie

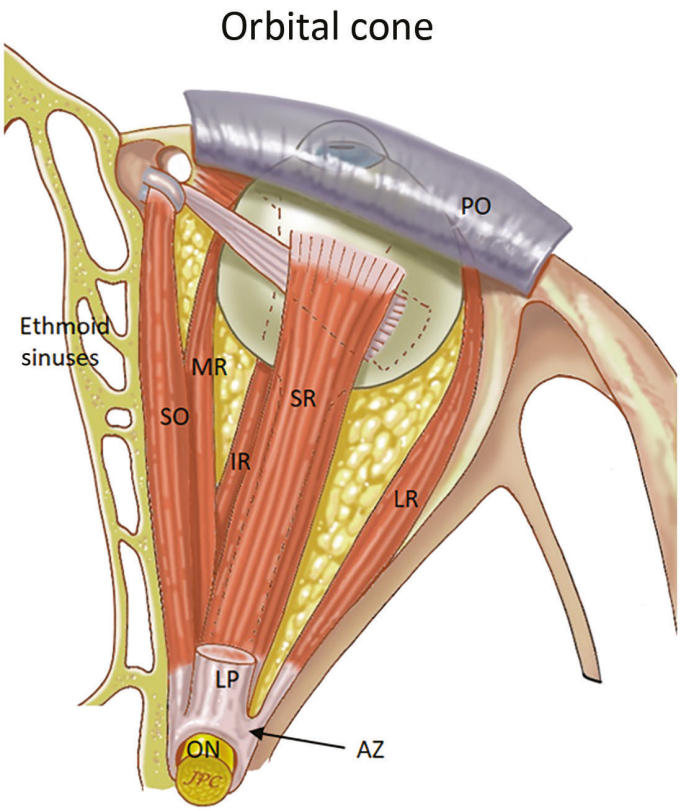

Fig. 19.1 Orbital cone: A view of the orbit from superior with the orbital roof resected, and the periorbita (PO) reflected anteriorly. The levator palpebrae (LP) has been truncated at its origin. The muscles originating from the Annulus of Zinn (AZ) and comprising the orbital 'cone' are the superior rectus (SR), lateral rectus (LR), inferior rectus (IR). The superior oblique (SO) runs superomedially. The inferior oblique muscle is not pictured. The optic nerve (ON) is in the centre of the cone.
©Jon Coulter, MA, CM1.

between the rectus muscles and ON. They present with early vision loss, axial proptosis, and diplopia, usually involving multiple fields of gaze.

Intracanalicular (optic canal) lesions present with early vision loss, optic nerve head oedema, and optociliary shunt vessels, but infrequently with diplopia or proptosis.

Tumours of the orbit can be divided into two major groups: those arising from the orbit, and those extending to the orbit from the surrounding cranium or sinonasal cavities. The most common tumours extending into the orbit are meningiomas and sinonasal carcinomas (Gardner and Stefko, 2014). Primary lesions and their locations can be found in Table 19.1 (Tailor et al., 2013).

Surgical planning

The orbit can be viewed as a clock with the optic nerve in the centre (Fig. 19.2). The safest surgical approach avoids crossing the ON, and can be determined by the lesion's location around the clock face (Paluzzi et al., 2015). For our purposes here, the remainder of the chapter will describe a right orbit. The mirror image would be used for the left orbit.

Table 19.1 Common locations of orbital masses

Intraconal	Extraconal
Cavernoma[a]	Hemangiopericytoma[b]
Optic nerve glioma	Lymphoid hyperplasia[b]
Optic nerve sheath meningioma	Atypical Hyperplasia[b]
Primary orbital melanoma	Lymphoma[b]
Metastasis	Pleomorphic adenoma
	Adenoid cystic carcinoma
	Lacrimal gland lymphoma
	Schwannoma[b]
	Neurofibroma[b]
	Metastasis

[a] less frequently extraconal

[b] less frequently intraconal

Lateral corridor approaches

Frontotemporal craniotomy (9:00–1:00), with orbitozygomatic osteotomy (6:00–1:00) for more extensive lesions

For lesions in the superolateral orbit posterior to the globe, a standard pterional incision, and elevation of a frontotemporal craniotomy may be used. This approach can be modified, for lesions inferior and lateral in the orbit (McDermott et al., 1990).

For an orbitozygomatic approach, the skin incision should be either bicoronal or three-quarter-coronal, extending from the ipsilateral tragus to at least the contralateral superior temporal line. Use interfascial dissection anteriorly to preserve the frontalis nerve. A straight line drawn from one end of the incision to the other should cross the targeted region. Dissection of the temporalis from the orbital rim is sufficient to reach the lateral orbit. If more extensive exposure is necessary, the temporalis can be mobilized completely from the temporal bone.

After performing a frontotemporal craniotomy, the frontal and temporal dura can then be dissected from the roof and the lateral wall of the orbit. The periorbita is dissected carefully from the inferior orbital fissure (IOF) to the supraorbital notch. A reciprocating saw is used to make a cut through the orbital roof at or just lateral to the supraorbital notch and through the body of the zygoma at the level of the IOF, protecting the periorbita and dura with malleable retractors. The cuts are connected using a high-speed drill, and the orbital roof and rim are then removed.

If necessary, an extradural clinoidectomy may be performed to decompress the optic canal. Drilling directly over the OC should be done using an 'eggshelling' technique with a diamond drill and copious irrigation. The bone can then be gently curetted from the underlying optic nerve sheath.

Bone removal posteriorly to the SOF and division of the meningo-orbital fold allows access to the parasellar regions and cavernous sinus.

Intraorbital lesions can be identified with palpation, ultrasound, or image-guidance. The periorbita is opened anterior to posterior,

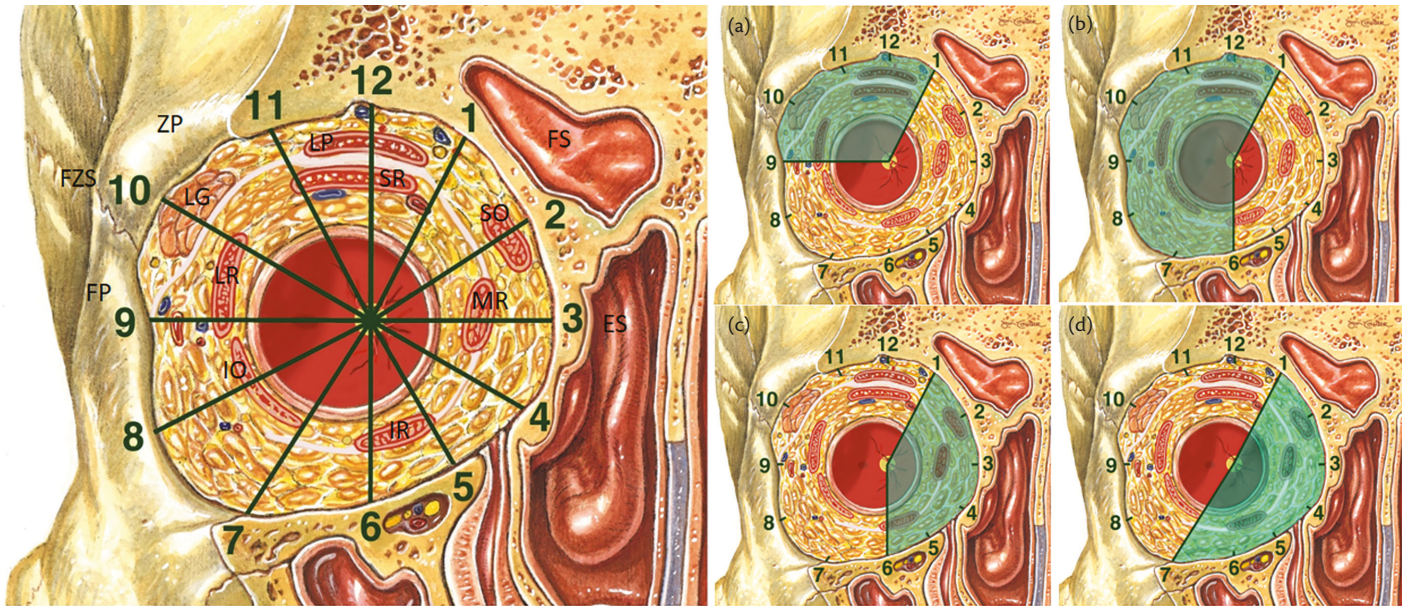

Fig. 19.2 Surgical planning: The 'clockface' centred on the optic nerve. Pertinent anatomic structures are the levator palpebrae (LP), superior rectus (SR), superior oblique (SO), medial rectus (MR), inferior rectus (IR), inferior oblique (IO), and lateral rectus (LR). The lacrimal gland (LG) is located superolaterally. The ethmoid sinus (ES) and frontal (FS) sinuses are located medially. The zygomatic process of the frontal bone (FP) joins to the frontal process of the zygoma at the fronto-zygomatic suture (FZS). The shaded portions of the clockfaces show the regions of the orbit exposed by the medial and lateral approaches. A frontotemporal craniotomy (A) can be combined with an orbitozygomatic osteotomy for more inferior lesions (B). A medial micro-orbitotomy (C) is the approach of choice for lesions anterior to the anterior ethmoidal artery from 1:00 to 6:00. Lesions posterior to the anterior ethmoidal artery in this location may be accessed using an endoscopic endonasal approach (D), or a combination of the two approaches.
©Jon Coulter, MA, CM1.

and the orbital fat is manipulated with cottonoids, q-tips, or an irrigating bipolar.

Fronto-orbital approach (9:00–1:00)

A less-invasive option for lesions in the superolateral orbit makes use of an incision made along the eyebrow from the supraorbital notch to the lateral edge of the cilia. A U-shaped pericranial flap based along the superior orbital rim is elevated preserving its inferomedial pedicle.

After limited dissection of the temporalis, a lateral burr hole is made at the keyhole, and the frontal dura dissected. A frontal craniotomy is then made from the burr hole extending as far superiorly as the skin incision allows and inferiorly along the orbital rim and roof. Drilling the posterior table of the frontal bone flush with the orbital roof, or removal of the orbital rim, maximizes access in this approach. An eyelid crease incision can also be used to provide a slightly more inferior trajectory with greater lateral access, though this limits the removal of the lateral and superior rims and requires bone removal from inside the orbit outwards.

For both of the aforementioned approaches, the removed bone can be replaced using titanium plates and screws or hydroxyapatite, with care taken to avoid entrapment of the extraocular muscles.

Lateral orbitotomy (8:00–10:00)

This is a classical approach for lateral orbital tumours (Maroon and Kennerdel, 1976). We favour an incision along an existing skin crease through the lateral commissure with lateral cantholysis. The aperture between the upper and lower eyelids becomes part of the effective incision providing exposure of the lateral orbital rim without a cosmetically unappealing incision in the mid-face.

The temporalis muscle is subperiosteally dissected and retracted laterally and the periorbita medially. Bony cuts are then made through the lateral orbital wall at the level of the IOF inferiorly and the frontozygomatic suture superiorly before the lateral wall is outfractured.

Using a retractor to protect the orbital contents, the greater wing of the sphenoid is then drilled to reach the orbital apex. Removal of the adjacent temporal bone allows the temporal dura to be dissected and the greater wing of the sphenoid to be drilled flush with the middle fossa floor.

To create a surgical corridor for intraorbital tumours, an incision through the periorbita is made parallel to the lateral rectus muscle, which can be retracted with a suture or vessel loop. Using microsurgical techniques of internal debulking and extracapsular dissection, the tumour can be safely removed.

Medial corridor approaches

Anterior medial micro-orbitotomy and transconjunctival approach (1:00–6:00)

After performing a conjunctival peritomy around the cornea, the medial rectus muscle is mobilized on a double-armed absorbable suture from its insertion site. A ribbon retractor displaces the globe laterally. If more lateral retraction is required, a lateral orbitotomy can be performed. After tumour removal, the medial rectus and inferior rectus can be reattached and the conjunctiva closed. While useful for lesions anterior in the orbit, the amount of retraction required for lesions posterior to the globe makes the endonasal approach preferable.

The transcaruncular approach is an approach to extraconal pathologies in these meridians. An incision is made between the caruncle and the plica semilunaris. The avascular plane between the lacrimal sac and periorbita is bluntly dissected posteromedially to the posterior lacrimal crest. The anterior and posterior ethmoidal arteries must be identified and coagulated in this approach to prevent sight-threatening orbital haemorrhage. Periorbita can be opened anterior to posterior if necessary.

Endonasal approaches (1:00–7:00)

The endoscopic endonasal approach (EEA) is well-suited for lesions displacing the optic nerve superiorly and laterally (Berhouma et al., 2014; Signorelli et al., 2015). Key to success with this approach to the orbit is a team including an ENT and neurosurgeon for every case, and an oculoplastic surgeon for intraconal tumours.

A uninarial approach consists of an uncinectomy, maxillary antrostomy, anterior and posterior ethmoidectomies, and sphenoidotomy to entirely expose the medial orbital wall. For intraconal, large, or orbital apex lesions, a binarial approach allows better manoeuvrability of the instruments posteriorly. This requires removal of the ipsilateral middle turbinate, wide opening of the sphenoid sinus, and posterior septectomy. If cerebrospinal fluid (CSF) is expected to be encountered during the surgery, a vascularized nasoseptal flap should be raised before the septectomy, usually from the contralateral side.

Important bony landmarks in the posterior sphenoid sinus and the structures they signify are as follows: carotid protuberance (cavernous carotid artery), lateral optico-carotid recess (optic strut), and medial optico-carotid recess (intersection of ON and carotid artery). Further superior and anterolateral bony removal exposes the ON, SOF, and orbital apex.

In most cases, fibrin glue, allograft, or fat graft is sufficient for reconstruction. If CSF is encountered, a vascularized nasoseptal flap can be used to decrease the incidence of postoperative CSF leaks (Hadad et al., 2006). Since it is not possible to suture the periorbita, the nasoseptal flap may be used to reconstruct the medial wall and prevent scarring of the rectus muscles.

Medial-inferior extraconal (1:00–5:00)

This approach can be used for orbital apex and ON lesions and for resection of medial tumours without intraconal extension. After performing the aforementioned steps, the lamina papyracea can be gently outfractured from anterior to posterior to expose the underlying peri-orbita. The bone overlying the orbital apex and ON can then be drilled with irrigation and gently elevated. For intraorbital tumours, the periorbita is opened over the lesion, which can then be removed with careful dissection. For tuberculum sella and planum meningiomas, the tumour can be removed from the OC by dividing the medial falciform ligament and opening the dura from medial to lateral over the superior aspect of the ON as it enters the canal. Recent studies have shown excellent visual outcomes with this technique (Gardner et al., 2008; Dehdashti et al., 2009).

Transmaxillary extraconal (1:00–7:00)

By anterior extension of the medial maxillectomy and removal of part of the pyriform aperture, more lateral extension can be obtained inferiorly along the floor of the orbit. With this approach, the pterygopalatine fossa and its contents can be dissected. By identifying V2 at the foramen rotundum, just deep to the infraorbital fissure, the infraorbital nerve can be identified and followed to the infraorbital canal.

This approach can be used for tumours that involve the middle fossa, orbit, infratemporal fossa, pterygopalatine fossa, or maxillary sinus (e.g. schwannomas, juvenile nasal angiofibromas). This approach requires knowledge of the course of the trigeminal nerve and the parapharyngeal segment of the internal carotid artery in order to avoid injury.

Medial intraconal (4:00–7:00)

For inferomedial intraconal lesions too posterior for the medial micro-orbitotomy (behind the globe), an external transconjunctival approach can be added to an inferior medial approach. A vessel loop is passed around the medial and inferior rectus muscles to aid in endoscopic identification and retraction. For wider access, the medial rectus can be tagged with a suture, detached from the globe, and displaced posteromedially while remaining attached to the Annulus of Zinn.

The tumour is first dissected along its lateral margin to avoid damage to the optic nerve, which is superior and lateral in this approach, as well as the ophthalmic and central retinal arteries which lie medial to the optic nerve in the orbit. Although bipolar cautery can be used to shrink the periorbital fat, it should be used sparingly to avoid damage to the intraconal nerves and blood supply to the optic nerve. After resection, the muscle can then be reattached to the globe. Closure is with the nasoseptal flap as mentioned earlier.

Superomedial modification (1:00 to 4:00)

If access superior to the medial rectus muscle is required, a superomedial orbitotomy may be added to this approach by removing the lamina papyracea, retracting the orbital contents, and drilling the medial roof of the orbit. This opens a narrow corridor between the medial rectus and superior oblique muscles. This approach is limited by the ophthalmic artery medially and by the ethmoidal arteries superiorly.

Fibrous dysplasia

Fibrous dysplasia (FD) is a congenital disorder in which immature bone and fibrous tissue replaces cancellous bone. Cranio-orbital dysplasia is a common manifestation, causing orbitofacial deformity, exophthalmos, ocular dysmotility, and visual impairment as it progresses (Amit et al., 2011).

On imaging, there are three types of FD: sclerotic (35%), cystic (25%), and mixed (40%). On MRI, these can appear quite extensive. The bony portions usually have very low signal on T2-weighted MRI, and the cystic portions and associated mucoceles show high T2 signals. Computed tomography (CT) scans show a 'ground glass' appearance and are essential for assessing the involvement of skull base foramina (Fig. 19.3) as well as guiding postoperative reconstruction.

Since FD generally progresses indolently and almost never in adulthood, observation may be the preferred course. Radiotherapy is contraindicated due to the high incidence of malignant

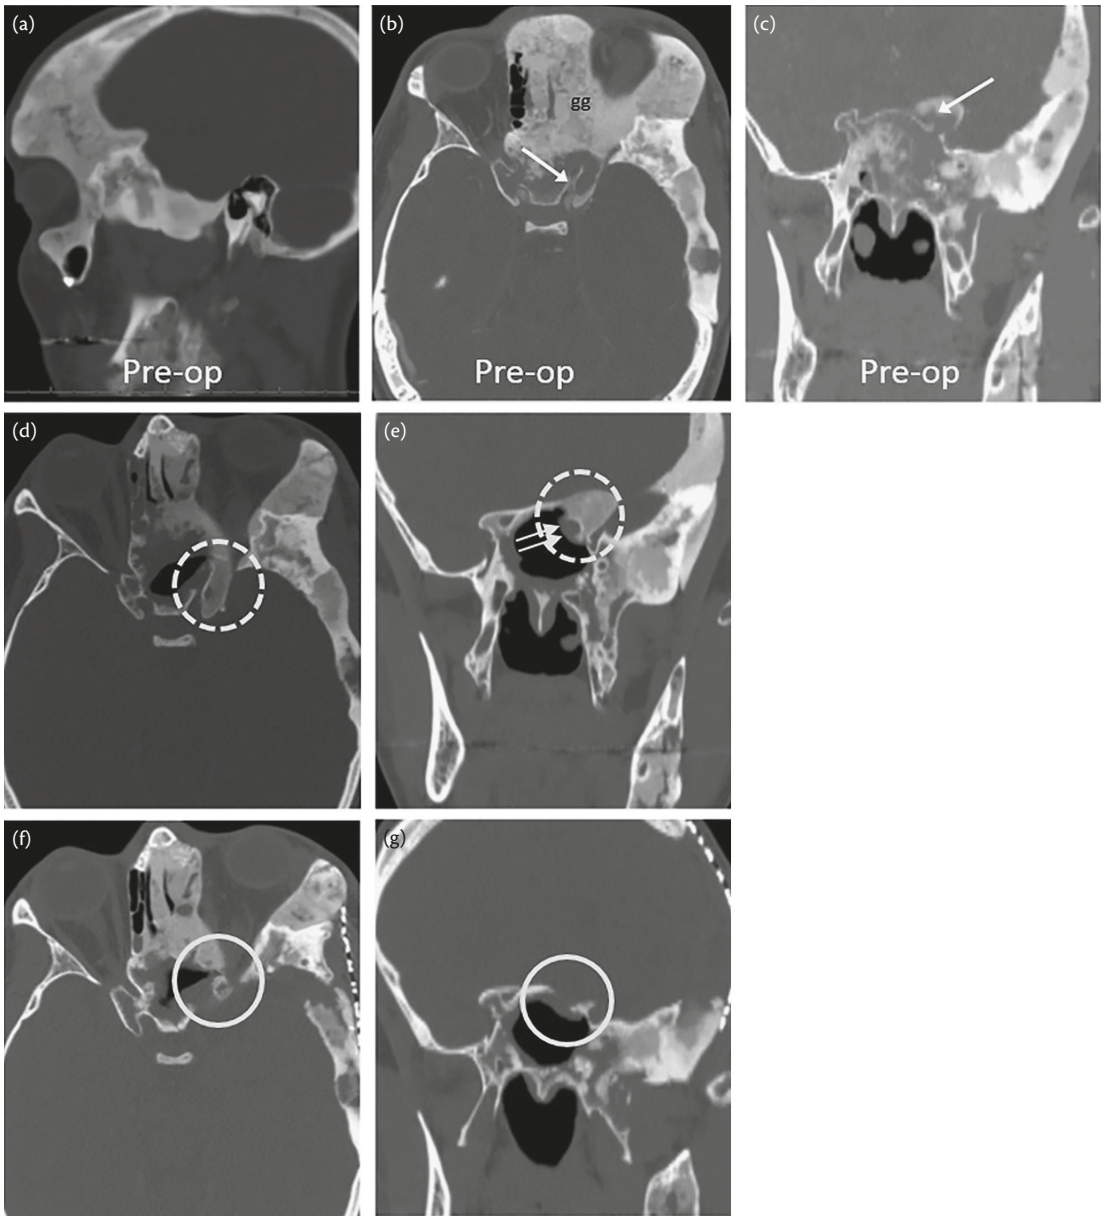

Fig. 19.3 Fibrous dysplasia: 22-year-old male with fibrous dysplasia involving the maxilla, mandible, temporal bone, frontal bone, and sphenoid bone on the left side. Bone algorithms of preoperative fine-cut CT (A, B, C) show the pathognomonic ground glass (gg) appearance. White arrows (B, C) demonstrate compression of the optic canal. The patient underwent endoscopic endonasal decompression of his left optic canal after developing progressive visual loss and optic neuropathy. This allowed an excellent medial decompression (double white arrows, E) and symptomatic improvement. 9 months later, he developed a superior visual field defect from his enlarged anterior clinoid (dashed circle, D, E). He underwent a left frontotemporal craniectomy and clinoidectomy for lateral and superior decompression of the optic canal (solid white circle, F, G). The patient's vision has been stable, but he has required additional operations for decompression of his infraorbital nerve and debulking of his mandible and maxilla.

transformation. Various medications have been used with inconclusive results.

For patients with cosmetic deformities, orbital reconstruction ranges from simple bone removal to a larger cranio-orbital approach with complete allograft reconstruction. ON decompression should be performed on patients with acute or progressive vision loss, while it is of questionable benefit for those with a chronically stable deficit. The choice of approach depends on the aetiology of the visual loss and may require more than medial decompression if there is cystic degeneration of the anterior clinoid process (Chen et al., 1997; Dumont et al., 2001).

Complications

Complications from orbital surgery are few but can be critical. Retrobulbar haematomas from medial approaches are avoided by coagulating the ethmoidal arteries. For tumours directly involving the ON and its meninges, preservation of the delicate pial blood supply is necessary to prevent visual loss. The risk of a postoperative hematoma is much greater for intraconal tumours.

An intraoperative CSF leak can be managed endoscopically with a vascularized nasoseptal flap to prevent meningitis. Microsurgical procedures may be required with a layered closure, fat graft, and

lumbar drain if a watertight seal is not possible. New diplopia following orbital surgery, related to oedema in the periorbital tissues, is usually temporary.

Controversies

The lateral orbitotomy and supraorbital 'keyhole' approach have increased in popularity as a direct 'minimally invasive' approach to lesions in the anterior and middle cranial fossa (Fig. 19.4). The disadvantage of these approaches is the narrow size of the surgical corridor due to the limited ability to displace the orbital contents. This makes vascular control and manipulation of larger tumours difficult. In addition, a clear understanding of the anatomy via a standard approach is critical before attempting these approaches. As yet, there is no consensus on the size or extent of the tumour that limits the use of these approaches as opposed to a full craniotomy.

Medial endoscopic endonasal decompression of the optic nerve in cases of compressive lesions of the optic canal and orbital apex, is also controversial. In cases of spheno-orbital meningiomas which often cause compression by hyperostosis, or in fibrous dysplasia, the endoscopic approach can provide safe decompression of more than 180-degrees of the optic nerve with minimal morbidity.

Results

The data at our institution is very encouraging regarding the endonasal approach for optic nerve decompression. In a series of 81 EEAs for 77 patients from 2003 to 2015 with decreased visual acuity from intraorbital lesions compressing the optic nerve, there were only two patients whose vision was worse after the surgery. Vision was improved in 31 eyes, and stable in 48.

We have also found that the lateral orbitotomy approach can be used to access lesions involving the middle fossa. Over a two-year period, we have performed 11 such operations, 6 of which were for spheno-orbital meningiomas (unpublished data). Proptosis and diplopia improved in these patients, and there were no new visual deficits. A watertight dural closure was difficult for those patients from whom affected dura was resected, which led to CSF leak in high-risk patients such as the obese and those with inhibited healing.

Conclusion

The anatomical location of the orbits adjacent to the middle and anterior cranial fossae and sinonasal cavity allows for a variety of approaches. The most appropriate surgical corridor will avoid crossing the vertical plane of the optic nerve and will also avoid excess

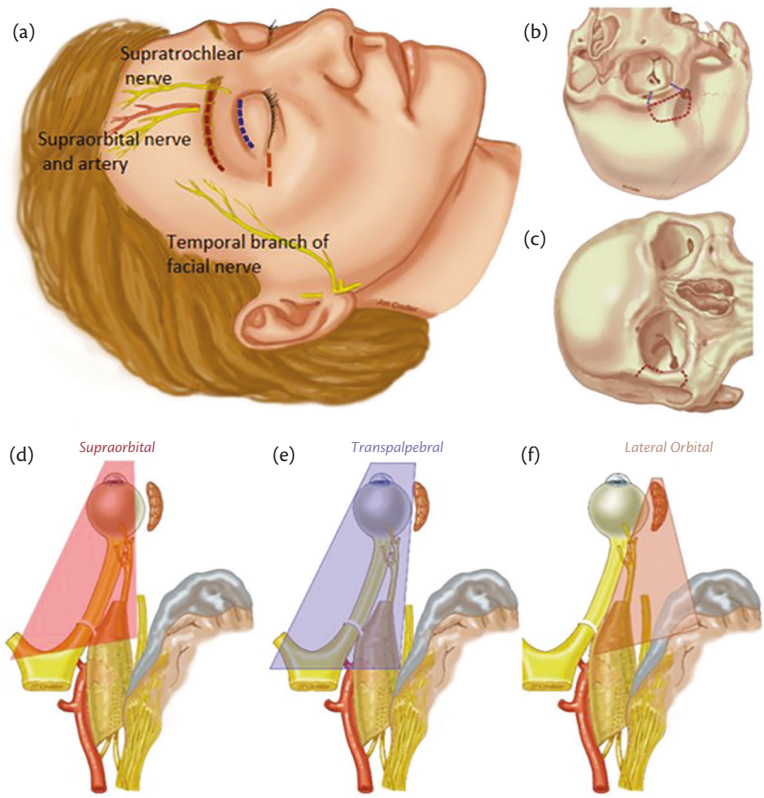

Fig. 19.4 Transorbital surgical corridors: panel A shows minimally invasive incisions for orbital approaches: supraorbital (dark red), transpalpebral (blue), lateral orbital (orange). A standard pterional or preauricular incision (not pictured) may also be used. Panel B outlines the bony cuts for the frontal craniotomy (red) with and removal of orbital rim (blue). Panel C shows the bony cuts in the lateral orbital rim. Panels G, H, and I show the potential intracranial structures that can be reached via transorbital approaches.

retraction of the globe. A multidisciplinary team with all available specialties is therefore ideal for management of orbital lesions.

Skull lesions

Giorgio Gioffre and Ivan Timofeev

Introduction

Skull vault lesions are rare and represent 1–2% of all bone masses. They are commonly an incidental finding or may be discovered during staging work-up for other diseases.

Different classification systems can be employed in order to categorize such lesions: primary (benign and malignant) or secondary as well as neoplastic and non-neoplastic (inflammatory and proliferative).

For many of these lesions the clinical and radiological features are often non-specific making the diagnosis cumbersome. Rather than being defined clinical entities, they frequently form part of a spectrum of disease where ruling out an unfavourable progression is of paramount importance.

Combining a basic knowledge of the epidemiology, clinical presentation, imaging findings, and histopathology is essential to differentiate these pathologies.

The aim of this chapter is to define the important features of each lesion, to offer an overview of the investigations and treatment, and to provide guidance for the differential diagnosis based on imaging. Therefore, pathological entities with similar radiological appearances are grouped together.

Predominantly lytic lesions

Metastasis

Metastases from extracranial primary neoplasms are the most common skull tumours, in 60% of cases origination from carcinomas of breast and lung (Colas et al., 2015). Other primary tumours that can metastasize to the skull are carcinomas of prostate, kidney, uterus, colon, liver, ovary, thyroid as well as other non-epithelial and bone tumours, while sarcoma and neuroblastoma are the most common primary causes in children (Mitsuya et al., 2011). Furthermore, the presence of a skull metastasis is associated with a secondary deposit in other bones in 90% of cases, and with brain metastasis in 30% of cases.

The prevalence of skull metastases is higher during the sixth and seventh decades of life. The majority of metastatic lesions appear as lytic, usually solitary and destroying either the inner or the outer table of the skull with invasion of the intra- or extracranial tissues.

Conventional radiography and computed tomography (CT) show single or multiple lytic lesions, typically lacking a sclerotic border, with indistinct margins, invading and infiltrating the adjacent soft tissues (**Fig. 20.1**).

Contrast-enhanced MRI is more sensitive than CT and radionuclide imaging in the characterization of skull metastases, allowing detection of dural and soft tissue invasion. The typical appearance is T1-hypointense, variable T2 signal changes, and variable contrast enhancement. When present, the enhancing pattern can be homogeneous, ring-like, or heterogeneous (Mitsuya et al., 2011). Bone scan and 18FDG PET show intense uptake, and may detect smaller calvarial metastatic deposits.

Blastic lesions are most commonly associated with primary carcinoma of the breast, prostate, colon, and bone. Their main feature is a bilateral symmetrical expansion of the diploe, with infiltrative borders and marrow replacement. Mixed radiological appearances are also possible.

From a clinical standpoint, they can be asymptomatic and often diagnosed in the context of staging of a known primary tumour, while less often they are the initial manifestation of an unknown malignancy. When symptomatic, painless, or painful swelling and headache are the most common symptoms (Stark et al., 2003; Mitsuya et al., 2011). Other symptoms are related to the primary disease or may be related to the presence of intracranial extension (neurological deficits, seizures, and other symptoms).

Differential diagnosis is with multiple myeloma, other skull lesions, postsurgical, or post-traumatic defects.

Treatment and prognosis are dictated by the nature and the clinical course of the primary tumour (**Fig. 20.2**).

Conventional fractionated radiation therapy remains the primary treatment. Radiosurgery can provide good tumour control in selected cases (Mitsuya et al., 2011), while bisphosphonates can be used in the palliative treatment of painful lesions (Mitsuya et al., 2011).

Indications for surgical treatment are: decompression of neurovascular structures, painful lesions, extensive infiltration of surrounding tissues and dura, obtaining tissue for histology (Mansfield, 1977; Stark et al., 2003).

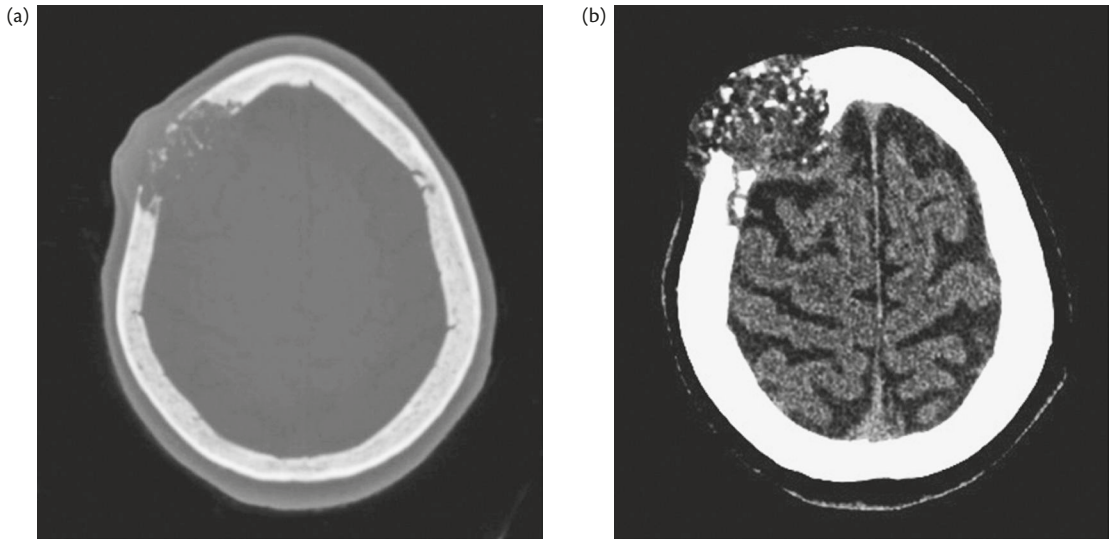

Fig. 20.1 Lytic lesions lacking a sclerotic border, with irregular margins, invading and infiltrating the adjacent soft tissues, representing metastasis.

Multiple myeloma

Multiple myeloma (MM) is a malignant disseminated disease of the bone marrow, characterized by a monoclonal proliferation of terminally differentiated plasma cells, replacing the normal marrow, and producing monoclonal immunoglobulins (Colas et al., 2015). MM is the most common primary malignant bone lesion (el Quessar et al., 1997) with a peak of incidence falling on the eight's decade. The aetiology is as yet unknown and it is possibly multifactorial, including genetic and environmental factors. It is associated with cytogenetic abnormalities in 80–90% of cases, the most common being chromosome 13 deletion.

Lesions are usually disseminated throughout the axial skeleton, and multiple skull lesions are found in more than 60% of patients with multiple myeloma. They usually arise in the diploe, sparing the inner table and deforming the periosteum, with a macroscopic appearance of a gelatinous red-brown tissue replacing the bone marrow.

Clinical presentation is in keeping with destruction of bone marrow and with the presence of abnormal circulating immunoglobulins. Skull involvement is usually asymptomatic, and detected during staging. However, symptoms may arise from skull base involvement with cranial neuropathies and proptosis, should orbital involvement occur. Serum and urine electrophoresis are part of the initial diagnostic workout. Diagnosis is confirmed by a bone marrow biopsy (Senapati et al., 2013).

MM can also present as a solitary lesion, representing a localized form of the disease (plasmacytoma) with no systemic manifestation. This is extremely rare in the skull (Senapati et al., 2013) and is thought to be a very early stage of MM, preceding the disseminated disease by several years (Kaur Gill et al., 2013).

In such cases, diagnosis is possible only after complete bone survey, bone marrow aspirate and after serum and urine electrophoresis have ruled out disseminated disease (Senapati et al., 2013).

X-ray and CT appearances are characteristic of multiple, well-demarcated, round, or oval osteolytic skull lesions. It can also present with diffuse sclerosis of the diploe and, less frequently, with skull osteopenia. MRI is useful in delineating meningeal disease and adjacent soft tissue involvement. Myeloma-related signal is mainly T1-hypointense and T2-hyperintense. Lesions tend to enhance with contrast on CT and MRI. Scintigraphy is insensitive given the exclusive osteolytic nature of the lesions.

Differential diagnosis is with postsurgical defects, metastases, haemangioma, brown tumours of hyperparathyroidism.

The mainstay of treatment is medical, through the combination of chemotherapy and focal radiation therapy. The reported rate

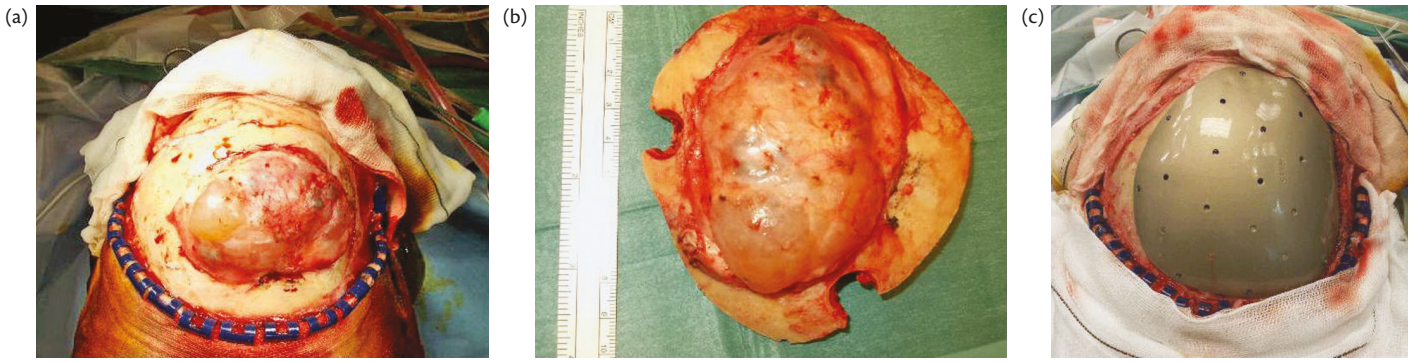

Fig. 20.2 Intraoperative findings—resection of calvarial metastasis with simultaneous titanium cranioplasty.

of 5 years survival is 20%, with a median survival of 3 years with conventional treatment protocols, and 6 months if left untreated. Chromosome 13 or 11q deletions are predictors of poor prognosis.

Plasmacytomas may be treated with surgical excision followed by radiation therapy (Kaur Gill et al., 2013; Senapati et al., 2013).

Haemangioma

Haemangiomas are a benign, mesenchymal, slow-growing intraosseous vascular tumour with predominantly vascular components.

Haemangioma is the second most common primary skull neoplasm, accounting for approximately 7–10% of primary skull tumours. It is three times as common in women as in men, and usually presents in the fourth decade of life. It is typically unifocal (Khanam et al., 2001) but can be multiple in up to 15% of cases. It is mostly found in the vertebral bodies, but when it arises in the skull is mainly found in parietal, temporal and frontal bones (Khanam et al., 2001). It mostly occurs as a sporadic solitary lesion, even though can arise as part of congenital angiomatosis. In some cases, it may be related to previous trauma.

Macroscopic features are those of subperiosteal, brownish-red lesions. They are often asymptomatic and found incidentally, can present with headache and a localized, slowly progressing, painful, and tender swelling, sometimes associated with a pulsatile sensation. Signs of seventh and eighth nerve compression can occur, for temporal bone localizations (Khanam et al., 2001; Colas et al., 2015).

Typically, the overlying skin is freely mobile. Soft tissues are rarely involved with the exception of infants. The occurrence of bruits or thrills can suggest the presence of an associated vascular malformation.

Skull radiography shows a well-circumscribed round or oval lesion with radiolucent honeycomb or trabecular pattern surrounded by a thin sclerotic rim. The classic 'sunburst' appearance is not frequently seen (Khanam et al., 2001).

CT usually shows a sharply marginated, well-circumscribed intradiploic osteolytic lesion with a thin peripheral sclerotic rim. In a third of cases, trabecular thickening with radiating spicules and hyperdense soft tissue contents can be present (Khanam et al., 2001; Colas et al., 2015). On MRI these lesions appear isointense on a T1- and hyperintense on a T2-weighted sequences. Usually no flow voids are displayed due to a very slow flow within the lesion and their small size. Haemangiomas are usually intensely contrast-enhancing.

Angiography can demonstrate hypervascular lesions, with a delayed persistent blush with a 'cluster of grapes' appearance mainly fed by the middle meningeal or superficial temporal arteries (Khanam et al., 2001).

Differential diagnosis for solitary haemangiomas is mainly with normal anatomic variant (vascular channel, foramen, emissary vein), postsurgical defects, dermoid, eosinophilic granuloma, metastases, cephaolocele, intradiploic arachnoid cyst, intradiploic meningioma, sarcomas (Khanam et al., 2001). Differential for multiple lesions is with lymphoma, osteoporosis, hyperparathyroidism.

Haemangiomas are a benign and slow-growing neoplasm that rarely requires treatment. Indications for surgery include correction of mass effect, cosmesis, and haemorrhage control. Surgery is the definitive treatment, with en-bloc removal together with a rim of normal bone. Curettage may lead to excessive bleeding and recurrence (Khanam et al., 2001). Unresectable lesions, deeply invading and permeating the surrounding tissues, may be treated with radiotherapy or super-selective embolization (Khanam et al., 2001). Malignant sarcomatous transformation is exceedingly rare.

Langerhans cell histiocytosis

Langerhans cell histiocytosis (LCH) is a multisystemic, idiopathic (Ralston et al., 2008) granuloma-forming proliferative disorder characterized by a spectrum of abnormal proliferation of Langerhans cells in various tissues and comprises a related group of three histiocytic disorders (Ralston et al., 2008; Colas et al., 2015): eosinophilic granuloma (70%), the localized benign form, characterized by a focal infiltration of histiocytes, with the calvarium involved in most cases (De Angulo et al., 2013); Hand-Schuller-Christian syndrome (20%), which is the multifocal chronic disseminated form; and Letter-Siwe syndrome (10%), the acute, malignant, disseminated type (Ralston et al., 2008).

LCH most commonly affects young people with 70% of patients under 20 years of age, and is most frequent in white males (90%). The specific incidence of eosinophilic granuloma, the localized form of the disease, is 0.4/100 000.

It predominantly involves the axial skeleton, where the neurocranium is frequently affected, especially in the frontal and parietal regions (Colas et al., 2015), followed by the mastoid, mandible, and facial bones.

While eosinophilic granuloma is a self-limiting, gradually enlarging, tender, unifocal calvarial mass, usually with a history of several months, Hand-Schuller-Christian and Letter-Siwe syndrome have a multisystemic involvement, with a more severe prognosis.

In eosinophilic granuloma, conventional radiographic imaging and CT show a sharply marginated 'punched out' lesion with scarce surrounding sclerosis and bevelled edges, involving both inner and outer tables (**Fig. 20.3**; also see Ralston et al., 2008). Mastoid localizations are characterized by marked bone destruction. The soft tissue within the lytic defect often displays contrast enhancement. MRI findings are those of a focal lytic T2-hyperintense soft tissue mass, often with extracortical extension, with a 'champagne cork' or a 'collar button' appearance, depending on their mono or bicortical extension. 18-FDG PET shows increased uptake in proliferating lesions (Ralston et al., 2008). Differential diagnosis is with other causes of lytic calvarial lesions (epidermoid, dermoid, postsurgical defect, metastases, skull tuberculosis). Lesions involving temporal bone have to be differentiated from a severe mastoiditis and rhabdomyosarcoma.

The natural history is variable, depending on factors such as age of onset, extent of involvement, presence of multiorgan dysfunction, and relapse. Mortality reaches 18% in multifocal disease. Treatment depends on the extent of disease; eosinophilic granuloma may spontaneously regress, but recurrence is reported in 30% of cases, often in a different site, mostly in children. Simple observation (De Angulo et al., 2013), local surgical resection, radiotherapy to treat recurrences, and combined irradiation and chemotherapy in case of multifocal calvarial involvement have been described.

Ewing's sarcoma

Primary Ewing's sarcoma (ES) of the skull is very uncommon (less than 4% of all cases), while the secondary haematogenous spread from other localizations is far more frequent (Salunke et al., 2011). The peak of incidence is between 15 and 25 years, predominantly in

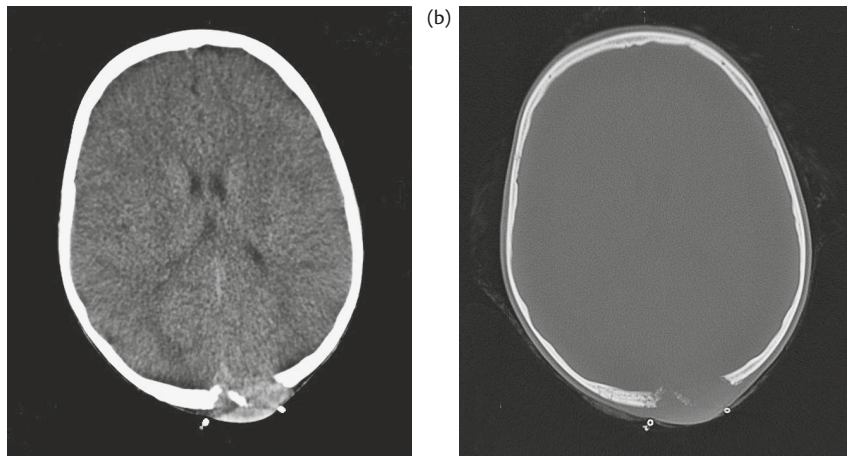

Fig. 20.3 LCH—'punched out' lesion with sharp margins, absence of significant sclerosis, and faint soft tissue enhancement.

males (Desai et al., 2000; Salunke et al., 2011) It usually involves the parietal and frontal bones, while very rarely affects the skull base (Desai et al., 2000; Salunke et al., 2011).

The histogenesis is uncertain, with likely origin from mesenchymal stem cells (Desai et al., 2000; Salunke et al., 2011).

The main macroscopic feature is a pattern of bone destruction associated with abnormal subperiosteal bone deposition.

Clinical presentation includes local swelling and signs and symptoms of raised intracranial pressure with focal neurological deficits (Desai et al., 2000).

Metastases tend to occur in 80% of cases in the first 2 years, mainly to lungs and other bones (Desai et al., 2000) even though cranial primary tumours seem to display a far less aggressive behaviour (Salunke et al., 2011).

The typical radiographic features of 'onion-skin' or 'sunburst' lesion might not be present. Most commonly ES of the skull presents as a non-specific lytic lesion with periosteal reaction and a contrast-enhancing content, best characterized by MRI, where the soft tissue components can have variable signal intensities (Desai et al., 2000).

Differential diagnosis is mainly with osteogenic sarcoma, primitive neuroectodermal tumours, rhabdomyosarcomas, metastatic neuroblastomas, and lymphomas (Desai et al., 2000).

Primary skull locations tend to have a better prognosis, compared with the axial skeleton.

The prognosis for patients with local recurrent disease is poor, with a 5-year survival following recurrence of 10–15% (Salunke et al., 2011).

Radical surgical resection followed by radiation and chemotherapy allows a 2-year disease-free survival rate of 55–60% (Desai et al., 2000).

Osteogenic sarcoma

Osteogenic sarcoma is a non-meningotheliomatous malignant mesenchymal neoplasm arising from multipotent mesenchymal cells of perivascular sheaths.

It is exceedingly rare in the skull, despite being the second most common overall primary bone malignancy after multiple myeloma. It most commonly occurs in males from the second to the fourth decade, and is often secondary to previous irradiation, Paget's disease, fibrous dysplasia, giant cell tumour, and chronic osteomyelitis (el Quessar et al., 1997). Macroscopic features are consistent with haemorrhagic soft tissue with necrosis and calcifications.

It typically presents as a rapidly growing mass, which is often painful (el Quessar et al., 1997). The associated clinical features are highly variable and depend on tumour location. A highly aggressive course is unfortunately common with rapid development of distant metastases predominantly in the lungs.

Plain X-ray and CT show a radiolucent, ill-defined lesion lacking adjacent sclerosis (no periosteal reaction) often with both intra- and extra-axial components, mostly enhancing. MRI displays a T1-hypointense, T2-heterogeneously hyperintense signal change, with intense enhancement after gadolinium. Imaging features depend on the histological type. The osteoblastic type can present with a typical 'sunburst' appearance, extending into the soft tissues, with associated thickened cortex although it can also display features of a non-specific enhancing lytic lesion with thickening of the surrounding bone and scattered calcifications. Differential diagnosis includes metastases, chondrosarcoma, osteochondroma, and benign and malignant meningothelial tumours (el Quessar et al., 1997).

Gross total resection with wide margins to achieve local control of disease is the goal of surgical treatment and is combined with irradiation and chemotherapy, in order to decrease local recurrence and metastatic spread (el Quessar et al., 1997). Despite treatment, the prognosis is poor with only a minority of patients achieving long-term survival.

Fibrosarcoma

Fibrosarcoma is a non-meningotheliomatous malignant mesenchymal neoplasm, which originates from the connective tissue in the bone marrow. It is a rare tumour, which mostly occurs secondary to a Paget's disease of the bone, prior irradiation, fibrous dysplasia, giant cell tumour, bone infarction or chronic osteomyelitis, and usually affects middle-aged adults (Mansfield, 1977). Skull involvement is often the consequence of the invasion from a nearby primary site (paranasal sinuses, face, scalp, dura).

Clinically it presents as a rapidly growing lesion, locally aggressive, and rapidly metastasizing to lungs and bones.

On plain X-ray and CT fibrosarcoma presents as an ill-defined non-specific lytic lesion with variably enhancing soft tissue content (Mansfield, 1977). MRI displays a T1-hypointense and

T2-heterogeneously hyperintense signal change with intense contrast enhancement. The differential diagnosis is largely with metastases and benign and malignant meningothelial tumours.

Gross total resection with wide margins to achieve local control of the disease is the goal of surgical treatment, combined with irradiation and chemotherapy.

Osteoclastoma (giant cell tumour)

Believed to originate from mononuclear cells of macrophage origin, is a very rare tumour of the calvarium, and typically arises at the epiphyses of long bones (Leonard et al., 2001; Harris et al., 2004).

It usually develops in the third and fourth decade of life, with a female preponderance (Harris et al., 2004). Rarely, it can present secondarily to Paget's disease: such cases are usually associated with the polyostotic form of the tumour, which commonly involves craniofacial bones, presents in an older age group, and tends to have a more favourable course compared to primary lesions (Leonard et al., 2001).

When located at the skull, osteoclastoma has a predilection for temporal and sphenoidal bones (Leonard et al., 2001; Harris et al., 2004).

Osteoclastoma tends to present as painful, progressively enlarging mass, which may occasionally be related to previous trauma.

Malignant degeneration occurs in 5–10% of cases (Leonard et al., 2001) while a pseudomalignant behaviour is not uncommon and is associated with pulmonary metastases (Harris et al., 2004).

Radiological features are those of a non-specific lytic lesion (Harris et al., 2004) with homogenously enhancing soft tissue content. Multilocular lesions can simulate an aneurysmal bone cyst or brown tumours in hyperparathyroidism. Unilocular lesion can radiologically resemble a giant cell granuloma, chondroblastoma and chondromyxoid fibroma (Harris et al., 2004). Also, imaging can also be indistinguishable from lytic metastases or direct invasion of a submucosal nasopharyngeal carcinoma.

Radical surgical resection is the gold standard, however not always achievable because of the location and infiltrative pattern. Preoperative arterial embolization can be considered to limit intraoperative bleeding. When partially resected these tumours have a tendency to recur within a relatively short time frame (1–2 years).

Giant cell tumours are generally radio-resistant and may undergo malignant transformation when irradiated (Harris et al., 2004). Radiation therapy has been advocated only for inaccessible non-resectable recurrence and when a clearly malignant behaviour is displayed. The receptor activator of NF-KB ligand (RANKL) signalling pathway that regulates osteoclast differentiation and activation has recently been shown to play a key role in the pathogenesis giant cell tumours and represents a promising therapeutic target, when surgical intervention is not feasible.

Aneurysmal bone cyst

Aneurysmal bone cyst (ABC) is a lesion composed of numerous thin-walled vascular spaces, separated by fibrous and mineralized tissue trabeculae, lacking normal endothelium.

Very rarely it occurs in the skull vault (1–6% of skull lesion cases) (Colas et al., 2015) with only 60 cases reported in the literature. It has equal sex distribution and usually affects patients younger than 20 years. It is also evenly distributed along the skull vault bones, involving symmetrically both inner and outer tables.

The pathophysiology of ABC is unclear, and there is debate whether it actually represents a neoplastic lesion. Local haemodynamic disturbances have been advocated to explain its occurrence.

ABC usually presents as a palpable tender mass, even though a form involving a predominantly intracranial growth, presenting with intracranial haemorrhage, has been described. It can also present in association with and secondary to fibrous dysplasia, giant cell tumours, and osteoblastomas.

Conventional radiography and CT imaging demonstrate a sharply defined lytic lesion with soap-bubble appearance with multilocular, scarcely enhancing spaces surrounded by thin inner and outer tables. MRI findings are consistent with a multiseptated lesion with fluid–fluid levels and blood degradation products. Angiography shows a hypervascular lesion. Findings consistent with a solid component may suggest a metastatic cause (Colas et al., 2015).

The neoplastic nature of an ABC is debated and its progression is often unpredictable and variable. Complete surgical excision is curative. In this regard, curettage and subtotal excision are associated with haemorrhage and high recurrence rates. Preoperative selective arterial embolization to avoid excessive blood loss might be considered.

If deemed non-resectable because of location or risk of haemorrhage, radiation therapy has been recommended. Cryosurgery and alcohol embolization have also been suggested to decrease recurrence rates of partially resected lesions.

Intraosseous lipoma

Intradiploic lipoma is one of the rarest bone tumours known (Kaneko et al., 2011), with only few case reports in the literature. It is a benign lesion, consisting of mature adipocytes in a matrix of thin bony trabeculae, originating from errors in the differentiation of mesenchymal stem cells covering the mature brain (Kaneko et al., 2011). They present clinically as a slowly growing lesion that spares the periosteum.

Imaging is in keeping with a fat filled cavity in the bone with no features of enhancement, infiltration, or erosion of a surrounding bone.

The differential diagnosis is with dermoid cysts, which appear more hyperdense, and from the reparative process after fracture or bone infarction, in which permeation of surrounding bone is seen. Fibrous dysplasia and meningiomata should also be taken into consideration.

Recurrence has not been reported and malignant transformation is exceptional. In view of benign clinical history radical resection is probably unjustified and in asymptomatic cases continued observation is acceptable (Kaneko et al., 2011).

Intradiploic epidermoid and dermoid cysts

These are benign calvarial lesions, which histologically represent inclusion cysts that result from entrapment of ectodermal or dermal elements during neural tube closure in embryonic development or rarely as a result of traumatic implantation. Epidermoid cysts contain only epidermal tissue and keratinized debris, whereas dermoids may contain dermal elements, such as hair follicles, skin glands, and teeth.

While most commonly diagnosed in children within a first decade of life these cysts can also be found in older children and adults, can affect both calvarial bones and skull base. They are generally less common than intradural lesions. Clinically they present as a

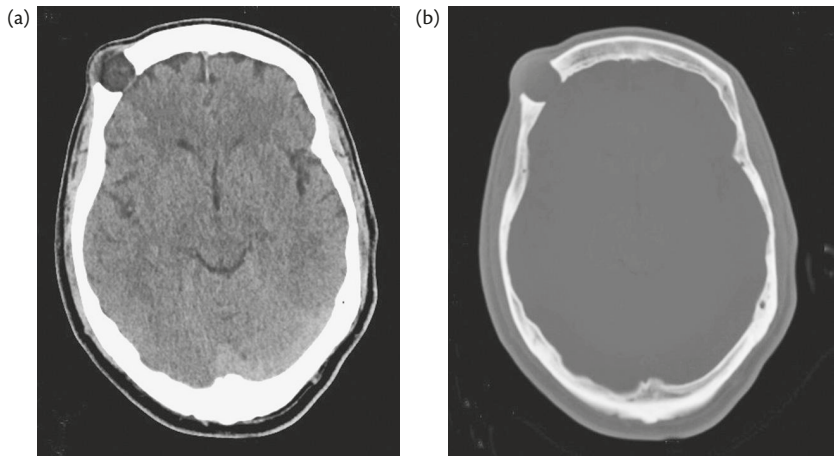

Fig. 20.4 Non-enhancing hypodense lesion with sharply defined bony margins characteristic of epidermoid cyst.

painless firm non-mobile slow-growing masses. Typically dermoid cysts have predilection to midline as well as sutures next to anterior fontanelle and epidermoids are commonly found in parietal, frontal, occipital bone, or next to the orbit. The cysts can affect outer or inner table or both. CT imaging demonstrates non-enhancing hypodense lesions with well-demarcated and often calcified margins and other zones of calcifications (Fig. 20.4). On T1 MRI the lesions are slightly hyperintense to CSF, on T2 isointense, on FLAR hyperintense, and on DWI demonstrate restricted diffusion. Ultrasound can also be utilized to diagnose and monitor both epidermoid and dermoid cysts (Riebel et al., 2008). Surgical treatment often considered for cosmetic reasons and to prevent the potential but rare complication of intracranial rupture of contents is usually associated with larger and more rapidly growing cysts involving the inner table. Operative options include open and endoscopic resection and curettage.

Overall prognosis is excellent and spontaneous regression can occur even with non-operative management.

Table 20.1 summarizes predominantly lytic lesions.

Predominantly blastic lesions

Osteoma and benign osteoblastic lesions

Osteoma is a benign mesenchymal tumour, macroscopically resembling mature lamellar bone. It originates from mature cortical bone and grows outward to form a solid dome-shaped mass, mainly in regions developing from membranous ossification. It is the most common primary calvarial tumour (Haddad et al., 1997), constituting up to 30% of craniofacial bone neoplasms, with a prevalence of 0.4% in the general population, and more frequently presenting in females with a F:M ratio of approximately 3:1, and a peak between the fourth and fifth decade of life (Colas et al., 2015). Usually located in the paranasal sinuses, it less frequently involves the calvaria and the mandible. When doing so it usually arises in the frontal bone, but can occur anywhere in the skull. It often involves the outer table of the skull (Haddad et al., 1997), but can arise from the diploe or from an inner table and are frequently found in proximity to the sutures, which are however normally spared (Colas et al., 2015).

Table 20.1 Predominantly lytic lesions

Metastasis	Metastatic cell infiltrates displaying the features of the primary lesion
Multiple myeloma	Pleomorphic, enlarged plasma cells, often in sheets with oval, eccentric nuclei, clumped chromatin, perinuclear halo, and cytoplasmatic inclusions ('Russell bodies')
Haemangioma	*Cavernous*: most common subtype in the calvaria, constituted by a mass of blood-filled sinusoidal channels lined with endothelial cells, set within a structure of fibrous septi and bony trabaculae as a result of bony remodelling *Capillary*: most common subtype in the vertebral bodies, consists of clumps of capillaries with associated necrosis *Venous*: consists of thick-walled venous channels, with reactive bone formation in a radiating pattern due to trabecular thickening
Langerhans histiocytosis	Monoclonal proliferation of Langerhans cells, with the characteristic presence of Birbeck granules, 'tennis-racket'-shaped cytoplasmic organelles with a central linear density and a striated appearance
Ewing's sarcoma	Sheets of cells with small, round hyperchromasic nuclei, scant cytoplasm, high nuclear/cytoplasmatic ratio, often forming pseudorosettes
Osteogenic sarcoma	*Osteoblastic*: 50% of cases, characterized by single or multinucleated atypical polygonal cells, with marked anaplasia and high mitotic figures in abundant immature osteoid. Other subtypes: *chondroblastic*, *fibroblastic*, *telangiectatic*
Fibrosarcoma	High cellularity with malignant collagen-producing fibroblasts, organized in sheets or fascicles with a 'herring bone' pattern with spindle-shaped nuclei, mild hyperchromasia, and high mitotic activity
Osteoclastoma	Vascular stroma with polyhedral and multinucleated giant cells, with prominent nucleolus. Areas with round mononuclear cells and spindle-shaped stromal cells usually coexist
Epidermoid and dermoid cysts	Inclusion cysts containing keratinized and stratified squamous epithelium. In dermoid cysts dermal elements (sebaceous and sweat glands, hair follicles, and so on) can be also present

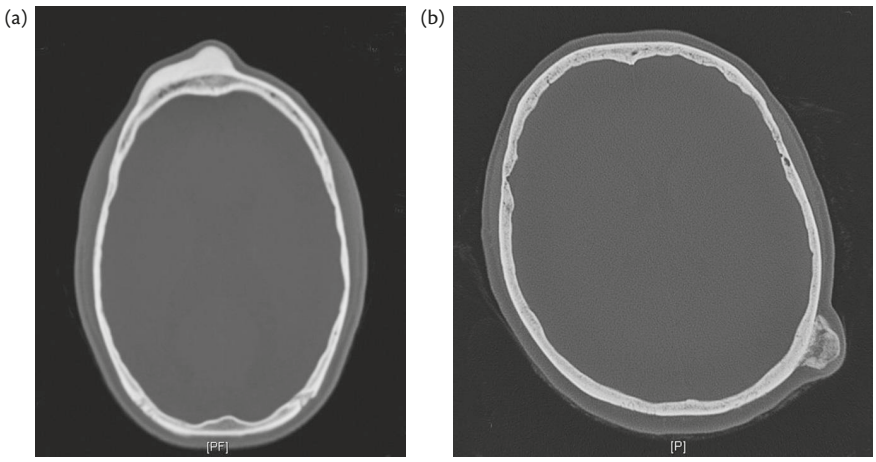

Fig. 20.5 Osteoclastic lesions—osteoma (A) and osteochondroma (B).

Most frequently asymptomatic, it presents as a solitary, painless, slow-growing, solitary, hard calvarial lesion, often only noticed as a cosmetic problem.

If multiple lesions are present, the possible diagnosis of Gardner's syndrome (autosomal dominant form of gastrointestinal polyposis characterized by the association of benign soft tissues neoplasms, thyroid cancer, and multiple osteomas of the skull and mandible) should be considered.

On X-ray and CT imaging osteoma usually appears as a dense, not enhancing, well defined lesion with variable central inhomogeneity (Fig. 20.5). MRI findings consist of homogeneous hypointense T1-weighted signal and variable signal on T2-weighted images, without involvement of the surrounding soft tissue or bone, and with no enhancement (Colas et al., 2015). Bone scan can show variable uptake, depending on the bone-synthesis phase of the lesion. When considering a differential diagnosis intraosseous benign and malignant meningothelial tumours (Fig. 20.6), and malignant non-meningothelial tumours ought to be considered.

Complete excision is the goal of treatment (Haddad et al., 1997) and is mainly undertaken for cosmetic reasons. If the lesion is small and arising from the outer table, it can be removed sparing the inner table by drilling or curettage. Formal craniotomy might be required for larger lesions or for those arising from the inner table, with subsequent simultaneous cranial reconstruction.

Other benign osteoblastic lesions are:

- Osteoid osteoma: benign osteoblastic neoplasm, uncommon in the calvaria as it most frequently arises from the long bones. Classically presents with pain occurring at night and relieved by aspirin.
- Osteoblastoma (also known as osteogenic fibroma): extremely rare in the skull with only sphenoidal location described. Similar to osteoid osteoma, but does not usually cause pain. The lesions tend to be more vascular than osteoid osteoma and sarcomatous change, although very rare, has been described (Figarella-Branger et al., 1991).

Osteoid osteoma and osteoblastoma are histologically undistinguishable, and conventional differentiation is based on the size of the former, measuring less than 1 cm and osteoblastomas being bigger lesions, which can cause tissue compression.

Chondroma (osteochondroma)

Chondroma is a benign osseocartilaginous tumour, macroscopically resembling cartilage, or ossified cartilage. It is the most common benign skeletal osseocartilaginous tumour, accounting for 9–10% of all bone tumours. It is mainly seen in women, from the second to the fifth decade of life, and usually occurs in bone formed by enchondral ossification, and given the almost exclusive intramembranous origin of craniofacial bones—in opposition

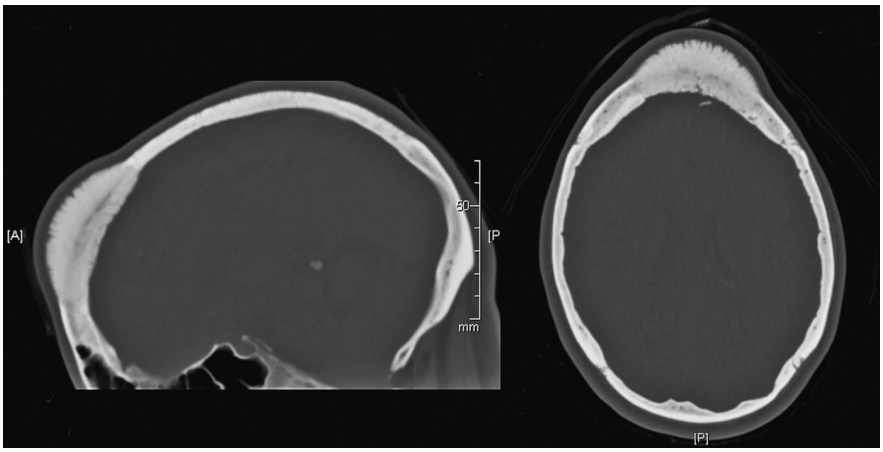

Fig. 20.6 Intraosseous meningioma—osteoblastic expansile lesion.

to the clivus and skull base, which develop by endochondral ossification—it is very rare in the neurocranium, representing less than 0.5% of intracranial tumours (Rathore et al., 2005). It therefore mainly arises in the skull base in the sphenoid (spheno-occipital synchondrosis), occipital (petro-occipital synchondrosis), and ethmoid (spheno-ethmoidal synchondrosis) areas. It has also been reported to occur in the choroid plexus and meninges, and when not arising in the skull base, the fronto-parietal skull is the most common location (Rathore et al., 2005).

It macroscopically appears as a non-pedunculated chondroid mass, or as a sessile exostosis, with or without a cartilage cap, depending on the ratio between osteoid and chondroid elements.

Clinically it presents as a slow-growing calvarial lump. When arising in the skull base, can give symptoms related to cranial nerves compression. Multiple lesions may be associated with Ollier's disease (multiple enchondromatosis) or Maffucci's syndrome (multiple enchondromatosis with subcutaneous haemangiomatosis) (Fountas et al., 2008).

These lesions share radiological features of a lobulated soft tissue mass, containing curvilinear matrix calcifications with scalloped endosteal bone resorption (Fountas et al., 2008). They appear moderately hyperdense on CT scan (Fig. 20.5) and hyperintense on T1-weighted MRI with a variegated pattern, depending on the amount of fat, fibrous tissue, vessels, and mineralized bone present. The cartilage cap can be slightly enhancing. Bone scan can demonstrate a variable uptake depending on the bone synthetic phase. The differential diagnosis is mainly with benign and malignant meningothelial tumours, intraosseous or with osseous invasion, and with malignant non-meningothelial tumours (sarcomas).

The mainstay of treatment is surgical, with complete excision (Fountas et al., 2008). When not completely resectable, decompression of the neural structures should be the primary aim. Transformation into chondrosarcoma is rare (1%), but more likely in the context of syndromic enchondromatosis (25–30%).

Hyperostosis frontalis interna

This condition consists of an irregular thickening of the inner table, diploe, and frontal squama, due to idiopathic deposition of new bone, typically in a nodular pattern. It tends to be bilateral, sparing the midline at the insertion of the falx (She and Szakacs, 2004). The incidence in the general population is 1.4–5%, and is most common in elderly white females, with a F:M ratio as high as 9:1 (She and Szakacs, 2004).

Its pathologic significance is debated, and it is almost always asymptomatic.

The aetiology of this condition remains unknown, but an associated endocrine imbalance may play a role. It is generally found in association with endocrinologic abnormalities (acromegaly, hyperprolactinemia), metabolic abnormalities (obesity, DM), hypertension, headache, CN deficits, seizures, dementia, and depression, and shows a very slowly progressive growth over the years (She and Szakacs, 2004).

CT and MRI show a nodular, symmetrical thickening of the frontal inner tables, which can reach a thickness up to 4 cm. There is little evidence in the literature regarding the surgical treatment of this condition, with lack of significant case series.

Table 20.2 summarizes predominantly blastic lesions.

Table 20.2 Predominantly blastic lesions

Osteoma	*Compact*: resembling cortical bone, with little fibrous tissue, almost exclusively arising from an outer table *Cancellous* (or trabecular): includes compact, trabecular, fibrous, and fat components, and usually originates from the diploe or the inner table *Fibrous*: made of lamellar bone, with a more cellular stroma usually eventually evolving into a 'compact' type
Osteochondroma	*Chondroma*: benign chondrocytes in scattered lacunae within an abundant hyaline cartilage matrix and with immunohistochemical positivity for s100 and vimentin *Osteochondroma:* benign chondrocytes capping an exostosis with cortex, trabeculae, and a normal marrow

Mixed lytic-blastic lesions

Neuroblastoma

Neuroblastoma is a tumour originating from the neural crest cells, whose development has been arrested in the neuroblast stage prior to becoming sympathetic ganglia cells. This explains its tendency to metastasize to the craniofacial skeleton, which shares the same neuroectodermal origin (D'Ambrosio et al., 2010a). It is the most common skull metastasis in children (D'Ambrosio et al., 2010a). The primary lesions arise from the adrenal medulla in 50% of cases with the remainder affecting the sympathetic chain.

It is most common during the first decade of life it does not show gender predominance.

Metastases occur in 50% of patients, and are typically blood-borne mainly to the liver, lungs, and bones. Metastatic involvement of the skull has been found in up to 25% of cases (D'Ambrosio et al., 2010b). When the craniofacial skeleton is involved, common presentations include easy facial bruising and exophthalmos in the case of orbital spread, or rapidly enlarging solitary or multiple masses of the calvaria, which can be associated with cranial nerve deficits (D'Ambrosio et al., 2010b). Skull base involvement and intracranial extension can also occur although generally the meninges act as a barrier to brain invasion.

Metastatic involvement of the skull can generate several different radiographic findings, including thickened bone, 'hair-on-end' periosteal reaction, lytic defects, and separation of sutures. CT usually shows a moderately hyperdense lesion, associated with permeative changes in the adjacent bone. MRI shows a T2-hypointense and T1-hyperintense signal change, with soft tissue infiltration often displaying a thick, 'plaque-like' peridural extension. Most lesions are contrast-enhancing.

The differential diagnosis is mainly with rhabdomyosarcoma, Langerhans cell histiocytosis, Ewing's sarcoma, and osteogenic sarcoma (D'Ambrosio et al., 2010b).

Radiation therapy is the mainstay of treatment, given the radiosensitive nature of the disease, and is used in combination with chemotherapy, and surgery, if focal compression of the neurovascular structures is present.

Paget's disease of bone

Paget's disease of bone is a chronic metabolic disorder characterized by abnormally excessive bone turnover (Ralston et al., 2008),

localized to a single bone or extending to the contiguous segments. It entails abnormal osteoclast activation, causing increased rate of bone resorption, with reactive osteoblastic hyperactivity and production of weaker, woven bone (Ralston et al., 2008). Paget's disease ranges from active lytic phases to reparative/quiescent ones; these may or may not coexist, with individual sites progressing at variable rates.

Incidence increases with age, reaching a prevalence of 3% in adults older than 40 years of age, and 10% in older than 80 years. There is equal sex distribution, and is most common in Caucasians and Ashkenazi Jews.

Skull involvement is present in 30–65% of cases, mostly in the frontal and occipital bones (Colas et al., 2015).

The aetiology is unknown. A genetic link exists with HLA DR2, with increased expression of genes that inhibits apoptosis, the most important being SQSTM1, which is a scaffold protein in the nuclear factor κB (NFκB)—ligand signalling pathway (Ralston et al., 2008).

Frequently asymptomatic, it is often discovered after an incidental finding of raised serum phosphatase alkaline (Ralston et al., 2008; Colas et al., 2015). It can also present as a painful, diffuse calvarial thickening. Entrapment neuropathies can occur if exit formaninae are narrowed, most frequently involving the eighth nerve with pulsatile tinnitus and hearing loss (pure sensorineural or mixed). Platybasia, associated or not with basilar impression, occurs in approximately 33% of patients, with potential brainstem compression, mostly in women. Depending on the extent of the disease, high output heart failure and secondary hyperparathyroidism can ensue, due to high vascularity and aggressive bone remodelling of the lesions. Sarcomatous transformation is reported to occur in less than 1% of cases (Hansen et al., 2006), mainly to osteosarcoma (50–60%), fibrosarcoma (20–25%), and chondrosarcoma (10%). Giant cell tumours are also associated with Paget's, and are frequently multiple in the context of polyostotic disease, with almost exclusive involvement of the craniofacial bones. These present at older ages compared to primary osteoclastomas, and tend to have a less aggressive behaviour (Leonard et al., 2001).

Three radiological forms are described, depending on the phase of the disease: an early destructive phase, which is characterized by osteolytic, radiolucent lesions ('osteoporosis circumscripta cranii', when involvement of the frontal bone prevails). Intense contrast enhancement reflects the increased vascularity of this phase. An intermediate-transition phase, which presents coexistence of lysis and sclerosis. Conventional radiography at this stage shows well-circumscribed areas of 'mottled' bone, and CT displays a 'cotton wool' like enlargement of the diploe. A late phase in which a sclerotic pattern prevails, resulting in a uniform thickening of the cortical bone and trabeculae.

MRI finding are T2-hyperintensity in the osteolytic phase, and variable T1 hyperintensity in the sclerotic stage, in relation to the status of the bone marrow replacement (Colas et al., 2015).

Bone scan shows radionuclide pick up, in relation to the osteoblastic hyperactivity.

A persistently lytic focus, not changing to sclerosis over time, with an enhancing content with no periosteal reaction is a suspicious finding for sarcomatous or giant cell tumour transformation.

The differential diagnosis is with skull metastases, osteosclerotic (prostate, breast, lymphoma) or osteolytic (lung, renal, thyroid), fibrous dysplasia, and all the causes of calvarial thickening (hyperostosis frontalis interna, meningioma). The mainstay of treatment is medical, with the goal of pain control, mainly achieved with osteoclast inhibitors. Close monitoring of the disease phases and imaging follow-up to detect malignant degeneration are warranted. Surgical treatment may be challenging because of the hypervascular nature of the disease, and profuse bleeding is common.

Fibrous dysplasia

Fibrous dysplasia is a congenital non-hereditary benign disorder of the mesenchymal precursor of bone. It is a consequence of the mutation of Gs alpha protein—encoded by GNAS gene—in osteoblastic progenitors' cells, resulting in an abnormal osteoblastic differentiation and maturation, with progressive replacement of normal bone by immature woven bone (Colas et al., 2015) mixed with fibrous connective tissue (Bowers et al., 2014; Wu et al., 2014).

It represents 2.5% of all bone tumours (Bowers et al., 2014), with an incidence of 1:4000–1:10 000. Males and females are equally affected, usually before the third decade of life.

It is monostotic in 75–80% of cases, but more commonly polyostotic in younger patients. Skull involvement is more common in the polyostotic form mainly involving the sphenoid, frontal, ethmoid, maxillary, occipital, and temporal bones (Bowers et al., 2014).

Clinical presentations include: painless localized bone swelling in the orbito-cranial territories, proptosis, entrapment cranial neuropathies (commonly the optic nerve), headache, seizures, spontaneous scalp haemorrhages (Bowers et al., 2014). In the polyostotic form, these findings come in association with long bones fractures and deformities.

Malignant degeneration is rare, seen in less than 1% of cases. The risk is greater in mono-ostotic locations, especially of the maxilla and mandible as well as following radiation therapy (Bowers et al., 2014). Osteosarcoma is the most common associated malignancy followed by fibrosarcoma and chondrosarcoma.

Lesions usually grow during childhood, and do not progress beyond puberty (Colas et al., 2015), with the end of skeletal maturation (Wu et al., 2014).

The polyostotic form of the disease can be part of McCune–Albright syndrome, characterized by the triad: polyostotic disease, café au lait spots, multiple endocrine dysfunction.

Three main radiological presentations have been described: pagetoid (35% of cases), characterized by alternating sclerotic and lytic features, with the sclerotic mainly involving the skull base, whereas the lytic lesions affect the cranial vault with a 'worm-eaten' appearance (**Fig. 20.7**). A sclerotic 'compact' form (50% of cases), characterized by homogeneous thickening of the bone, thought to represent the least active form. CT shows a ground-glass appearance (Bowers et al., 2014) mainly at the skull base. A cystic or 'lytic' (15% of cases) type, thought to represent the most active form, showing a non-homogeneous pattern of expanded bone on CT with radiolucent lesions surrounded by a thin sclerotic area resembling an eggshell. The cystic changes appear hyperintense on T2-weighted MRI, whereas areas of sclerosis show marked hypointensity (Bowers et al., 2014). The lesions are variably and inconsistently enhancing after gadolinium administration.

Differential diagnosis is with a wide range of conditions, given the polymorphic nature of the disease including Paget's, neurocutaneous

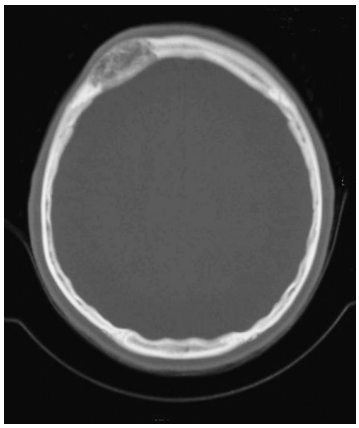

Fig. 20.7 Fibrous dysplasia exhibits a non-homogeneous pattern of expanded bone with radiolucent lesions surrounded by a thin sclerotic areas.

disorders, meningioma, brown tumours, osteopetrosis, hyperostosis frontalis interna, thalassemia, and craniometaphyseal dysplasia.

Surgical indications depend on the presence of progressive neurological impairment, the extent of the disease, and the age of the patient. When indicated, complete surgical resection is the goal of treatment. If not feasible, the aim is to achieve decompression of the neural structures (Bowers et al., 2014). Single stage bone reconstruction may be necessary. The lesions are radio- and chemo-resistant and radiotherapy has been reported to increase the risk of sarcomatous transformation.

Table 20.3 summarizes mixed lytic-blastic lesions.

Traumatic and congenital lesions

Sinus pericranii

This condition consists of a venous transdiploic venous channel, connecting the intracranial venous system with an epicranial or subgaleal vein (Bouali et al., 2015). It is a very rare finding, usually diagnosed from childhood to the third decade.

Sinus pericranii is mainly located along the sagittal sinus, in the midline frontal region, but can occur also more laterally. Two types are described: 'closed' type, where the flow comes from and drains into a dural sinus, and 'drainer' type, where blood drains transdiploe (Bouali et al., 2015).

Clinical presentation is of a soft, reducible mass in proximity of the midline, fluctuating with Valsalva manoeuvre and with changes in head position (Bouali et al., 2015). Neurological impairment is uncommon, but the disturbance of flow along the superior sagittal sinus has been thought to be the potential cause for non-specific symptoms such as headache, vomiting, and bradycardia (Bouali et al., 2015). Different aetiologies have been proposed: congenital, in association with other vascular anomalies, especially Von Hippel–Lindau syndrome; mixed congenital-traumatic, implying the presence of a large number of emissary veins which are torn by transient increases of ICP (coughing, straining), eventually allowing the formation of a blood varix progressively eroding the skull; traumatic, when an emissary vein or a dural sinus are torn by a skull fracture, causing a venous epidural haematoma.

Arteriography shows an enhancing transdiploic vascular channel, communicating with the intracranial veins, that may be anomalous and slowly filling.

The differential diagnosis includes vascular malformations of the scalp (cavernous haemangioma), ruled out by CT and MRI angiography, which show the lack of involvement of the intracranial circulation. Also pseudomeningocele, cranioschisis, growing skull fracture, scalp dermoid cyst should be considered (Bouali et al., 2015).

Surgical correction is indicated mainly for cosmesis, prevention of massive intracranial haemorrhage, and risk of air embolism, and is achieved mainly through craniotomy/craniectomy, closure of the communication between the extracranial veins and the intracranial venous sinus, and excision of the extracranial component with subsequent cranioplasty. Endovascular closure has also been described (Bouali et al., 2015). The prognosis of this condition is generally good.

Cephalohematoma

This consists of a subperiosteal haemorrhage, by definition stopping at the sutures. It occurs as a result of birth trauma, in 1% of live births, but can be also non-traumatic, if coagulopathy coexists. It is most common in in the parietal convexity, and may become apparent 24–48 hours after birth; it progresses over a few days, and usually resolves within 4 weeks, even if it can take longer (Kaufman et al., 1993). If it does not resolve after a month, calcification may occur in the site where the periosteum was lifted, with remodelling of the outer table.

The differential diagnosis is with caput succedaneum, which crosses the sutures and resolves after a few days, and with subgaleal haemorrhage, which similarly crosses the sutures and may extend towards the neck. CT imaging may be required to rule out depressed skull fracture and meningocele.

Head wrapping has been described, and may promote resorption. Needle aspiration of the fluid prior to wrapping is debated, since it may introduce infection. Surgical removal by drilling may be required if calcification occur, mainly for cosmetic reasons (Kaufman et al., 1993).

Table 20.3 Mixed lytic-blastic lesions

Paget's disease	Microscopic features vary between the different phases of the disease; in the early lytic-destructive phase giant multinucleated osteoclasts prevail, causing aggressive resorption and marrow substitution by fibrovascular tissue; the transition to the late sclerotic phase comprises an intermediate phase, with an increase in osteoblastic activity, leading to a final stage of decrease in osteoblastic activity with disappearance of the vascular stroma leaving a sclerotic, brittle bone with an atrophic marrow. Such sclerotic bone, made up of thickened trabecular, lacks structural strength ('pumice bone')
Fibrous dysplasia	Whorls of fibroblasts, immature woven bone, and cartilage—with bone trabeculae floating within a fibrous stroma forming 'Chinese letter' shapes

Leptomeningeal cyst

This is an intradiploic pseudocyst, without epithelial lining, occurring almost exclusively as a consequence of a skull fracture mainly in children under the age of three. When not related to a skull fracture, an epithelial lining is usually present ('true intradiploic leptomeningeal cyst') and the aetiology may be congenital or might involve a post-traumatic enlargement of Pacchioni's granulations (Menkü et al., 2004). It is most common (50%) in the parietal region, followed by frontal and occipital.

Such finding is usually associated with a blow to the calvaria, and can be thought as a retained form of growing fracture, with rupture of the inner table and intact outer table incorporating a dural and arachnoidal tear, associated or not with parenchymal injury and herniation through the meningeal breach. This is followed by subsequent enlargement of the fracture to form an intraosseous defect, due to the pulsation of the arachnoid and brain through the defect itself (Açikgöz and Tekkök, 2002) causing remodelling of the bony edges (Menkü et al., 2004). Growing fracture are associated instead with mechanical failure of both the inner and outer tables, and a cyst might develop trans- and beyond the diploe, forming a leptomeningeal pseudocyst (pseudomeningocele) (Açikgöz and Tekkök, 2002).

It presents as a soft, pulsating, fluctuant mass, more prominent with the patient supine, occurring in 50% of cases within a year of the original injury, and is occasionally associated with seizures or focal neurological deficits.

CT and MRI show the herniated meninges and brain. MRI has higher specificity to assess the involvement of brain parenchyma and the status of the dura. Differential diagnosis is mainly with epidermoid and congenital arachnoid intradiploic cyst (Menkü et al., 2004).

Surgical treatment consists in the resection of the cyst, with or without amputation of the herniated brain. Closure of the dural defect is necessary to prevent recurrence (Açikgöz and Tekkök, 2002). Cranial reconstruction is often needed.

Surgical management of anterolateral skull base lesions

Michael D. Cusimano and Michael P. Meier

Introduction

The following section outlines major considerations in the treatment of anterolateral skull base lesions. The essential anatomy, including the nasosinal region and anterior fossa, is presented. The challenge of choosing the appropriate surgical approach is highlighted. We report on the principles of preoperative investigations and explain the perisurgical treatment of patients with lesions of the anterolateral skull base.

The chapter focuses on surgical decision-making and the techniques used in managing anterolateral lesions. Detailed descriptions of the anterior interhemispheric approach, supraorbital minicraniotomy, extended endoscopic endonasal approach, orbitozygomatic approach, and the Fisch approaches are provided. Ultimately we present and discuss the surgically relevant nuances of four selected cases to highlight and illustrate the decision-making and controversies when applying certain approaches.

Neuroanatomy

Neurosurgeons must be masters of surgical anatomy. Not only must they understand the anatomy for the localization of lesions for diagnosis, but they also must master relational anatomy and the anatomy of the surgical corridors to lesions inside and outside the brain. In terms of the anterolateral approaches to skull base lesions, surgeons must understand the relational anatomy above, below, and across the anterolateral skull base. In terms of surgical corridors, this means understanding nasal and orbital anatomy, as well as cranial and transcranial anatomy.

The key to understanding the whole central skull base is the sphenoid bone, with its central body, lesser and greater wings, and the pterygoid plates, perforated by multiple foramina and bounding several fissures and the sphenoid sinus. The sphenoid provides passage to the internal carotid arteries, the middle meningeal arteries and presides over cranial nerves (CN) I-VI. Neurosurgeons must appreciate its anatomy from the primary different perspectives of anterior to posterior, posterior to anterior, lateral to medial, medial to lateral, superior to inferior, and inferior to superior in addition to rotated views that correspond to different head positions. It forms the core of the middle fossa and combines with the frontal bone and bones of the orbit and nasal complex to complete the anterior fossa and the structures above and below those regions.

The frontal bone provides the major structure of the anterior fossa. The frontal sinuses are extremely variable in size and position involving the lateral supraorbital ridge and orbital roofs. The frontal, sphenoid and ethmoid sinuses must be carefully studied on preoperative imaging, and should the surgical corridor necessitate transgressing these sinuses, appropriate reconstruction should be planned. The orbital roof is generally very thin, corrugated, and can be simply removed with an osteotomy. When combined with tenting of the dura inferiorly across a broad base, the subfrontal corridor is widely opened without the need for frontal lobe retraction.

The sphenoid and frontal bone make a good portion of the orbit, but the other bones of the orbit including the zygoma are critical in understanding lesions that transgress this area and the anterolateral approaches.

Folds of dura form the falx cerebri, and a division of the meningeal layers of the lateral wall of the cavernous sinus provide a home for cranial nerves III, IV, VI, and V2, before they transgress the superior orbital fissure and foramen rotundum (V2).

Preoperative

Workup of anterolateral skull base lesions

A detailed clinical history will shed light on the pathology of the lesion and help decide whether surgery is indicated and define the urgency of any procedures. A full neurological assessment should include an ophthalmological exam with visual acuity, pupillary reflexes, and a search for relative afferent pupillary defects, colour vision, and the perfusion of the disc with fundoscopy. A standardized cognitive assessment such as the Montreal Cognitive assessment (Nasreddine et al., 2005) can be extremely useful in monitoring a patient's progress. Since frontal lesions may not present with localized motor symptoms, special attention to these factors will be important in addition to testing olfaction. We routinely have patients assessed by a multidisciplinary team including a neurosurgeon, neuro-ophthalmologist, endocrinologist, and ear nose throat (ENT) surgeon. If needed, formal visual fields, optical coherence tomography, baseline hormonal blood work, and others thereafter complete

the specialist's examinations. If necessary, preoperative discussion with otorhinolaryngology, medical oncology, neuroradiology, and radiation oncology within a multidisciplinary setting may be helpful in planning optimum care.

Imaging

We routinely use computed tomography (CT) to help image bony anatomy and pathoanatomy (e.g. hyperostosis), paranasal sinus landmarks (e.g. sphenoid septae) and, if required, vascular anatomy with CT angiography (CTA). Three-plane volumetric MRI T1- and T2-weighted scans without and with contrast are also routinely used in defining the relationship of the tumour to the brain, skull base transgression, orbital contents, vessels, and other local structures. Special attention to the arachnoid plane or to focal peritumoral oedema, which may represent a breach of the arachnoid plane, is important in terms of treatment and prognosis.

We rarely resort to conventional digital subtraction angiography for neoplastic lesions but it is routinely used to clarify ambiguous CTA results or vascular lesions. We infrequently use preoperative embolization of highly vascularized lesions, for example in juvenile nasopharyngeal angiofibromas. In cases where metastatic spread from another organ malignancy is suspected, full body CT or even a positron emission tomography (PET) scan may be performed.

Differential diagnosis

A history in which symptoms are rapidly progressive, particularly with multiple cranial neuropathies, without a long prodrome should raise suspicion of an infection or a malignant entity. Lesions of the anterolateral skull base will vary depending on the region of the world and the endemic conditions in those regions. A useful memory aid in defining the differential diagnosis is that of 'Tumour, Pus, or Blood'. Tumours may be primary benign (e.g. meningioma, pituitary adenoma, craniopharyngioma) or primary malignant (e.g. esthesioneuroblastoma, chordoma, chondrosarcoma) or secondary (e.g. direct spread of sinus cancer or haematogenous spread of a distant metastasis), infectious (e.g. fungal, bacterial, tuberculous, or other) or inflammatory lesions, and vascular lesions such as aneurysms. Tumours may also be classified based on the presumed cell type of origin (e.g. bone, cartilage, meninges, nerves, endothelial cells).

Planning for surgery

Major considerations prior to surgery should include diagnosis (i.e. history and physical examination), special investigations to confirm or refute the clinical diagnosis, and making a decision on whether to treat or observe. In slow growing lesions, or debilitated, elderly patients, surgery may not be the primary treatment. Physically fit patients should be considered for surgery if the patient requires a tissue diagnosis, oncologic cytoreduction, or decompression of neural structures (e.g. visual loss or raised intracranial pressure). Major considerations including the anticipated pathology, and whether the lesion is likely to be completely resected. Other options, for some tumours are subtotal resection plus radiation, or biopsy alone followed by radiation or chemotherapy as adjuvant treatments. Maintaining functionality with optimum long-term outcome including survival and quality of life are key. In accordance with the above-mentioned, the surgical approach is naturally selected on considering the tumour location, but also on the surgeon's experience and familiarity.

The surgeon should visualize every step of the operation prior to beginning the procedure. The astute surgeon who seeks expertise will do the same after surgery and reflect on the factors for or against success encountered with each patient and make careful documentation of each case. Preoperatively briefing the surgical team can be useful. Surgical steps entail presurgical and anaesthetic preparation (e.g. blood component preparation, anticonvulsants for epileptogenic lesions), patient positioning, the approach respectively tissue preparation, tumour resection, and reconstruction. Surgeons need to be aware of each step, the associated risks, and the required equipment. Preparation of the particular equipment such as neuronavigation, neurophysiologic monitoring with selection of the specific modalities, ultrasound, microinstruments, cavitron ultrasonic surgical aspirator, endoscope with choice of appropriate optics, fibrin glue, and others. The anaesthesiologist needs to be informed about the expected surgical time, blood loss, particular dangerous surgical phases as well as required extra drugs. It is recommended to mention any need for antibiotics, corticosteroids, or means to lower intracerebral pressure such as mannitol, hyperventilation, and positioning before the skin incision.

Naturally if a lumbar drain needs to be inserted, it has to be performed before the final patient positioning. We use this routinely if there is an expected large cerebrospinal fluid (CSF) leak due to widely opened basal cisterns to the nasal cavity to reduce CSF pulsation pressure against a multilayer closure. We also use drains routinely for extradural or intradural procedures where less brain retraction is desired and there is minimal risk of brain herniation.

When the choice concerning the surgical approach has been made, further considerations include patient positioning and preparation techniques. The patient is always positioned and all pressure points are carefully protected. While in a comfortable position, the patient is securely strapped onto the operating table so as to allow safe rotation in such a way that gravity widens access to deep anatomy without brain retraction. The patient is positioned with the head above the body to ensure venous drainage. Depending on the location of the pathology the head is held neutral or rotated and fixed in a three- or four-point head holder. We always try to avoid brain retraction by removing sufficient bone and by using gravity to allow the brain to fall away from the surgical access path. The neck needs to be extended in order to achieve a sufficient surgical view.

Reconstruction of any defect should be considered when deciding on the surgical approach. Allogenic tissue such as fascia lata and fat is often ideal while synthetic or animal-based products, although sometimes acceptable are often more costly. We try to preserve cranial periosteum at all costs unless we need a vascularized flap such as to repair a widely opened defect with exposure to the aerodigestive tract. We have seen many cases where pericranium was sacrificed to repair a simple dural defect when a fascia lata or synthetic graft would have done as well or better. Subsequently, the patient has required repeat surgery or radiation or both, only to have the compromised scalp be the source of healing problems, which have even, on occasion, been fatal. In general, if one is not planning to use the pericranium as a vascularized flap (e.g. to cover the nasal cavity), the best place to leave it is with the scalp. Leaving it on the bone and then de-vascularizing or denervating it should be avoided whenever possible.

In cases where a frontotemporal craniotomy is included, we regularly perform an interfascial dissection. The superficial layer of the

temporalis fascia is dissected together with the superficial temporalis fascia and kept on the scalp flap. The dissection is continued anteriorly on the deep facial plane deep to the fat pad and superficial to the deep temporalis fascia to prevent injuries to the frontalis branch of the facial nerve.

Patient selection and decision-making

General treatment options in skull base surgery include conservative treatment, surgery, and radiation therapy as well as the combination of these. In the management of anterolateral skull base lesions benign tumours causing symptoms due to tissue displacement rather than invasion and amenable to complete resection will be surgical candidates. Malignant radiosensitive skull base lesions and lesions in moribund patients are recommended for radiation treatment. Occasionally, atypical lesions should be biopsied and further management decided based on tissue diagnosis. Asymptomatic lesions where imaging characteristics suggest benign behaviour may be observed with periodic imaging. However, the final treatment decision has to be made by the patient supported by a competent neurosurgical consultation.

Anterolateral approaches entail various advantages including good basal access, a wide working range in different angles, space to look up as well as down, ideal conditions for reconstruction (e.g. of the frontal sinus) and minimization of brain retraction.

Two issues should be considered in deciding on an approach, the anatomy of the lesion and the most likely pathology of the lesion.

Anatomical indications for the anterolateral and orbitozygomatic approaches include lesions involving the orbit (superior orbital fissure, superior or lateral optic canal, posterior, superior, and lateral wall), sphenoid bone, parasellar space, tentorial incisura, basal cisterns, optic nerve, optic chiasm, circle of Willis, mesial temporal lobe, basal frontal lobe, anterolateral midbrain, and infratemporal fossa.

Pathological indications for anterolateral and orbitozygomatic approaches include vascular lesions like aneurysms of the anterior communicating artery, proximal internal carotid artery, posterior communicating artery, or the upper basilar artery and tumours including meningiomas, schwannomas, craniopharyngiomas, pituitary adenomas, chordomas, chondrosarcomas, different types of bone tumours, and secondary meningeal-based tumours. Skull base infections for example aspergillosis are also indications. Lesions requiring resection or decompression rather than biopsy should be approached this way.

Surgical approaches

Frontal anterior interhemispheric approach

The anterior interhemispheric approach is a common and frequently used technique for lesions at the anterior skull base. This approach is best for midline lesions without a large lateral extension. Lesions at the lower frontal skull base, not presenting on the surface or interhemispheric fissure are reached by a superiorly placed approach, whereas suprasellar lesions require a lower skull opening. Similarly, deep-seated lesions can be well accessed by a contralateral paramedian craniotomy.

Position: Supine with the back elevated so as to raise the head above the heart and the head fixed either neutral or slightly extended for lesions at or below the skull base so as to allow gravity to permit the frontal lobes to fall away from the skull base or slightly flexed for those above the skull base.

Incision: Usually along the coronal suture bilaterally to the top of the pinna or to the tragus. Be sure not to shorten the potential pericranial flap by using the so-called 'soutar' style incision, which in our opinion has no advantages. We generally do not make low frontal scalp incisions so as not to sacrifice the vascularized pericranium, as noted earlier. However, for very small lesions or those very unlikely to require pericranial salvage, a straight incision behind the frontal hairline or at one forehead wrinkle might be appropriate. For unilateral lesions, particularly those requiring some temporal fossa exposure, a reverse question-mark type incision is appropriate. The skin flap including the galea and the periosteum is elevated in a single layer wherever possible to assure appropriate moisture and blood supply during the procedure. If a vascularized pericranial flap is planned for reconstruction, we prefer to leave the periosteum on the skull and to elevate it separately from the other layers of the scalp and keep it vascularized and innervated at its base.

Craniotomy: Two or more burr holes are drilled on the midline, then the superior sagittal sinus (SSS) is stripped from the skull to avoid damage. A keyhole burr hole is also placed at the keyhole unilaterally. The craniotomy can be bifrontal or carried out such that the skull flap extends about 1 to 1.5 cm to the contralateral side facilitating access on both sides of the falx cerebri.

Dura and intradural: The dural opening depends on what access is required. Often the SSS is suture ligatured at its base and the remaining falx cerebri divided to give full midline access, as for example with an anterior communicating artery aneurysm or midline meningioma. Alternatively, a semicircular unilateral opening with the base towards the superior sagittal sinus or a unilateral cruciate opening or a semicircular flap with the base on the orbital rim are all potential options depending on what access is required. In general, we like to have a sufficient corridor and if possible, to keep the dura on the brain to avoid dehydration and facilitate normal dural closure. Bridging veins draining into the superior sagittal sinus are now exposed and efforts should be taken to preserve these. After approaching the anterior interhemispheric fissure sufficient CSF is drained to reduce the retraction required later once the surgical target has been reached.

Reconstruction: After finishing the intracranial procedure and before skin closure the burr holes should be sealed with a bridge cranioplasty technique (Cusimano et al., 2012) or alternatively with the more expensive titanium MRI compatible, low profile miniplates to improve the cosmetic result of the forehead craniotomy. If the frontal sinus is opened, watertight dural closure, vascularized coverage, or frontal sinusectomy with defunctioning is required. In the event of frontal sinus opening, methylmethacrylate, silastic, and other similar artificial reconstructive materials should be avoided, given the high risk of infection.

Supraorbital craniotomy and minicraniotomy

The supraorbital subfrontal approach facilitates good exposure to the ipsilateral anterior skull base, the suprasellar and parasellar region, and in rare cases can even allow access to anatomical structures of the contralateral and retroclinoid area. Since Fedor Krause (Krause, 1908) first reported the approach in 1908, many modifications have been described resulting in smaller craniotomies with acceptable cosmetic results. The Perneczky group (van Lindert et al.,

1998; Reisch et al., 2003) reported the surgical technique of the supraorbital keyhole craniotomy through an eyebrow skin incision which benefits from minimal brain retraction with optimal access to deep-seated skull base lesions.

Position: To utilize the advantages of this approach, the patient's head needs to be rotated and extended to accurately reach the surgical target. For ipsilateral lesions, the head is rotated to 15° whereas contralateral lesions require an angle of up to 30° to 60°.

Incision: Considering the individual anatomy of the frontal paranasal sinus the skin incision is placed lateral to the supraorbital foramen running within the eyebrow and extending a few millimetres laterally.

Craniotomy: Following retraction of the orbicular and the occipitofrontal muscles a small burr hole is placed posterior to the temporal line after detaching the anterior edge the muscle. Once the anterior fossa is reached a minicraniotomy is initiated by cutting a straight line parallel to the glabella in a lateral to medial direction. Thereafter a C-shaped line is sawn from the burr hole to the medial border of the previous cut. Before the dura is opened it is recommended to drill the inner edge of the bone above the orbital rim to improve intraoperative manoeuvrability.

Dura and intradural: A curved dural incision with a pedicle flap based towards the orbit. The most crucial step to avoid significant brain retraction is the drainage of CSF by opening of the chiasmatic and internal carotid cisterns or by usage of a lumbar drain as described earlier. After the removal of the skull base lesion, closure is performed in reverse order. Note that this approach sacrifices the pericranial flap and if the pathology demands resection of the skull base along with vascularized pericranial reconstruction, another approach should be chosen.

Endoscopic surgery

The advent of the fully endoscopic binasal approach to the skull base began with the work of Cusimano and Fenton, first reported in 1996 (Cusimano and Fenton, 1996). The first approach was performed in 1993 and consisted of a binasal exposure, posterior septotomy, wide exposure of the skull base including sphenoidal, ethmoidal and, if necessary, maxillary sinus opening. It has been frequently presented at scientific conferences and has gained widespread popularity (Di Ieva et al., 2014). As the transsphenoidal approach to the sellar and suprasellar space is covered in a different chapter, the following will address the specific characteristics of the extended endoscopic endonasal approach (EEA) to lesions of the anterior skull base.

Major limitations of the EEA are large, firm lesions, and those that markedly extend beyond the skull base midline or encase important arteries. Opening of the anterior skull base from below is limited due to the necessity of mobilizing the optic nerves. We perform the procedure as a two nostril, four-hand endoscopic procedure, which always requires the support by an ENT surgeon with particular experience in nasal sinus surgery (Cusimano and Fenton, 1996; Cusimano et al., 2012; Cusimano et al., 2013). Furthermore, for extended approaches where we know there will be wide opening of the basal cisterns and a high flow CSF fistula, we routinely insert a lumbar drain preceding the surgical procedure and we always use a vascularized nasoseptal flap. A practice that we have employed since 1996–1997 with very good success.

Preparation and positioning: After placing the lumbar drain the patient is positioned supine with the back elevated 10 degrees. When approaching the sella the head is placed neutral so that the forehead is parallel to the floor and neutrally fixed in a four-point head clamp, whereas for more rostral located lesions the head may need more retroflexion. The abdomen and the right leg are prepared to harvest fat and fascia lata for the skull base reconstruction. The nasal cavity is then temporarily packed with soaked adrenalin 1:100 000 concentration topical pledgets. We apply a 0° endoscope for the nasal phase and 30°, 45°, and 70° endoscopes for the skull base procedure. We routinely prepare neuronavigation and a micro-doppler to safely localize the inferior cerebellar artery (ICA) and anterior cerebral arteries.

Approach: The procedure is initiated by reducing the middle turbinates bilateral and followed by the harvesting of a naso-septal flap, which is usually performed on only one side. For a better overview of the patient's anatomy the natural sphenoid ostium is sought and accessed even if the sphenoidotomy is not required. The septostomy is introduced by fracturing the posterior vomer and perpendicularis plate as required, which is then taken off the sphenoidal rostrum. The bone is stored in bacitracin and will eventually be used for the reconstruction. If desired the sphenoidotomy is now accomplished on either side. For more rostrally located lesions (e.g. at the planum-tuberculum junction or cribriform plate), the posterior (or anterior) cells of the ethmoid sinus are opened and taken down laterally to the lamina papyracea. If the approach is taken far anterior beyond the course of the posterior ethmoid artery olfaction is likely to be impaired. However, as tumours at this location commonly invade the olfactory filaments most of the patients are already anosmic preoperatively and ideally this should be confirmed in the clinic. The anterior fossa floor should be drilled, assisted if necessary with Kerrison rongeur, or lifted away with osteotomes. We routinely preserve the bones with osteotomes, which has the benefit of preserving bone for the reconstruction.

The tumour is initially devascularized with bipolar cautery of feeding vessels like the posterior ethmoidal arteries bilaterally. The dura is opened widely so as to expose the base and anterior, posterior, and possibly lateral edges of the tumour. After a biopsy to confirm the diagnosis, the lesion, depending on its size, is debulked centrally. Once debulked, the margin and adjacent arachnoid plane are carefully accessed. The arachnoid is preserved and 'undressed' from the tumour by working in the cleavage plane between the tumour and the arachnoid. Sequentially debulking and dissection of the margin allows progressive tumour removal. Keeping the arachnoid with the patient allows preservation of critical structures like the anterior cerebral arteries.

Reconstruction: For the avoidance of complications due to postsurgical CSF leaks it is crucial to perform a layer-by-layer reconstruction assisted with lumbar drainage. Therefore, we always use fascia lata and fat graft. Some countries have dural substitutes which can also be used. Fat can be used for dead space occlusion as well as to support a fascia lata duraplasty, which ideally is placed underneath the excised dural edges using an 'in-lay' position (Cusimano and Suhardja, 2000). While the lumbar drain is kept closed until the fascia lata is adequately placed, the drain is then opened, and CSF is continuously drained during the rest of the closure. Next, we apply bone chips that are placed overlapping and wedged with the resection margins of the skull base. This is supported by placement of some tissue glue, which furthermore adheres the vascularized septal mucosal flap. The reconstruction is supported and secured by

packing of the nasal cavity with polyvinyl acetal sponges or pallets packed inside a glove. Nasal silastic trumpets are advanced to the level of the choanae, which enable nose breathing and support the packing. The lumbar drain is clamped on the second postsurgical day and removed the following day.

Orbitozygomatic approach

In the mid-1980s, Pellerin et al. (1984) and Harbuka et al. (1986) first described the orbital-cranial-zygomatic (OCZO) or simply, orbitozygomatic approach (OZY or OZO) to the anterior, middle, and upper part of the posterior cranial fossa. The OZY approach is an extension of the classic frontotemporal craniotomy and combines the advantages of wide skull base access, short working distances with excellent manoeuvrability with minimal brain retraction. We have used the approach extensively since 1991 to approach a wide variety of lesions (van Furth et al., 2006). The anatomical and pathological indications for this very versatile approach have been listed earlier as the indications for anterolateral approaches.

There are multiple variations of the approach. The most common variant is simply the orbito-cranial segment osteotomy, which includes only the superior and lateral orbit with zygomatic bone and not the zygomatic arch. This approach is excellent for pathologies in the anterior cranial fossa and to the level of the oculomotor trigone such as anterior circulation aneurysms. Lesions more posterior than the oculomotor trigone, benefit from removal of the zygomatic arch. For midline structures, we simply perform the osteotomy of the superior orbital rim and roof unilaterally, or if taken across the nasofrontal suture, bilaterally. We routinely perform the craniotomy initially and then the osteotomy of the orbit, the so-called 'two-piece technique', since we find this efficient and safe with visualization of all pertinent anatomy. Alternatively, a one-piece technique that incorporates craniotomy and orbital osteotomy into a single construct as described by Al-Mefty (Al-Mefty, 1987) and others (Jane et al., 1982; Ikeda et al., 1991) is also possible.

Position: Similar to an ordinary frontotemporal craniotomy the patient's head is rotated, depending on the anatomical regions that require access, contralaterally to about 10–45°. The neck is slightly extended to allow gravity to pull down the frontal and temporal lobe.

Incision: Starts anterior to the tragus and is continued up to the hairline near the midline, either curved or in question-mark shape as if for a small trauma flap. Forming the skin flap an interfascial dissection is carried out together with the periosteum, which is mobilized up until the orbital rim. The supraorbital nerve and its accompanying vessel are freed out of the supraorbital foramen with small osteotomes. Careful dissection of the periorbita to a depth of 2.5 to 3 cm, followed by detaching the temporalis muscle from its fossa and the zygomatic arch precede the frontotemporal craniotomy.

Craniotomy and osteotomy: We prefer a bridge cranioplastic technique of craniotomy (Cusimano and Suhardja, 2000) to expose frontal and temporal regions as required by the surgical target. The orbitozygomatic osteotomy is accomplished by five separate sequential bone cuts. One surgeon makes the cuts and the other protects the orbital contents. The anaesthetist is alerted since any manipulation of the orbital contents can induce a profound trigeminal-vagal response with severe bradycardia. The dura is covered with long cottonoid slabs and a brain spatula but without retraction. The first cut is made by the surgeon standing at the head of the bed. The cut starts just lateral to the supraorbital notch and extends posteriorly about 2.5 cm from the inner table of the skull. The surgeon then moves to the side of the head. Starting from the posterior end of the first cut, the second is carried out along the posterior orbital roof approximately half way to the inferior orbital fissure. The third cut is then accessed at the inferior temporal fossa and sawed from the inferior orbital fissure supero-posteriorly to come into the previous cut. For the fourth cut the saw blade is placed into the orbital cavity at the inferolateral edge with the blade in the inferior orbital fissure to direct the cut downwards and outwards along the zygomatic bone or so-called 'malar eminence'. Initially the deeper cut is done with the tip of the blade in the inferior orbital fissure and, subsequently a reciprocating saw is held more posteriorly and superficially up until the midpoint of the zygomatic bone. The saw is now removed and repositioned at the posterior edge of the zygoma to saw back up to end at the previous cut, staying above the zygomaticofacial foramen to avoid opening of the maxillary sinus. The last cut is taken obliquely through the most posterior part of the origin of the zygomatic process. Following these five bone cuts, the orbitozygomatic bone piece is now freed up by tapping the remaining bone bridges with an osteotome. Depending on the need for additional exposure further adjustments can be performed to expose, for example, the petrous internal carotid by removal of the condylar fossa and by inferiorly subluxating the glenoid capsule and head of the mandible. Once the osteotomy is fashioned, if further work such as removing the middle fossa floor to access transbasal or infratemporal lesions is required then this can now be performed.

Dura and intradural: This depends on the primary origin of the lesion and whether the need is greater in the anterior or middle fossa or equal access to both is required. Cavernous sinus and Meckel's cave lesions should be approached extradurally if possible. If intradural access is required, then we most often perform a C-shaped opening of the dura centred on the Sylvian Fissure. The dura is tented upwards to widen the surgical corridor.

Reconstruction: The pathology and surgical resection defines the reconstruction. We generally try to replace dura and always do if the bone of the anterolateral skull base has been removed. In the event of an opening into a paranasal air sinus, we try to de-function the sinus or cover it with vascularized tissue. The osteotomy is carefully replaced into the anatomical position with care taken to avoid any strangulated fat around the edges. We do not try to suture opened periorbita unless they are quite small. The osteotomy is usually fixed with titanium miniplates or with heavy non-absorbable sutures placed through tiny drill holes. The craniotomy is fixated with multipoint fixation to the native skull and to the osteotomy. If possible, the bridge technique is used and burr holes filled with autologous sawed-bone dust after the hole has been stitched across with non-absorbable suture. Alternatively, prefabricated burr-hole covers or some sort of bone substitute can be used if finances permit.

Fisch approaches

Although not anterolateral in approach, the infratemporal fossa approaches can be used to access lesions in the middle fossa up to the back of the orbit. They are among the most challenging surgeries for neurosurgeons as well as otolaryngologists. Fisch et al. (Fisch, 1978; Fisch and Pillsbury, 1979) was the first to describe three different approaches for tumours of the pyramidal tip, clivus, and parasphenoid region that involve essential neurovascular structures such as the carotid artery, jugular vein, and cranial nerves V–XII. These are

inferolateral approaches that work from the skull base and below, looking upward towards the skull base. As such they are ideally suited for lesions in the temporal bone region and as far anterior as the middle fossa floor and pterygomaxillary fissure. Key features of the Fisch A, B, and C approaches are described as follows.

Indications for type A approaches lesions involving the infralabyrinthine and apical compartment of the temporal bone including glomus jugulare tumours, meningiomas, cranial nerve schwannomas, as well as cholesteatomas, and lower clivus chordomas.

Technique: Type A: Initiating a craniotemporo-cervical skin incision the facial nerve is identified and its main branches are exposed. The skin of the external auditory canal along with the tympanic membrane, and the ossicles down to the stapes footplate will have to be removed subsequently. Despite the adverse result of a conductive hearing loss the inner ear function is preserved. A radical mastoidectomy is performed to expose the fallopian canal thereafter. A groove is then created in the anterior epitympanum between the geniculate ganglion and the roof of the zygoma to translocate the CN VII within it. The carotid artery has to be exposed and can, if required and if the patient can sustain it, be ligated distal to the lingual branch. The sigmoid sinus may also require ligation cranial to the tumour that already occludes the sinus (e.g. glomus jugulare) and the temporomandibular joint is displaced anteriorly. A subtotal petrosectomy enables visualization of the carotid wall, the infralabyrinthine bone, the posterior fossa dura, and the inferior sigmoid sinus up to the jugular foramen. Following tumour dissection the Eustachian tube has to be occluded and the external auditory canal is blind sac closed. Dead space occlusion is then carried out with abdominal fat and temporalis muscle.

Type B: Lesions of the clivus, foramen magnum, sphenoid sinus, and epipharynx are preferably managed through *type B approaches*. After a subtotal temporal bone resection, the zygomatic arch, the temporalis muscle, and the facial nerve are reflected inferiorly. The temporomandibular joint is disarticulated and the mandibular condyle is resected to expose the foramina ovale and spinosum. The Eustachian tube, the middle meningeal, and the mandibular division of CN V are obliterated and the petrous carotid artery is skeletonized. Post-tumour resection, blind sac closure of the external auditory canal is performed and the temporalis muscle is reflected with the zygomatic arch, which is reattached with wires.

Type C: The type B approach might be extended to a *type C* approach in order to access the nasopharynx, pterygomaxillary fossa, and the parasellar region. Therefore, the orbital process together with the lateral orbital rim is folded inferiorly and the pterygoid process is resected. The approach furthermore entails the temporary section of some CN VII branches and eventually a V3 section. By lifting the middle cranial fossa dura exposure of the infracavernous carotid segments is achieved which allows the surgeon to approach lesions such as extensive juvenile nasopharyngeal angiofibromas or radiation failure squamous cell carcinomas.

Postoperative

Potential postoperative complications should be carefully considered and discussed with the patient and team prior to any surgical procedure. The surgical plan must be developed with potential complications in mind and should include methods to prevent such complications. The surgeon should rehearse plans personally and with the team and openly discuss methods of prevention. The surgeon should reflect on the surgery postoperatively and provide honest detailed descriptions and do a postoperative discussion with the surgical team.

Maintaining the safety of the patient and so the avoidance of complications should be a key surgical goal. For example, brain retraction is avoided at every opportunity by removing bone that obscures access and by achieving brain relaxation through adequate head-up positioning, hyperventilation, and hyperosmolar agents. We insert lumbar drains preoperatively to improve the surgical corridor and reduce brain retraction. CSF drainage during surgery helps avoid post-op CSF leaks in cases where trespassing of the meninges is planed or considered possible. To avoid postoperative keratitis and ulcers in cases with trigeminal and/or facial nerve involvement, a tarsorrhaphy is performed in selected cases prior to the onset of the major surgical intervention. All patients with periorbital work, trigeminal or facial nerve or greater superficial petrosal nerve involvement should get routine and frequent corneal lubricating ointments every 2–4 hours and ophthalmological assessment.

Perioperative antibiotics repeated every four to six hours intraoperatively associated with meticulous and careful tissue handling and closure help to overcome the risk of infections, especially when nasal air cells have been opened. We suggest continuing antibiotic prophylaxis until the lumbar drain and packing of the nasal air cells has been removed. Whenever possible we prefer to have the patient extubated before the transfer to the intensive care unit to allow for a neurological assessment as early as possible. This permits the team to immediately initialize necessary investigations and adequate treatment in the event of a neurological deficit.

Routine postoperative imaging is performed as a CT scan after a 6–12-hour period, frequently augmented by contrast enhanced scans. In selected cases and in postoperative complications other imaging modalities such as CTA, perfusion scans, or MR imaging are requested. In general MRI scans are of most value when performed in a remote fashion, in particular in benign extra-axial lesions and in cases where the resection cavity has been filled with autologous substances (e.g. fat). Air or blood may obscure tissue planes on MRI in the early postoperative period.

The postoperative assessments are completed at least twice a day by the neurosurgical team and other specialties as required. Nurses contact the patient at home after discharge from hospital. MRI assessment and postoperative clinical assessments are routinely done by all the teams who saw the patient preoperatively, so as to reassess the patient regularly as an outpatient.

Case example(s) and discussion of controversies

Case 1

A case of 31-year-old man with increased ocular pressure and restricted eye movements on the left. A CT head scan revealed a large lesion at the middle cranial fossa, extending into the left orbit with distinct bone remodelling (Fig. 21.1). The neurological exam showed a left proptosis, with his residual eye movement being superior 0%,

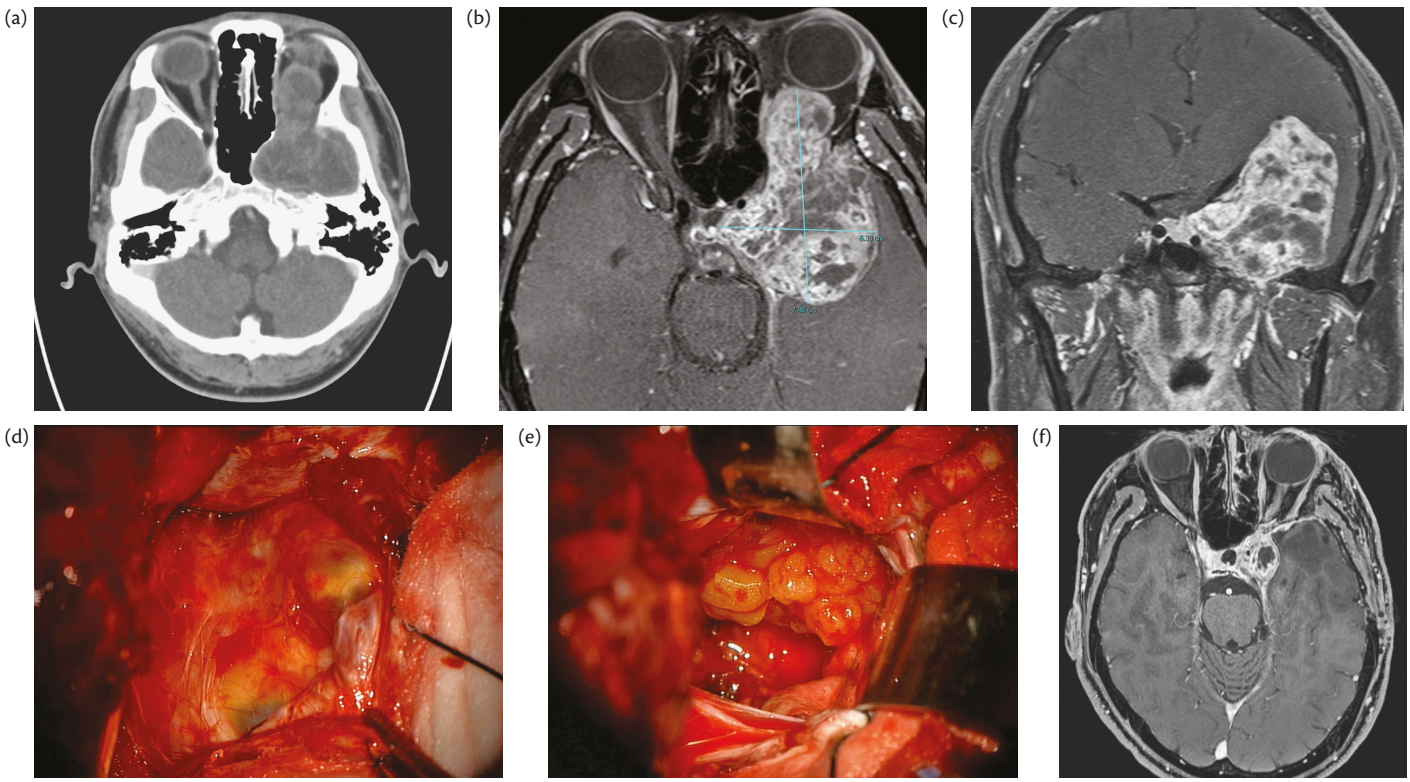

Fig. 21.1 (A) Axial CT head scan showing an extensive skull base lesion with distinct bone remodelling. (B) Axial T1 Gad-enhanced MRI showing the partially solid, partially cystic lesion growing into the orbit and pushing the cavernous sinus to the right.
(C) Coronal T1 Gad-enhanced MRI showing the left ICA dislocated inferomedial and the middle cerebral artery (MCA) pushed upwards.
(D) Intraoperative microscopic view showing the tumour underneath the inner wall of the dura at the cavernous sinus. (E) Intraoperative microscopic view of the fat-like looking tumour. (F) Six-month postsurgical axial T1 Gad-enhanced MRI with the fat graft inside the small residual lesion.

inferior 60%, lateral 80% and medial 90%. He had a mild afferent pupillary defect and a decreased sensation of about 10% in all trigeminal divisions. The MRI scan showed a large 7.4 × 6.6 × 5.3 cm, multicystic, partially solid, inhomogeneous contrast-enhancing lesion of the middle fossa, that was growing into the orbit and pushing down into the infratemporal fossa. It looked like it had grown below the superior rectus muscle, suggesting that it might have arisen from the superior division of CN V3.

We decided to perform a left frontotemporal craniotomy with left orbitozygomatic osteotomy and left subtemporal decompressive craniectomy as described earlier. The procedure was performed after insertion of a lumbar drain, under continuous neurophysiological monitoring with neuronavigation and ultrasound. The second cut of the orbital osteotomy was facilitated due to the widened superior orbital fissure (SOF). After the approach was completed, we could appreciate the bone remodelling of the orbit, the SOF, and the lesser sphenoid wing. We started the extradural dissection to the middle fossa, sacrificing the middle meningeal artery. We performed an interdural approach to the lateral wall of the cavernous sinus starting at the SOF and taking it to the foramen rotundum and then posteriorly, carefully separating the outer dural layer from the inner perineurial layer. We incised the perineurium parallel to the fibres of V2 and exposed the bright yellow looking tumour. The partially suckable tumour was removed as piecemeal. At the anterior part of the cavernous sinus the tumour was stuck to several fibres, which is why we left a small piece here, the posterior part as well as the intraorbital part was good to resect. The resection cavity was finally checked with the ultrasound and the endoscope, confirming extensive tumour resection. The reconstruction was performed with a duraplasty, including fat graft at the orbit and at the left cavernous sinus region, and titanium plate cranioplasty. The final pathology revealed a schwannoma. At 18 months this patient is doing very well, has a Karnofsky score of 100, and without deficit or evidence of recurrence.

Case 2

The second case is a 71-year-old man who had a 6-month history of short-term memory loss, bradyphrenia, and irascible personality change, as well as progressive lethargy. In addition to his cognitive and olfactory deficits, he had normal CN II through XII and no papilledema. Imaging revealed a contrast-enhancing lesion of the anterior skull base suspicious for an olfactory groove meningioma with a small amount of transcranial involvement (Fig. 21.2). The decision was made for an open craniotomy with microsurgical tumour removal. Although the tumour origin is at the midline, due to the size of the lesion, the wide based anterior skull base attachment, and the lateral extension beyond the midpupillary line, in our opinion this lesion would be better and more feasibly managed through a transcranial orbitofrontal approach.

After bicoronal skin incision, a large scalp flap with preservation of the pericranium was carried out. The bifrontal craniotomy was then followed by an orbital cranial osteotomy ('orbital bar removal') to achieve the lowest possible anterior skull base access thus minimizing the need for brain retraction. As the tumour extended more

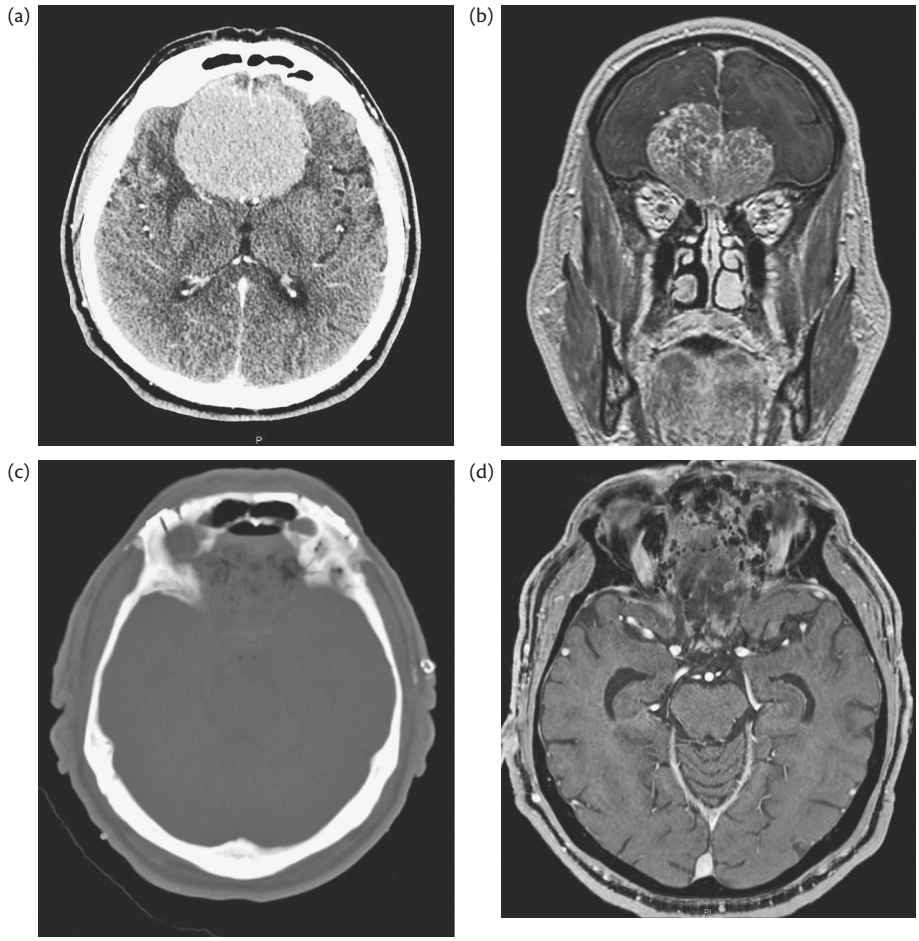

Fig. 21.2 (A) Axial CT head scan showing an anterior skull base lesion homogenously contrast-enhancing with displacement of the bilateral A2 segment posteriorly. (B) Coronal T1 Gad-enhanced MRI showing the lesion attached to the cribriform plate. (C) Postsurgical axial CT bone window showing the skull base reconstruction. Note the low craniotomy at the anterior skull base with removal of the orbital bar. (D) Six-months postsurgical axial T1 Gad-enhanced MRI scan showing complete tumour removal, note the extradural air bubbles at the level of the ethmoid air cells without evidence of residual tumour.

to the right, an orbital osteotomy with removal of the entire orbital roof was performed on the right, whereas the left orbit was only partially exposed. The tumour removal was initiated by an extradural devascularization of the tumour supplying vessels (e.g. anterior and posterior ethmoidal branches), followed by the intradural tumour resection without the need for any brain retraction. We performed a duraplasty with the well-preserved pericranium and sealed the anterior skull base with bone wax and tissue glue. Pathology confirmed a WHO grade 1 meningioma.

This case could have been done by several different approaches, including unilateral and bilateral ones. A minicraniotomy approach would be possible but given the deep cribriform plates and bifrontal exposure as well as the height of the exposure and the potential need to have a pericranial flap reconstruction, we did not choose it as ideal. A true pterional approach would be possible but certainly limited and with few options for skull base reconstruction and therefore a potentially higher risk of residual tumour. A unilateral subfrontal approach using a low craniotomy with or without an orbital cranial osteotomy are also both possible but if there is a need for a bilateral repair of the skull base because of tumour extension, a pericranial flap repair might be limited, particularly if the frontal sinuses are large. The interhemispheric approach with preservation of the pericranial flap could easily access the lesion but dissection of the interhemispheric fissure is likely unnecessary here and would not add much to the exposure, resection, or reconstruction. An EEA is possible for the central part of the lesion but would not be as efficient for complete resection, particularly when this is so easily accessed via an orbital cranial approach without brain retraction. It would also have a large skull base defect that would not be as easily repaired as the pericranial flap. It might also be complicated by significant bleeding and more chance of residual tumour. The bilateral subfrontal-orbitocranial approach we utilized allowed easy and efficient access to, and resection of, all the tumour, involved dura, and bone with no brain retraction and a complete vascularized repair of the skull base defect.

Case 3

A 62-year-old female underwent an MRI head scan five years prior to our visit, due to worsening of her migraines. At that time, a small lesion in the midline of the anterior fossa was identified. Regular follow-up throughout the following years displayed continuous growth of the extra-axial, contrast-enhancing, dural-based lesion

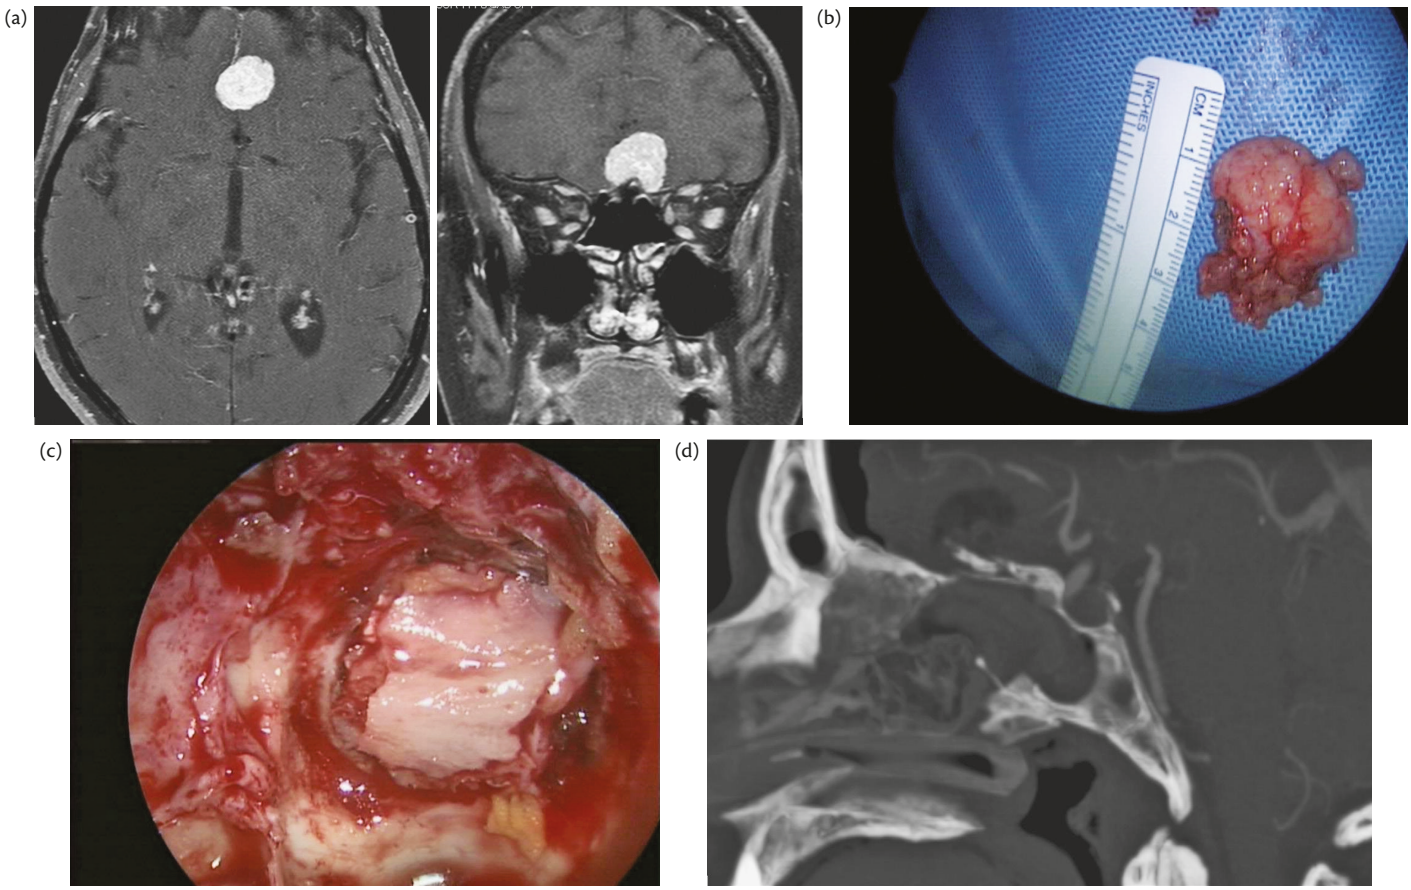

Fig. 21.3 (A) Axial and coronal T1 Gad-enhanced MRI showing the lesion attached to the cribriform plate. (B) Intraoperative picture showing the size of the tumour. (C) Intraoperative microscopic view of the skull base reconstruction before placement of the mucosal flap. (D) Postsurgical sagittal CT showing the anterior skull base reconstruction.

(Fig. 21.3). Eventually, after extensive discussion of all treatment options including observation, gamma knife, and fractionated radiotherapy, the patient requested to undergo surgery for resection of the anterior fossa lesion. We felt the lesion, most likely a cribriform plate meningioma, would be best approached using an extended EEA to resect the tumour. After placing a lumbar drain, the drain was clamped, the patient was positioned, and the EEA was performed. A full sphenoidotomy including exposure of the planum sphenoidale, and the cribriform plate was fashioned under assistance of neuronavigation and endoscopes up to 70 degree. The anterior fossa bone was drilled just below the tumour, and at the level of the dura, a piece of bone was mobilized that showed a punctuate hyperostosis, suggesting it was the origin of the tumour. After confirming sufficient bony opening, the dura was bipolared and incised. Initially internal debulking was carried out and then we gradually dissected around the lesion in the arachnoid cleavage plane. Once the lesion and critical structures were identified and protected, the tumour was delivered from the frontal lobe, leaving the arachnoid intact. The dural edges were bipolared. The right olfactory tract was entirely intact, the left although distorted was still in continuity. The skull base reconstruction was then initiated by opening of the lumbar drain, followed by placing small fat pieces around the dural opening to support the fascia lata graft, which was subsequently placed overlapping and under the edges of the dura. Additionally, the anterior skull base was reconstructed with two small bone pieces, before tissue glue was applied to adhere the vascularized septal mucosal flap. The postsurgical course was unremarkable and pathology confirmed a WHO grade 1 meningioma. At 18 months, the patient remains well with intact right sided olfaction, a Karnofsky score of 100 and no tumour recurrence.

Case 4

A 56-year-old female presented with a Bell's palsy, when a CT head scan incidentally revealed an anterior fossa skull base lesion. Initially the lesion was monitored, as the lesion was felt to be asymptomatic, the MRI scan showed a dural-based contrast-enhancing lesion most consistent with a cribriform plate meningioma, and the patient recovered from the Bell's palsy. However, the tumour showed progressive growth up to the size of 4.0 × 2.5 × 3.5 cm (Fig. 21.4).

After discussion of all treatment options the patient requested to undergo surgical removal of the tumour. Because of the size, but much more due to the superior extent and an anterior bend of the lesion we felt a craniotomy would be the more definitive, efficient, and safer approach.

We placed a lumbar drain; we did a bicoronal skin incision and turned the scalp flap together with the periosteum. A left greater than right frontal craniotomy just across the midline was performed. A frontal sinus mucosa exenteration was necessary. An orbitocranial osteotomy and orbitotomy was performed to achieve the lowest possible anterior skull base access thus minimizing the need for brain

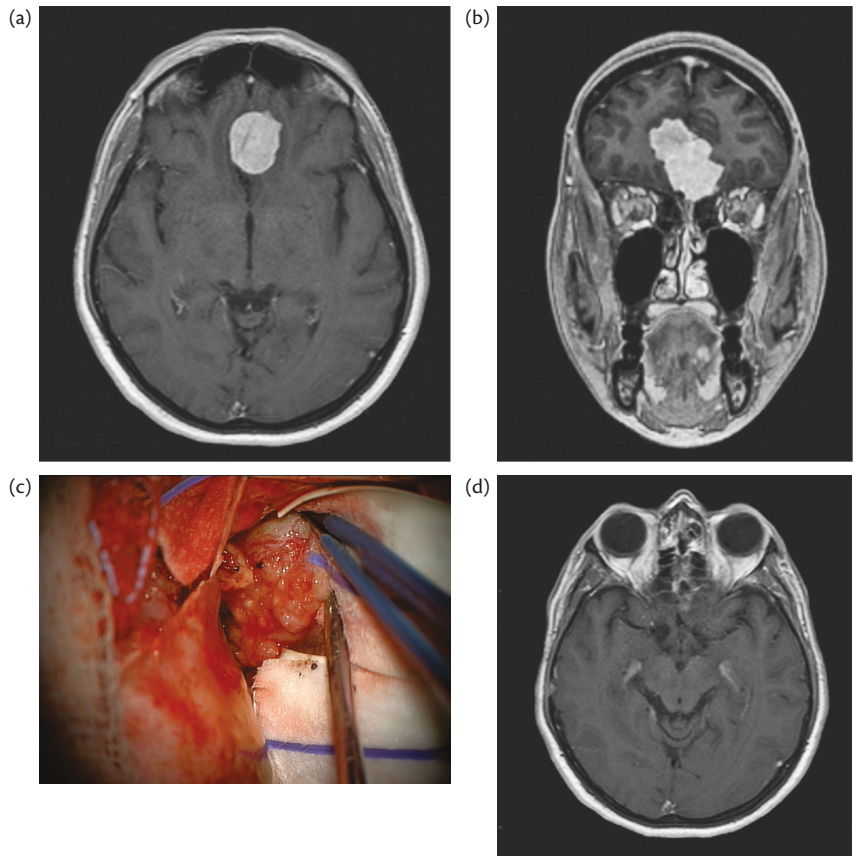

Fig. 21.4 (A) Axial and (B) coronal T1 Gad-enhanced MRI showing a large, multilobulated, anterior fossa lesion originating from the cribriform plate. (C) Intraoperative anterolateral, subfrontal microscopic view of the firm tumour. (D) Postsurgical axial T1 Gad-enhanced MRI showing complete tumour resection.

retraction. The orbital osteotomy with removal of the entire orbital roof was performed on the left, whereas the right orbit was only partially exposed. The midline osteotomy was taken as low as the nasofrontal suture. We took out the crista gali and bipolared the base of the SSS. The tumour removal was initiated by an extradural devascularization of the tumour supplying vessels (e.g. anterior and posterior ethmoidal branches), followed by an intradural tumour resection. We could see the olfactory tract, which was totally infiltrated and distorted by the tumour. The tumour was initially debulked from within and then it was dissected in the arachnoid cleavage plane. The origin was at the posterior aspect of the cribriform plate and the anterior planum sphenoidale, where it had gone through the dura with an area of hyperostosis. The tumour was excised with the involved lower falx, the hyperostotic origin was removed, and the blood supply as well as the anterior skull base was bipolared with removal of all involved bone and dura. We performed a fascia lata and fat graft duraplasty and sealed the anterior skull base with bone wax and tissue glue, which was followed by a cranioplasty. The procedure was performed under ultrasound and neuronavigation guidance, the pathology revealed a WHO grade 1 meningioma. The patient remains well with intact cognition, a Karnofsky score of 100, anosmic but without recurrence after 20 months of follow-up.

Cases 3 and 4 are presented to allow discussion of the capabilities and limitations of EEA. Skull base endoscopy offers various approaches that must be adapted to different kinds of lesions. One major limitation of EEA are lesions with significant lateral extent. Typically the laminae papyracea limits the lateral exposure of the anterior fossa in most cases but in a case where the optic nerve can be mobilized, this may not remain limiting. Although angled endoscopes allow excellent lateral or anterior visualization, instrumentation to operate in extreme positions endoscopically is sometimes limiting and craniotomy becomes much more efficient and complete in terms of tumour resection. Beyond that, the length of available instruments sometimes limits the removal of lesions with broad superior extension. Especially in firm and partially calcified lesions, or highly vascular lesions, such as meningiomas, one cannot expect the lesion to descend after partial debulking from inside the tumour. However, this can partially be provoked by applying a mild Valsalva manoeuvre.

A potential challenge in endoscopic approaches, particularly the ones requiring repeat surgery and those in a radiated bed, is the ability to safely prevent meningitis by adequate reconstruction. In these cases, this was not an issue, but reconstruction should be considered in decision-making in every case. As opposed to large skull base defects the sealing of smaller defects is much easier to manage, especially when applying all the aforementioned means of a layer-by-layer skull base reconstruction. Although we felt that that the lateral extension of the cribriform plate meningioma in case 4 would be amenable through an EEA, we eventually decided to perform a craniotomy because of the extensive superior extension of the lesion.

The outcome was excellent in this case. Ultimately, surgeons should use those approaches with which they can achieve the best overall result for their patient.

Sporadic vestibular schwannoma

Sporadic vestibular schwannoma (VS) is the commonest tumour of the cerebellopontine angle and comprise 6–8% of all intracranial tumours. The inferior branch of the vestibular nerve of the eighth cranial nerve is the origin in approximately 65–75% of all patients. Some authors report it is as high as 90%, with the superior branch in the remainder; cochlear nerve origin is rare (Komatsuzaki and Tsunoda, 2001; Khrais et al., 2008). Vestibular schwannomas were originally thought to originate at the of oligodendrocyte-Schwann cell junction between the central and peripheral nervous system but current data instead suggest an association with the sensory ganglia of the vestibular nerve in the internal auditory canal (Xenellis and Linthicum, 2003; Roosli et al., 2012; Tryggvason et al., 2012).

Historically, only large, life-threatening tumours were diagnosed and treated. In the 1920s, surgical mortality associated with VS removal exceeded 70%. Historical neurosurgical leaders achieved paradigmatic improvements of treatment. Using intracapsular removal Cushing decreased surgical mortality to 30% (Cushing, 1917), but high mortality from recurrent tumours became a problem (Olivecrona, 1950); Dandy again performed radical surgery, at a cost of a higher risk of facial nerve sacrifice (Dandy, 1934). Olivecrona pioneered radical surgery with facial nerve preservation (Olivecrona, 1950). The next developments were microsurgery by House and radiosurgery made possible by Leksell (Norén et al., 1993). Today, mortality from treatment is a rarity. Treatment options include wait and scan, microsurgery, radiosurgery, and radiotherapy. Individual therapeutic choices are made depending on tumour size, symptomatology and expected natural history (**Fig. 22.1**).

Epidemiology of sporadic vestibular schwannomas

A wider indication for work-up and better access to MRI imaging has led to an increased detection of schwannomas. Stangerup and coworkers found a linear relationship between the number of MRI scanners and incidence of vestibular schwannomas in Denmark (Stangerup et al., 2004). In the United States, vestibular schwannomas were diagnosed in 10/million/year in 1991 (National Institutes of Health, 1991). Population studies in autopsy material, however, detected a prevalence ranging between 0.8 and 2.4% which indicated that most schwannomas went undiagnosed (reviewed in Schmidt et al., 2012).

The group of Tos and Thomsen reported a Danish incidence of 3.1/million/year in 1976 which increased to 22.8 in 2004 and fell back to 19.8 in 2008 (Stangerup et al., 2010). Recently, the incidences were estimated to be 12 and 14 cases per million population for the United States (Babu et al., 2013) and United Kingdom (Evans et al., 2005), respectively. The latest Danish incidence estimate was 35/million/year (Sass et al., 2018). The differences between the countries may well reflect local diagnostic routines and registration, but biological differences may exist between populations; American data show a dominance for Caucasians among those registered in The Surveillance Epidemiology and End Results (SEER) database (Gal et al., 2010) (**Fig. 22.2**).

The commonest age at diagnosis has remained in the interval 50–64 years, and the gender distribution is equal. The mean size of schwannomas has decreased and hearing is better at diagnosis in recent decades compared to the 1980s (Gal et al., 2010; Stangerup et al., 2010).

Aetiology, ionizing radiation, and cellular phones.

Schwannomas are benign tumours with WHO grade 1 (**Fig. 22.3**). Malignant nerve sheath tumours are rare, but comprise an important differential diagnosis to all radiologically diagnosed schwannomas. They can be suspected from aggressive clinical behaviour and require histopathological evaluation for diagnosis. The genetical profile of schwannomas has been studied widely. Mutations are usually found in the neurofibromin (*NF2*) gene on chromosome 22q12.2 which is biallelically inactivated in most sporadic vestibular schwannomas as in neurofibromatosis type-2 associated schwannomas. The mutations in sporadic tumours are usually small deletions. The gene product is a 590 amino acid protein named merlin (schwannomin) (Lee et al., 2012; Lassaletta et al., 2013), which is a tumour suppressor gene. Merlin suppresses a large number of different intracellular growth-promoting signals which can explain a tumorigenic effect from a single gene defect (**Fig. 22.4**). Between 5 and 10% of patients with vestibular schwannomas have additions on 9q34 or 17q. Angiogenesis is indispensable for tumour growth, but the relationship between angiogenetic factors and tumour growth is unclear. Small studies have, however, detected some improvement and retarded schwannoma growth with the VEGF-inhibitor bevacizumab.

The only well-established risk factor for sporadic vestibular schwannoma is ionizing radiation (Ron et al., 1988; Preston et al.,

2002; Schneider et al., 2008), although other environmental and biological factors such as radiofrequency fields, noise, smoking, chemicals, socioeconomic status, parity, and hormone replacement have been studied. Unexpectedly, income and education were associated with tumour diagnoses in two studies (Inskip et al., 2003; Schuz et al., 2010). Parity and hormone replacement therapy were also associated with increased risk of tumours (Schoemaker et al., 2007; Benson et al., 2010b), while current smoking appeared to protect from schwannomas in two case-control and one cohort study (Schoemaker et al., 2007; Benson et al., 2010a; Palmisano et al., 2012). Noise was reported as a causal factor in 1985 (Preston-Martin et al., 1989), but could not be corroborated (Edwards et al., 2006; Fisher et al., 2014). Chemical exposure is difficult to evaluate retrospectively. Asbestos and toluene show conflicting findings but the well-known carcinogen benzene was repeatedly reported to have an association with schwannomas (Pettersson et al., 2014).

Radiofrequency fields and mobile phones fall into a controversial area (Pettersson et al., 2014). The case-control studies conducted by Hardell and colleagues suggested a dose dependent correlation between mobile phone use and risk of vestibular schwannomas (Hardell et al., 1999; Hardell et al., 2005; Hardell et al., 2013). In contrast, larger studies and studies with prospective designs have failed to corroborate any associations between mobile phone use and vestibular schwannomas. The INTERPHONE case-control study (Interphone Study Group, 2011), which is the largest study on mobile phones and vestibular schwannoma still in 2016, found an odds ratio of 0.85 (95% CI: 0.69–1.04) for regular use of mobile phones and 0.76 (95% CI: 0.52–1.11) for ≥ 10 years of mobile phone use. A cohort study conducted in Denmark found a relative risk of 0.87 (95% CI: 0.52–1.46) for mobile phone subscribers of 11 years or more (Schuz et al., 2011). A recently updated UK cohort study (Benson et al., 2013) found a relative risk for any use of mobile phones slightly above one (RR = 1.19, 95% CI: 0.81–1.75), a similar estimate for 10 years' use or longer (RR = 1.17, 95% CI: 0.60–2.27), and the highest risk estimate for 5–9 years of use (RR = 1.46 (95% CI: 0.94–2.27), which agrees with the latest Swedish findings (Pettersson et al., 2014). The latter study also scrutinized laterality of tumours and preferred side of phone use without finding any association above chance. Furthermore, experimental carcinogenic effects from radiofrequency exposures below guideline limits do not occur (AGNIR, 2012). Taken together, there is no support for a strong etiological relationship between cellular phones and vestibular schwannomas.

Natural history

It is no longer believed that all patients with newly diagnosed tumours benefit from surgery. Subsequently, data on natural history during MRI follow-up has become available. Slow or no growth was detected in many patients. A meta-analysis (Yoshimoto, 2005) of 26 studies and 1340 patients showed growth in 46% (95% CI 43–48) and regression in 8% (95%CI 6–10) during a mean follow-up period of 38 months. The mean annual growth rate was 1.2 mm in growing tumours. Many of the progressing tumours grew very slowly and only 40% were treated. Natural history was mostly studied in smaller tumours selected for conservative treatment, but a number of patients with larger tumours were also included; many of these also regressed in older patients. Hence, initial conservative management is possible, preferably in older patients with few symptoms in spite of large size tumours.

Thirty-eight months is a short follow-up time for benign tumours, but studies with longer follow-up are available. Stangerup and Caye-Thomasen (2012) found 29% growth rate and 1% decrease during long-term follow-up of intraextrameatal tumours less than 20 mm (Fig. 22.5). For intracanalicular tumours, Kirchmann et al. (2017) found tumour growth in 37%, 61% of which grew into the posterior fossa, after 9.5 years of follow-up. Neither Stangerup nor Kirchmann found tumour progression after the fifth year of follow-up.

Treatment goals

The slow growth of most vestibular schwannomas and availability of radiological surveillance allows safe management without extensive surgery. The number of surgeries for vestibular schwannomas has decreased. Lately, 17% of registered American patients were followed with scanning and 21% were treated with radiosurgery (Gal

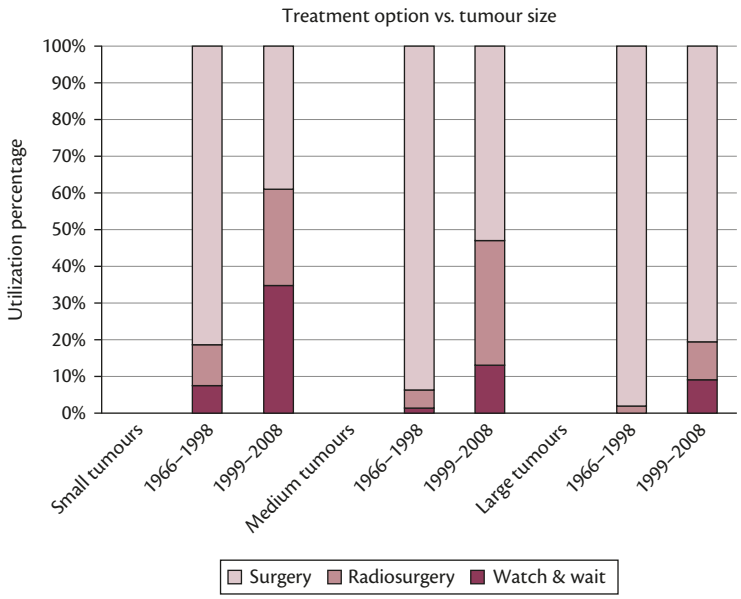

Fig. 22.6 The changing management of vestibular schwannomas. In this figure tumour size is defined as small (<1.5 cm), medium (1.5–2.5 cm), and large (>2.5 cm).

Reproduced with permission from Jaymin Patel, Rohit Vasan, Harry van Loveren, et al, The changing face of acoustic neuroma management in the USA: Analysis of the 1998 and 2008 patient surveys from the acoustic neuroma association, *British Journal of Neurosurgery*, Volume 28, Issue 1, 2014 © The Neurosurgical Foundation, reprinted by permission of Taylor & Francis Ltd, www.tandfonline.com on behalf of The Neurosurgical Foundation.

et al., 2010). The therapeutic goals have changed from radical tumour removal to tumour control and preservation of neurological function (Kemink et al., 1991; Park et al., 2006; Seol et al., 2006). Many small tumours are treated by radiosurgery or followed radiologically to select the fast-growing lesions for treatment. Larger tumours are more often treated with subtotal or partial surgery (Fig. 22.6). Frequently, one goal of surgery is to tailor a residual for gamma knife radiosurgery. Subtotal removal decreases the need to dissect already compromised nerves from the tumour-nerve interface and appears to correlate with better facial nerve outcome (Park et al., 2006; Schwartz et al., 2013). Hearing preservation of larger tumours is also more frequent with subtotal removal (Iwai et al., 2015). Although the proportion of morbidity in all patients with known vestibular schwannomas may have decreased, the actual number of complications has increased (Patel et al., 2013). The paradoxical finding reflects a different case-mix with an increased proportion of large tumours, but also decreased surgical experience. A continued primary focus on neurological outcomes and surgical techniques are important (Rahimpour et al., 2016); an increased proportion of non-radical operations will ensue.

Growth of residual schwannomas

A lower propensity towards radical resection translates into higher frequencies of tumour recurrence. The relationship between extent of removal and risk of recurrence probably depends on surgical techniques, tumour biology, and selection of cases. In addition, follow-up strategies may differ between surgeons and centres. Bloch et al. described 3% recurrences within five years of near total removal and 32% in subtotal (Bloch et al., 2004); Schwartz et al found recurrence rates of 21–22% at a mean follow-up of 3.7–3.9 years (Schwartz et al., 2013). Several later patient series fail to corroborate such a difference between near total and subtotal. Instead they describe 5-year recurrence rates of 7–9% following near total or subtotal removal without a major difference between near- and subtotal (Sughrue et al., 2011; Chen et al., 2014b; Syed et al., 2017) (Fig. 22.7). Retrospective recurrence data are difficult to evaluate also because radiologically demonstrated progression does not necessarily imply a treatment failure to the extent that additional therapy was indicated; in most series only approximately half of all patients with demonstrated regrowth have received additional treatment (Sughrue et al., 2011; Syed et al., 2017). All residuals are not biologically equal. An isolated residual on the brainstem has a lower supply of energy and nourishment than a well vascularized residual in the internal

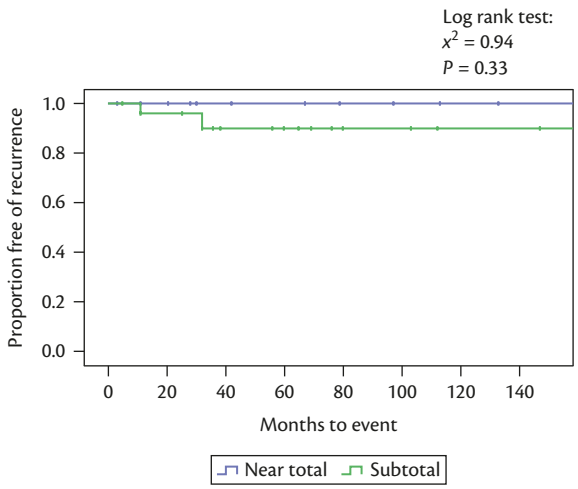

Fig. 22.7 Recurrence following subtotal and near total resection of vestibular schwannoma.

Reproduced with permission from M.I. Syed et al., The behaviour of residual tumour after the intentional incomplete excision of a vestibular schwannoma: is it such a bad thing to leave some behind?, *Clinical Otolaryngology*, Volume 42, Copyright © 2016 John Wiley and Sons.

acoustic meatus, which can influence the potential to recur. In small incidental schwannomas, growth is usually detectable within 3–5 years of conservative treatment (Stangerup and Caye-Thomasen, 2012), but the biology of inert incidental tumours is probably different from residuals of once large lesions. Actual long-term data are lacking and we do not know how recurrence rates will increase with even longer follow-up.

Primary gamma knife radiosurgery and tumour control

Radiosurgery utilizes sharp dose gradients achieved with multiple focused beams, which is geometrically possible only with small treatment volumes. Hence, small tumours are the commonest indication. Initially, tumour shrinkage was the expected treatment effect which was seen in most patients. The first nine cases were treated between 1969 and 1974. In 1993 Norén et al. reported the earliest series of 254 patients (Norén et al., 1993). He found tumour shrinkage in 55%, stable tumours in 33% and 77% hearing preservation, but high incidences of mostly temporary facial and trigeminal nerve deficits. Subsequently, the radiation doses were decreased without detectable loss of tumour control while radiation complications were minimized. The goal of treatment shifted from shrinkage to 'control', which is defined as absence of progression during long-term follow-up after more than 1–2 years. Importantly, successful treatment includes temporary post-treatment tumour swelling in up to 30% of radiosurgically treated patients. Recently patients received marginal doses of approximately 13 Gy and were reported to have tumour control of 97% with a mean follow-up of 6 years (Boari et al., 2014), 92% at a mean follow-up of 9 years (54) and also 92% with a 12.5-year mean (10-year minimum) follow-up (Hasegawa et al., 2013). Régis et al. use 12 Gy to the margin with a reduction to 11 if hearing is serviceable (Régis et al., 2013a). Long-term control rates of 98–99% were found with early retreatment of suspected failures or selection of only Koos grade 1 tumours (Régis et al., 2013a). Koos grading is described in Table 22.1. The control rates in case series do, however, not necessarily reflect a treatment effect. The control rates can be adjusted to express the influence of radiosurgery on control, since natural history does not entail progression for the majority of tumours. Miller et al. (2014) estimated the actual radiosurgically achieved 10-year control rate to 78–87%. It is also discussed whether radiosurgical control differs between tumours that were stable and tumours that grew before treatment. Investigators who have studied the cohorts separately do, however, not find any influence by previous growth rates on long-term tumour control (Meijer et al., 2008; Niu et al., 2014; Wangerid et al., 2014) (Fig. 22.8). Fractionated radiation has been described as a successful for vestibular schwannomas, but selection of cases and limited follow-up makes conclusions regarding long-term efficacy difficult (Combs et al., 2005; Choy et al., 2013; Litre et al., 2013).

Table 22.1 Koos grading scale

Grade	Description
1	Tumour only involves internal auditory canal
2	Tumour extends into cerebellopontine angle but does not encroach onto brainstem
3	Tumour fills the entire cerebellopontine angle
4	Tumour displaces brainstem and adjacent cranial nerves

Source data from Koos, W. T., Day, J., Matula, C., & Levy, D. I. (1998). Neurotopographic considerations in the microsurgical treatment of small acoustic neurinomas, *Journal of Neurosurgery*, 88(3), 506–512.

Combined micro- and radiosurgery, salvage radiosurgery, and tumour control

The rationale for accepting an up to 30% risk of recurrence, after subtotal resection, includes the availability of subsequent radiosurgery and the belief that subsequent radiosurgery provides tumour control. Radiosurgery of a residual, stable, or growing, lead to tumour control in 11/11 treated patients treated by Hori (Hori and Maruyama, 2013) while others have reported control rates around 90%, similar to long-term data on primarily treated schwannomas. Van de Langenberg et al. (2011) reported tumour control 90% after less than 3 years follow-up of intentional subtotal surgery of large schwannomas followed by gamma knife radiosurgery (Rowe et al., 2007) and Iwai et al. (2015) found 10-year tumour control of 86% with 95% House-Brackman 1–2 and 42% hearing preservation. With previously operated schwannomas, larger size (>6 cm^3) was a risk factor for treatment failure which required salvage surgery in a few patients. Ionizing radiation is an established risk factor for tumorigenesis and a number of case reports have described rapidly growing tumours and even gliomas in patients treated by radiosurgery. The absolute risk is, however, very low. Reviews of treated patients and reviews of malignant schwannomas do not support malignant transformation or induction of secondary malignancies at any detectable rate (Demetriades et al., 2010). Residual and recurrent tumours were treated by radiosurgery or microsurgery (Jeltema et al., 2015; Nonaka et al., 2016; Samii et al., 2016b; Wise et al., 2016; Huang et al., 2017).

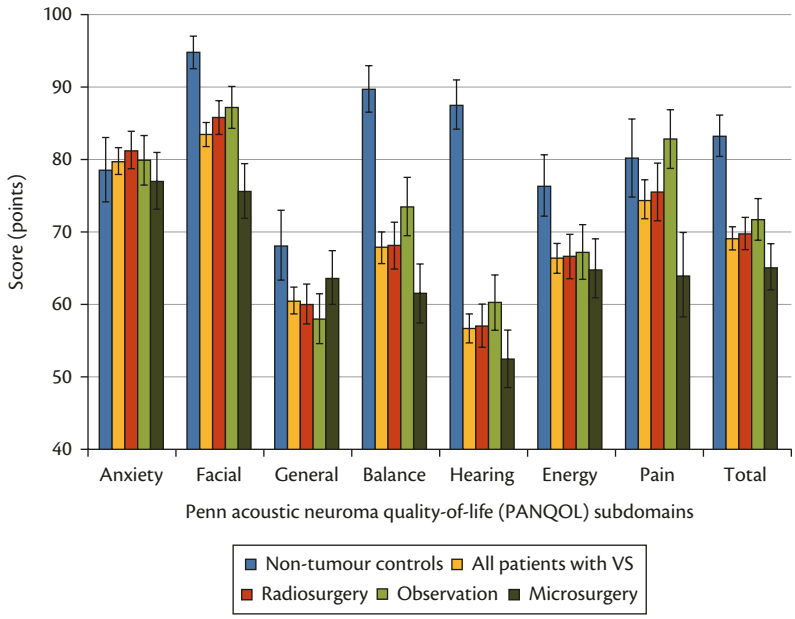

Fig. 22.9 Long-term health-related quality of life using disease specific outcomes in vestibular schwannoma.
Carlson, M., Tveiten, O., and Driscoll, C., et al, Long-term quality of life in patients with vestibular schwannoma: an international multicenter cross-sectional study comparing microsurgery, stereotactic radiosurgery, observation, and nontumor controls, *Journal of Neurosurgery*, Vol. 122, No. 4 (2015) with permission from JNS Group.

Symptoms and quality of life

At diagnosis, most patients have one or more of the typical components of the triad of: hearing deficit, vertigo, and tinnitus. Harun et al. reported the respective frequencies at presentation at 93%, 67%, and 84% in a consecutive series of 1200 patients (Harun et al., 2012). The facial and trigeminal nerves may also be affected, but are more frequently affected by treatment; headache is a possible symptom before treatment but can remain or occur after surgery. Neurological symptoms are central for subjective discomfort and suffering, since only a small fraction of patients are diagnosed with potentially life-threatening tumours. Patients with vestibular schwannomas do report a reduced quality of life compared to a reference population (Harun et al., 2012). Preservation or regained quality of life is the primary management objective which may be difficult to achieve. Broomfield and O'Donoghue recently (2016) surveyed 568 members of members of the British Acoustic Neuroma Association regarding quality of life; they reported that their schwannomas had changed overall quality of life for better in 18%, a little worse in 38% and a lot worse in 19%. 'A little worse' was distributed equally among treated and conservatively followed patients while surgical treatment dominated among those reporting 'a lot worse'. In various studies 61–76% of patients have returned to work 6–12 months after treatment, but the proportions appear to be similar regardless of surgical approach or radiosurgery. Quality of life appears to be slightly better in patients followed conservatively than operated, and appears to be slightly better following radiosurgery than microsurgery (Carlson, Tveiten, et al., 2015; Golfinos et al., 2016). Taken together, treatment effects and differences between treatments are difficult to evaluate. Quality of life is a treacherous term. Physicians care more about health-associated issues, especially those that are affected by the specific disease and its treatment. The commonest instrument, SF-36, actually measures health-associated factors rather than actual quality of life. It is possible to have a low quality of life in spite of good health and minimal treatment morbidity and vice versa. Our reasonable priority is the specific symptoms of disease and their relative health impact (Fig. 22.9). Even so, the topic is complex and influenced by individual coping, permanence of deficit, duration, expectations, and how caregivers actually deal with different symptoms. Textbook knowledge comprises concern for facial nerve function, tinnitus, and unilateral loss of hearing but the prospective studies of Carlson and coworkers instead described dizziness and headaches as the strongest predictors of long-term reduced quality of life (Carlson et al., 2015a; Carlson et al., 2015b). It is possible that comparison of ever-present deficits such as hearing loss and facial nerve function to periodic disabilities such as dizziness and headaches is difficult. Constant symptoms may be ranked as less bothersome as they are predictable and can be adjusted to. It is also possible that the awareness among caregivers is better and that these deficits are dealt with consciously before treatment, avoided during treatment, and rehabilitated after.

Hearing deficit and worsening of hearing with wait and scan, micro-, or radiosurgery

Preserved hearing and useful hearing are usually defined as a pure-tone audiogram (PTA)with less than 50 dB loss and a Speech Discrimination Score (SDS) greater than 50% according to American Association of Otolaryngology-Head and Neck Surgery Classes (AAO-HNS) A or B, and Gardner-Robertson classes I or II. Gardner-Robertson classification is described in Chapter 25. At inclusion in a prospective study on 538 patients, 11% had class A and 12% class B hearing (Tveiten et al., 2015). A subgroup of 128 patients was followed with observation only for a mean of 7 years. Class A hearing decreased from 32% to 22, class B from 32% to 23, class C increased from 8 to 11%, and class D from 30 to 44%. Sughrue found 50% loss of functional hearing during 26–52 months of follow-up (Sughrue et al., 2010) while Stangerup et al. (2008) followed 334 patients with good hearing and speech discrimination more than 70%, suitable for 'wait and scan', for ten years. In those patients,

hearing was preserved in only 31%. However, patients with perfect discrimination (100%) at inclusion had an 88% preservation rate. Intracanalicular schwannomas comprise a subgroup with very small tumours. Without treatment, audiometrically measured serviceable hearing was preserved for a mean of 9.5 years in 34% and speech discrimination is preserved in 58% (Kirchmann et al., 2017). During a mean follow-up of 44 months, Régis (Régis et al., 2013a) found more than 10 dB hearing loss in 38% including 5% who became deaf. The hearing outcomes without treatment are dismal for most patients.

With treatment, microsurgery of cases selected for surgery showed hearing preservation of serviceable hearing in 8–51% of retrospective series (reviewed in Samii et al., 2006; Tveiten et al., 2015) and 14% in the microsurgical subgroup comprising 139 of 539 patients in a prospective cohort study (Tveiten et al., 2015). Microsurgical series have a wide range of outcomes as they reflect different selection of patients and different timing of surgery. Most importantly, however, individual surgical skill and experience in patient selection are crucial for microsurgical results and experienced surgeons consistently report predictable good hearing in selected patients (Samii et al., 2006; Rahimpour et al., 2016). Depending on patient selection, series show 10–70% hearing preservation. Following initially favourable hearing outcomes, however, 15–20% of patients may experience further loss of initially preserved hearing (Wang et al., 2013).

After radiosurgery, further decline of hearing is to be expected with 5.9 dB/year during the two first years and 1.9 dB/year thereafter (Yomo et al., 2012) and sudden deafness may occur. Carlson (Carlson et al., 2013) described 23% preservation of serviceable hearing after 10 years, which is similar to the natural history. Comparative data on a potential benefit of radiosurgery are conflicting. Régis et al. found 60% preserved hearing with radiosurgery compared to 14% in untreated controls after 5 years in an open, prospective comparative study (Régis et al., 2013b) and Boari claimed especially good results in young patients with excellent hearing pretreatment (Boari et al., 2014). In contrast, Tveiten et al. failed to detect a benefit in a two-centre prospective trial. Their radiosurgical cohort comprised 240 patients followed for 7 years; class A decreased from 25 to 7%, class 2 from 22 to 12%, class C from 12 to 11 and class D increased from 41% to 70. Significant difference of hearing preservation between radiosurgery and natural history could not be asserted and outcomes actually appeared worse after radiosurgery (Tveiten et al., 2015). Two ongoing randomized controlled studies comparing initial radiosurgery and initial conservative treatment will hopefully give a more confident answer on a potential hearing preserving effect of radiosurgery (https://www.clinicaltrials.gov: NCT 02249572 and NCT 01938677).

Tinnitus

Tinnitus is speculated to be caused by ephaptic transmission, cochlear dysfunction, loss of efferent vestibular fibres and cortical reorganization. Cortical reorganization is one reason to why sectioning of a cochlear nerve may fail to cure tinnitus. Tinnitus usually has a high frequency pitch and is reported in 70–80% of all patients at diagnosis (Baguley et al., 2006; Tveiten et al., 2015). It is constant in approximately two-thirds and intermittent in the remaining third of patients. David Moffat's group classified tinnitus as mild tinnitus, which is only perceived in silence, moderate which is perceived over ambient background noise and severe tinnitus, which also interfered with sleep (Quaranta et al., 2007). They found moderate tinnitus in 2–26% and severe in 11–24%. The influence of treatment on tinnitus is variable and findings are not sufficiently reproducible. Several authors suggest that tinnitus can be ameliorated by hearing preservation at surgery or cochlear nerve section rather than preserving a non-functioning nerve. Tinnitus outcome is, however, unpredictable, and not statistically different between conservative management, microsurgery, and radiosurgery. During a mean follow-up of 3 years, most patients reported unchanged tinnitus, improved in 6% and worsened in 16% (Quaranta et al., 2007). Tinnitus alone is not an indication for surgical treatment and tinnitus was not found to significantly affect quality of life in larger groups, although individual patients may experience suffering described as catastrophic. Handicap from tinnitus is not directly related to severity. With time, most patients appear to adjust to remaining tinnitus.

Vertigo and dizziness

Dizziness is the most significant audiovestibular predictor of quality of life in patients with vestibular schwannomas and was consistently associated with long-term quality of life reduction in patients with sporadic vestibular schwannomas regardless of conservative or active treatment (Gauden et al., 2011; Jufas et al., 2015). More than 50% of vestibular schwannoma patients experienced dizziness, usually unsteadiness and vertigo only in 8%, still 8 years after diagnosis (Carlson et al., 2014). A prospective cohort study (Andersen et al., 2015) reported spinning vertigo in 11% and severe dizziness in 9% at baseline. Loss of response to caloric testing of the horizontal semicircular canal, 'canal paresis', was detectable in more than 70% of investigated patients. Canal paresis and postural unsteadiness correlated with moderate-severe dizziness while relationship with hearing and tumour size were less clear. Central compensation allows adjustment and subsequently a large group of schwannoma patients do not experience dizziness in spite of vestibular deficits, especially when vestibular loss is gradual. It is probable that larger tumours and stable loss of vestibular function allows better compensation and coping. Dizziness in the absence of large tumour size, growth, or other symptoms is an unusual indication for surgery. Surgery does allow section of the vestibular nerves to discontinue any erratic signalling. Disabling vertigo was resolved in 17/19 patients undergoing hearing preservation surgery for otherwise asymptomatic small vestibular schwannomas (Samii et al., 2016a). The indication is, however, controversial since surgery did not predictably improve dizziness in studies with other patients harbouring larger tumours. Selection of patients and microsurgical refinement may be keys to the good results. Many patients improve spontaneously and vestibular rehabilitation is necessary also after surgery (Thomeer et al., 2015).

Facial nerve function

Facial nerve palsy is consistently ranked, together with hearing deficit, as the most significant impairment after treatment for vestibular schwannoma (Carlson, Tveiten, et al., 2015). The House-Brackmann grading of facial function is described in Table 22.2. Facial nerve dysfunction causes difficulties with corneal protection, eating, drinking, and speaking. In addition, psychological distress can cause decreased self-esteem, anxiety, and depression, which are more important predictors of social disability in patients with facial paralysis (VanSwearingen et al., 1998). Unexpectedly, however,

Table 22.2 House-Brackmann grading

Grade	Gross function	Motion
1 **Normal**	Normal symmetrical function in all areas	
2 **Mild dysfunction**	Slight weakness noticeable on close inspection May have slight synkinesis At rest, normal symmetry	Forehead—moderate to good function Eye—complete closure with minimal effort Mouth—slight asymmetry
3 **Moderate dysfunction**	Obvious but not disfiguring difference between sides Noticeable (but not severe) synkinesis, contracture, or hemifacial spasm At rest, normal symmetry and tone	Forehead—slight to moderate movement Eye—complete closure with effort Mouth—slightly weak with maximum effort
4 **Moderately severe dysfunction**	Obvious weakness and/or disfiguring asymmetry At rest, normal symmetry and tone	Forehead—none Eye—incomplete closure Mouth—asymmetrical with maximal effort
5 **Severe dysfunction**	Only barely perceptible motion At rest, asymmetry	Forehead—none Eye—incomplete closure Mouth—slight movement
6 **Complete paresis**	No movement

facial nerve deficit had very little bearing on long-term quality of life scores (Carlson et al., 2015b). In agreement, Lassaletta et al. (2013) suggested that the visibility of a facial nerve paresis caused surgeons to put inappropriate emphasis on facial palsies compared to other postoperative symptoms.

Vestibular schwannoma patients rarely (<5%) present with facial nerve deficits and this raises the possibility of a facial nerve schwannoma. The facial nerve is primarily affected in patients with large tumours. Hence, new facial nerve deficits are not expected to occur during follow-up of non-growing lesions. Following microsurgery, facial nerve outcomes reflect surgical skill and goals. The risks vary with tumour size, extent of resection, and surgical experience. Temporary facial weakness is fairly common for larger tumours while permanent deficits occur in up to 20% of radically operated large tumours; considerably less in smaller or subtotally operated tumours. Radiosurgery is performed with low radiation doses, high resolution MRI, and modern dose planning which allow a low incidence of facial nerve deficits; they occur in less than 1% of patients (Yang et al., 2009; Régis et al., 2013a; Wangerid et al., 2014).

Intermedius nerve damage may occur in over 50% of patients operated by microsurgery, but is frequently noticed only if specifically looked for (Yang et al., 2009; Noonan et al., 2016). The symptoms comprise dry eyes and taste alteration. Lack of lacrimation is especially problematic when combined with a sensory deficit or inability to cover the cornea and dysgeusia can affect quality of life severely in persons for whom the sense of taste is important.

Headache

Persistent headaches were reported in 0–77% of participants of retrospective studies (reviewed in Carlson et al., 2015a) and surveys after vestibular schwannoma surgery. The headaches were usually of tension-type. They were frequently severe after three months but declined and became insignificant in many patients during further follow-up. Retrosigmoid craniotomies were associated with most complaints and subsequently speculation of causality has included traction of dura following healing of the incisions, aseptic meningitis correlated with CSF pseudocysts or bone dust from drilling and secondary mildly increased intracranial pressure from stenosis of venous sinuses. Cases that 'prove the concept' of each of the theories have been described and measures that decrease the amount of bone dust by replacing drilling with ultrasonic bone removal decrease the incidence of headaches. Only recently did Carlson et al. study headaches prospectively in patients treated by observation alone, microsurgery or radiosurgery (Carlson et al., 2015a). The incidence at presentation was 60%, which agrees with an estimated life-time prevalence of headaches in the general population. Headaches improved in 10% following observation, 14% following radiosurgery, and 19% following microsurgery; and worsened in 10% with observation, 14% with radiosurgery, and 25% following microsurgery. Long-term outcomes do not show statistically significant differences between the groups, although microsurgery was associated with more headaches during the first year after treatment. Younger age, previous migraine, a previous history of headaches and greater anxiety and depression predicted worse headaches after treatment and are also predictors of headache in the general population. Headaches remain severe after 1 year in 6–9% of all patients regardless of treatment and were then an important cause of decreased quality of life. Patients with conservatively managed vestibular schwannomas had headaches at twice the rate of controls (Breivik et al., 2012).

Non-vestibular schwannomas

Biologically and pathologically, non-vestibular schwannomas are very similar to vestibular schwannomas. They grow slowly and also appear to respond to radiosurgery (Pollock et al., 2002). Epidemiological data are derived from surgical series in specialized centres and may reflect selection bias. It is, however, clear that non-vestibular schwannomas are rare and comprise 6–10% of intracranial schwannomas or less than 1% of all intracranial tumours. The commonest of these are trigeminal nerve schwannomas, followed by jugular foramen schwannomas and facial nerve schwannomas.

Distinctly rare schwannomas are found on the oculomotor, trochlear, hypoglossal, and abducens nerves in that order. Tumours may also occur in the cochlea or vestibule. Occasional schwannomas that were not related to the cranial nerves have been discovered in the third ventricle, pituitary, or frontal base. Schwannomas also occur extracranially in the head and neck areas, intraorbitally, and elsewhere in the body, but will not be covered in this chapter.

Trigeminal schwannomas

Trigeminal schwannomas comprise 1–8% of intracranial schwannomas (MacNally et al., 2008; Chen et al., 2014a) (Fig. 22.10). The commonest presenting symptom is facial hypesthesia, followed by headache, dizziness, and ataxia. The tumours can arise along any portion of the trigeminal root, ganglion, and nerves, although locations centred around the ganglion are commonest. The tumours were originally classified according to their location by Geoffrey Jeffersson (Jefferson, 1953) as A–C, while 'D' was added later (Table 22.3). The commonest location is C, which describes a dumbbell tumour perched *en cheval* on the petrous bone, extending from the middle fossa to the posterior through the porus trigeminus.

Similar to vestibular schwannomas, the focus of management goals has shifted from radical removal to preservation of function and long-term control. Microsurgery for trigeminal schwannomas thus aims at bulk removal with preservation of intact rootlets, unless clinical behaviour or histopathology indicates an aggressive tumour. Nevertheless, microsurgery and cranial base techniques have increased complete removal of trigeminal schwannomas that were rarely radically operated in the premicrosurgical era. Schwannomas predominantly located in the cavernous sinus are preferentially approached frontotemporally with a Dolenc-technique (Dolenc, 1994) that includes extradural removal of the anterior clinoid process and dissection of the temporal dura off the cavernous sinus inner dural membrane. The posterior fossa component can be radically or near radically removed via the widened porus trigeminus in patients with moderate posterior fossa tumour extensions. Larger posterior fossa components require division of the tentorium and drilling of the anterior part of the petrous ridge or a second suboccipital approach (Yoshida and Kawase, 1999). A suboccipital trajectory is sufficient for a posterior fossa tumour and the petrous bone can be drilled intradurally to access Meckel's cave from the posterior fossa. Microsurgical removal of small trigeminal schwannomas is feasible with low morbidity. Small schwannomas are also usually controllable with radiosurgery, while its use can be prohibited by tumour size and close proximity to the optic apparatus. Trigeminal schwannomas that fail radiosurgery have been operated without added morbidity or loss of tumour control by conservative surgery

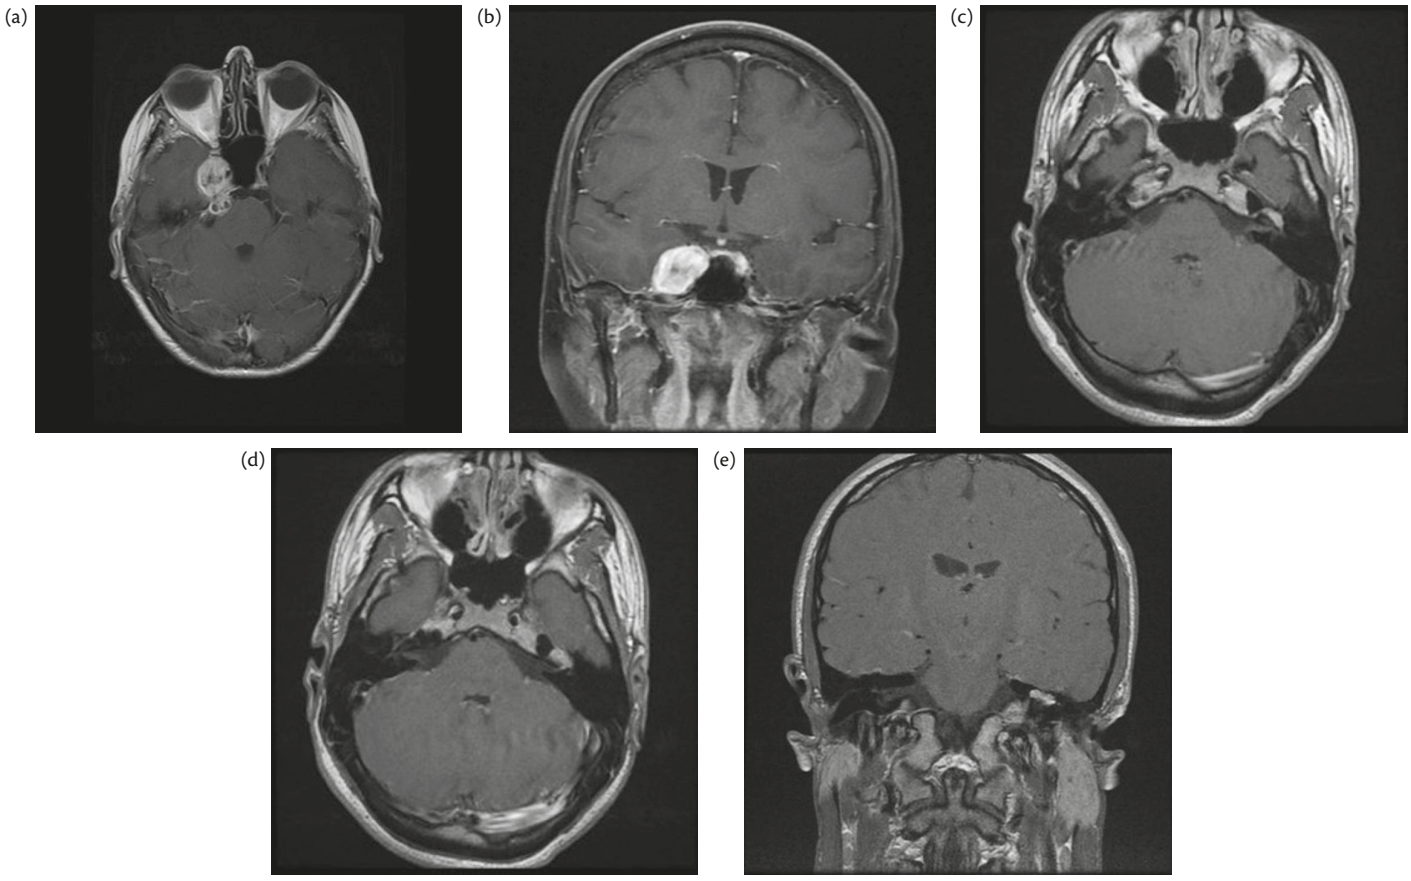

Fig. 22.10 Trigeminal and facial schwannomas. Axial (A) and coronal (B) T1-weighted MRI with gadolinium contrast illustrating a trigeminal schwannoma. The axial image illustrates the characteristic dumbbell shape with one portion extending from Meckel's cave into the posterior fossa and one portion extending from the cavernous sinus into the middle cranial fossa. Axial (C, D) and coronal (E) T1-weighted MRI imaging with gadolinium contrast illustrating the extension of the left-sided contrast-enhancing schwannoma along the labyrinthine and tympanic segments on either side of the geniculate ganglion.

Table 22.3 Modified Jeffersson classification of trigeminal schwannomas

Type	Main location	Frequency
A	Middle fossa	40%
B	Posterior fossa	22%
C	Dumbbell tumour; middle and posterior fossa	32%
D	From postganglionic nerves	6%

Ramsden, et al, Trigeminal schwannomas, *British Journal of Neurosurgery*, Volume 22, Issue 6, 2008 © The Neurosurgical Foundation, reprinted by permission of Taylor & Francis Ltd, www.tandfonline.com on behalf of The Neurosurgical Foundation.

and an aim of functional preservation. In those with predominant medial extension in relation to the carotid artery, an extended endoscopic endonasal transpterygoid approach may be considered. Following entrance into the maxillary sinus the posterior wall is drilled to access the pterygopalatine and infratemporal fossae. At the petrous apex, the trigeminal ganglion straddles the horizontal segment of the petrous internal carotid artery.

The surgical outcome regarding trigeminal nerve function depends on technique and management priorities; with meticulous cranial base microsurgical techniques and acceptance of near- or subtotal resection, a high degree of surgical radicality is possible with 10% improvement of sensation and less than 10% deterioration (Chen et al., 2014a) while earlier or more radical series reported higher rates of trigeminal functional loss. Surgery of larger tumours and cavernous sinus extensions may cause diplopia, and mortality occurred in older series. Trigeminal dysfunction can be very bothersome in spite of minimal visible deficits. New trigeminal symptoms were studied in patients operated for skull base meningiomas (Westerlund et al., 2012). Most patients seemed to adjust to numbness or mild neuropathic pain, while ocular symptoms and rare anaesthesia dolorosa are causes of major morbidity.

Third, fourth, and sixth nerve schwannomas

Schwannomas of the third, fourth, and sixth nerves are very rare and most commonly encountered in patients with neurofibromatosis type 2. Sporadic ocular nerve schwannomas comprise less than 1% of intracranial schwannomas and are discovered incidentally or during work-up for headaches or diplopia; partial ocular nerve palsy is the common symptom; available literature comprises reports of a total of 40–100 cases of each kind. They can arise anywhere along the nerves and occur in the intradural compartment, cavernous sinus wall (oculomotor and trochlear), inside the cavernous sinus (abducent) or orbit and have slow growth rates that motivate 'wait and scan' in many patients with minimal symptoms. Symptomatic tumours or growing tumours can be managed by radiosurgery if small and distant from the optic apparatus while microsurgery is feasible for all tumours. Non-radical surgery with a primary goal of preserving functional nerves may need to be combined with subsequent radiosurgery for tumour control. Radical surgery is technically feasible, but not with preservation of neuronal function. Results of nerve grafting have not been reported. Nerve grafting of the smaller nerves (trochlear and abducent) is theoretically possible, while occulomotor functional recovery following grafting is unlikely, as nerve suture has been shown to be futile.

Facial nerve schwannomas

Facial nerve schwannomas comprise less than 2% of intracranial schwannomas. Like other schwannomas, they grow slowly, are sensitive to stereotactic radiosurgery and tumour control is usually feasible. Facial schwannomas can occur anywhere along the nerve. The geniculate and tympanic segments are most commonly affected (**Fig. 22.10**). Three types of tumour can be discerned. One common location is the internal acoustic meatus, where they mimic vestibular schwannomas and extend into the cerebellopontine angle. These tumours are not dissectible from the facial nerve. The second type of tumours grow in the nerve in the fallopian canal and may appear as a contrast enhancing (on MRI), thickened segment of the nerve. A third typical location is around the greater petrosal nerve and the geniculate ganglion, which produces an exophytic extradural tumour on the subtemporal surface of the petrous bone.

Extensive loss of axonal function can occur before facial paresis develops. Hence, many facial nerve schwannomas present with tinnitus and hearing loss if located in the internal acoustic meatus or mass effect if located subtemporally. Schwannomas in the petrous bone usually cause facial nerve dysfunction, unless they are incidental findings. Radical surgery of facial nerve schwannomas comprises complete resection with nerve sacrifice and subsequent grafting. Hence, the surgical goals must be preconceived and transparent. Nerve grafting cannot be expected to provide better facial function than House-Brackman III, and is thus usually reserved for patients with manifest high-grade facial nerve palsy. For patients with large tumours and good facial function, subtotal removal with the prospect of added radiosurgery in case of tumour progression is a good alternative. The subtemporal tumours arising from the geniculate ganglion are removed near totally with a subtemporal epidural approach, which preserves facial function (Ichimura et al., 2010). Small tumours may grow very slowly and can be monitored with radiological surveillance. Gamma knife radiosurgery is feasible for small tumours that progress clinically or radiologically.

Schwannomas of the lower cranial nerves in the jugular foramen

Jugular foramen schwannomas include tumours originating from the glossopharyngeal, vagal, and accessory nerves; they comprise less than 3% of all intracranial schwannomas (**Fig. 22.11**). Glossopharyngeal tumours are probably the commonest, but it is frequently impossible to discern the nerve of origin. Originally, many tumours were detected during work-up for increased intracranial pressure. Such presentation still occurs but specific neurological deficits are more common. A partial or total jugular foramen syndrome and swallowing difficulties are present in approximately half of all patients while 30–60% show vestibulocochlear symptoms.

The tumours can be located anywhere along the nerves. Kaye and Samii proposed a classification of A, B, C, and D depending on origin and growth pattern (Kaye et al., 1984; Samii et al., 1995). Jugular foramen type A schwannomas occupy the cerebellopontine angle, type B are intraforaminal with intradural extension, type C are extracranial (not further covered here), and type D dumbbell shaped intraextra cranial. For radical removal, intracranial type A tumours are approached by the retrosigmoid approach whereas type B and D tumours require a retrosigmoid/transpetrous approach. A transpetrous approach with facial nerve transposition

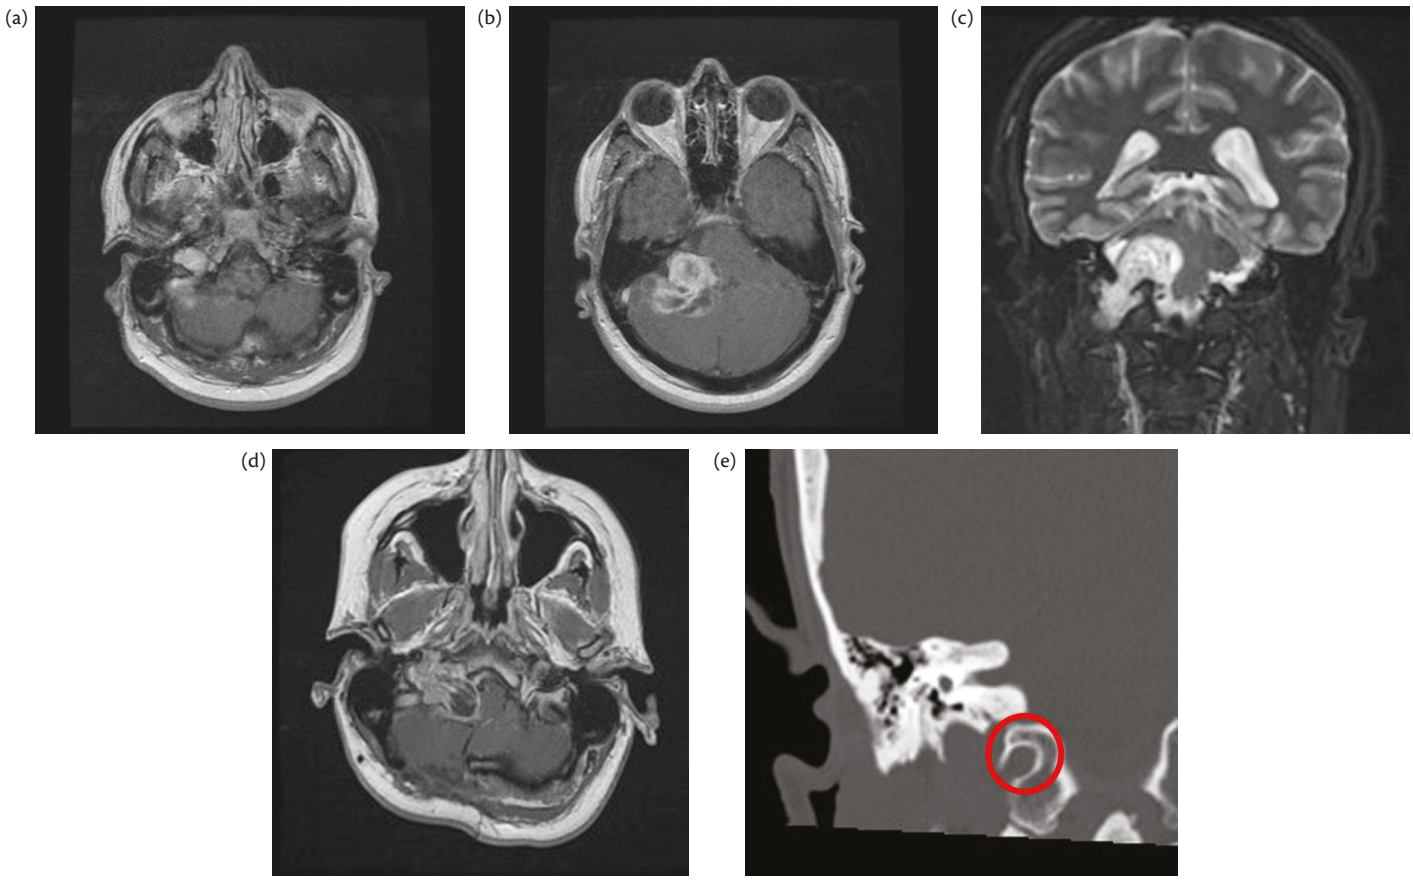

Fig. 22.11 Lower cranial nerve schwannomas. Axial (A, B) T1-weighted MRI with gadolinium contrast and coronal T2 (C) short T1 inversion recovery (STIR) MRI sequences of lower cranial nerve schwannoma. The tumour can be seen exiting the jugular foramen. Recurrent hypoglossal schwannoma (D) on T1-weighted MRI with gadolinium contrast. The hypoglossal canal can be identified easily on coronal computed tomography (CT) scan (E) as the Eagle's beak (circled in red). A hypoglossal schwannoma expands the hypoglossal canal and abolishes the Eagle's beak appearance. This can help to distinguish hypoglossal schwannomas from other lower cranial nerve schwannomas.

was frequently used in the past, but largely abandoned because of resulting facial nerve morbidity. Cranial nerve morbidity following gross total or near total resection has been reported in up to 100% for the lower cranial nerves, facial nerve morbidity in 11–80%, and vestibulocochlear morbidity in 4–45% (Park et al., 2016). Radical surgery of jugular foramen tumours carries a high risk of impaired lower cranial nerve function with ensuing hoarseness, dysphagia, or aspiration. Lower cranial nerve dysfunction may require tube feeding, gastrostomy, or tracheostomy for a shorter or longer period which has a strong negative impact on quality of life (Mathiesen et al., 2007). The tumours grow slowly and functional preservation has become a major objective for jugular foramen tumours. Intradural decompression and tailoring for radiosurgery allows medium term growth control with preservation of glossopharyngeal, vagal, and accessory nerve function (Park et al., 2016). Long-term data more than 10 years have, however, not been assessed or published and the expectation of long-term control reflect generalization of radiosurgical outcomes in vestibular schwannomas. Schwannomas of the spinal accessory nerve are surgically accessible with minimal morbidity other than unilateral spinal accessory paresis.

Hypoglossal schwannomas

Intracranial hypoglossal schwannomas are rare and only described in small clinical series and case reports describing approximately 100 cases. They appear to be more commonly cystic and rapidly progressing or recurring than other schwannomas (Fig. 22.11). Hemiatrophy of the tongue and hypoglossal paresis are typical symptoms. Up to half of all patients with unilateral hypoglossal paresis harbour a benign or malignant tumour around the cranial base. A hypoglossal schwannoma is reached intradurally and in the hypoglossal canal via a lateral, partial transcondylar approach. Hypoglossal function appears to recover rapidly following radical removal of a schwannoma with subsequent grafting (Mathiesen et al., 2009). The functional benefit of grafting and the feasibility of subtotal removal with or without adjuvant radiosurgery have not been sufficiently evaluated. Case reports with limited follow-up suggest that subtotal surgery with adjuvant radiosurgery is feasible also for hypoglossal schwannomas. Unilateral hypoglossal palsy is reported not to affect speech; hence several authors have argued that the handicap would be well tolerated. However, the impact on swallowing and quality of life has not been critically analysed.

Controversy: 'The small incidental acoustic'

The management of small, incidental vestibular schwannomas is subject to controversy. 'Wait and scan' is recommended to many

patients. Small tumours can technically be treated by micro- or radiosurgery, hence many patients choose a treatment. The controversies are should the patient be treated or followed, and which treatment is a better if active treatment is selected.

1. 'Active treatment' is based on the risks of symptomatic progression or growth, added to the uncertainty of pathology. Approximately a third of all patients with good hearing lose functional hearing during 3-year follow-up. A tumour may grow to a size where the risk of facial nerve complications, which is close to negligible for the smallest tumours, becomes a reality. It is also possible that the tumour grows to a size when radiosurgery is not feasible, and the choice becomes obsolete. Finally, early removal is preferable in the unlikely event that the tumour is malignant. Ideally, early treatment offers cure of the tumour and preservation of hearing and facial nerve function.

'It is better to take a higher risk early to gain cure and preserve hearing'

2. 'Wait and scan' is based on the benign natural history. The main arguments are that only one-third of small incidental vestibular schwannomas grow during 5-year follow-up and late growth is possible but not to be expected. It is likely that treatment is futile in patients who have stable tumours, since neither surgery nor radiosurgery can predictably improve hearing, vertigo, or tinnitus. In addition, microsurgery and to a lower extent radiosurgery exposes the patient to inherent treatment discomfort and morbidity in addition to exposing the patient to a stochastic risks of treatment complications. Demonstrated tumour growth or sometimes symptomatic progression are indications for treatment.

'It is better to avoid unnecessary treatment, treatment can be delayed without a statistically worse final outcome', 'The best way to preserve long-term hearing'

2.1 'No active treatment with radiosurgery' is based on (1) the belief that the goal of radiosurgery is 'tumour control', which already is the expected 5-year outcome without any treatment in approximately 70% of the patients. (2) Radiosurgery may have complications. Radiation to the facial and vestibulocochlear nerves may damage function. The treatment risk for facial nerve palsy is 1–2% and hearing is expected to deteriorate slowly during follow-up after radiosurgery, although opposing data have been published. Ionizing radiation is known to carry a risk of chromosomal damage and subsequent tumour induction or malignancy.

'For cure the tumour should be removed and the albeit low but uncontrollable risk of malignancy should be avoided'

2.2 'No active treatment with microsurgery' is based on the belief that (1) surgery requires hospitalization and absence from regular life with inherent morbidity and pain; (2) severe complications including death are, although rare, a real to the few who suffer from these; (3) most surgical series suggest higher rates of facial nerve complications and short-term hearing loss after microsurgery than radiosurgery.

'The tumour should be treated, and the possible acute severe complications of microsurgery are unacceptable' or '*Radiosurgery is the best strategy to preserve long-term hearing'*

The controversy reflects the variation in the medical evidence and individual values. There is general consensus regarding literature data, but large studies and meta-analyses only provide mean-figures for complication rates and outcomes in large populations of different patients and surgeons. Thus, individual treatment risks cannot be blindly extrapolated from large clinical studies. The risks vary with individual surgeon skills and experience; the surgeon and patient can also agree on treatment goals that affect risks of recurrence and morbidity. Ionizing radiation increases tumour incidence on the population level, but has only a marginal effect in individual patients. Rapid growth and malignant histology have been described in a few tumours, but the literature does not describe a sufficiently high risk to avoid radiosurgery. Tumours may grow and hearing may be lost during follow-up, but severe worsening is very rare. The best rationale for radiosurgery is literature support of better long-term hearing outcomes; however, different studies have different results and conclusions. The scientific challenge is to assess whether the patient shares similarities with the population that showed benefit rather than the other subgroups.

Most importantly, individual patient's values regarding outcomes and acceptable risks vary. With a transparent risk assessment, different patients may opt for wait and scan, radiosurgery, or microsurgery for an identical tumour. It is the duty of the surgeon to share knowledge and experience in a transparent way without hiding personal experience and results and also to empower the patient to make a shared decision; the decision should reflect the patient's values and the surgeon's knowledge and professional ethics.

Glomus tumours

Omar Pathmanaban and Andrew King

Introduction

Glomus tumours are slow-growing, abundantly vascular tumours, which occur in the anatomically complex jugulotympanic region of the lateral skull base. They are usually benign, but locally invasive, and extend into the adjacent petrous bone, as well as cerebellopontine angle (CPA) and neck in some cases. The tumour spreads through low resistance pathways such as air cells, peri- and intravascular spaces, Eustachian tube, and skull base foraminae, as well as by erosion of bone.

Clinical presentation

Glomus tumours are generally indolent and can progress to a significant size before diagnosis due to a lack of symptoms or subtle symptoms, which are not recognized as a cause for concern. When symptoms become apparent, they are representative of the biological hallmarks of glomus tumours, namely hypervascularity, which produces pulsatile tinnitus in 90% of patients, and local invasion, leading to conductive hearing loss in 80% of patients (Fayad et al., 2010). Otalgia and aural fullness occur in around 10% of patients (Fayad et al., 2010). Other anatomically localizing neurological symptoms relate to the path of invasion in the lateral skull base (**Table 23.1**). Vertigo may occur with labyrinthine incursion and sensorineural hearing loss with cochlear involvement. Cranial nerve palsies vary in frequency between published series and neural invasion may occur in the absence of preoperative deficits because of the functional compensation afforded by slow progression (Makek et al., 1990). Dysphagia and/or dysphonia may be evident at presentation due to compromise of the glossopharyngeal and vagal rootlets at the jugular foramen; the location of these lesions makes any of the lower cranial nerve syndromes possible (**Table 23.2**). Facial motor deficits may be evident in a proportion of patients (Fayad et al., 2010; Jackson et al., 1990; Makek et al., 1990). Facial sensory disturbance and diplopia are sometimes seen due to extension into the CP angle through the jugular foramen or along the petrous face with trigeminal and abducent nerve encroachment, respectively. In the case of a significant intracranial tumour component, focal/lateralizing neurological deficits and or obstructive hydrocephalus can also occur due to brainstem compression. Horner's syndrome may be seen with large tumours secondary to brainstem compression or more likely, damage to sympathetic nerves due to internal carotid artery encasement and invasion. Otoscopy classically reveals a red mass (**Fig. 23.1**) in the middle ear in more than 90% of cases and is sometimes described as having the appearance of the setting sun (Fayad et al., 2010).

Clinical anatomy and classification

Glomus tumours of the cranial base can be broadly categorized using three anatomical descriptions:

- Glomus tympanicum—confined to the middle ear
- Glomus jugulare—confined to the jugular foramen
- Glomus jugulotympanicum—involving both jugular foramen and middle ear

Glomus tympanicum tumours arise from paraganglia along the middle ear course of Jacobson's nerve (inferior tympanic branch of cranial nerve IX). Glomus jugulare tumours (**Fig. 23.2**) may arise from paraganglia associated with the jugular bulb adventitia, along Arnold's nerve (auricular branch of cranial nerve X), or the jugular fossa course of Jacobson's nerve (Forbes et al., 2012). The fragile jugular plate of the middle ear floor (thin cortical bone separating the hypotympanum from the jugular bulb inferomedially) is the path of tumour progression between jugular and middle ear compartments and is the defining anatomical landmark with regards to the name attached to the tumour. With large jugulotympanic tumours, the point of origin is academic and can only be inferred. However, determining the anatomical stage of glomus tumours is clinically important, because tumours restricted to the middle ear can be removed by an otologist via a transtympanic approach and minimal morbidity, whereas advanced tumours require more invasive skull base approaches. The two most commonly used radiology staging systems are the Jackson-Glasscock classification (**Table 23.3**) and the Fisch classification (**Table 23.4**) (Jackson et al., 1982; Fisch and Mattox, 1988).

Table 23.1 Anatomically localizing symptoms

Symptom	Anatomical structure involved
Deafness	Middle ear/Cochlea
Dizziness/Vertigo	Labyrinth/CPA—cranial nerve VIII
Dysphonia	Jugular foramen—cranial nerve X
Dysphagia	Jugular foramen—cranial nerves IX/X
Facial weakness	Petrous bone/CPA—cranial nerve VII
Facial numbness	Petrous apex/CPA—cranial nerve V
Double vision	Petrous apex/CPA—cranial nerve VI
Headache	Brainstem/fourth ventricle—hydrocephalus
Tongue wasting	Hypoglossal canal—cranial nerve XII

Imaging

Combined CT and MR imaging are the modalities of choice for diagnosis and staging of glomus tumours of the temporal bone. Axial and coronal thin section CT imaging clearly delineates the extent of bone invasion, which usually has irregular edges. MR further defines the relationship to skull base neurovascular structures and tumour extension into the CPA (Fig. 23.3). T1-weighted and T2-weighted MR images characteristically show mixed signal intensity described as 'salt and pepper' appearance reflecting hypervascular signal voids (high-flow tumour vessels) together with focal areas of high signal intensity due to intratumoural blood products (Rao et al., 1999). T1-weighted gadolinium enhanced images show avid contrast uptake and demonstrate a smooth tumour contour.

Catheter angiography is not usually required diagnostically in the modern era, but is useful in select cases where the diagnosis is not clear and in all surgical cases (where embolization is performed preoperatively—see treatment section later on in this chapter). A dense hypervascular tumour blush is seen (Fig. 23.4) often with early venous filling due to intratumoural arterio-venous shunting and usually multiple external carotid arterial feeders (notably ascending pharyngeal) with further supply from the internal carotid and/or vertebral arteries in large tumours (Rao et al., 1999).

Other investigations and consultations

Audiometry should be performed to determine hearing loss. Laryngoscopy is performed to assess function of the vocal cords. Endocrinology consultation with plasma and 24-hour urine collection for biochemical measurement of metanephrines and catecholamines is performed in all cases, even when there are no symptoms of catecholamine hypersecretion. This is because a minority of cranial base paragangliomas are secretory and there is also the possibility of multifocality with additional undetected secretory paragangliomas. The more recently available test for 3-methoxytyramine (dopamine derivative) should ideally be checked in all patients. It can be used as biomarker for malignancy and recurrence after treatment as well as risk of haemodynamic instability (Eisenhofer et al., 2012). Genetics consultation should be part of routine management and genetic counselling and testing is advised for all cases even in the absence of family history. The purpose of genetic testing is to determine risk for the individual in terms of tumour progression and synchronous and metachronous tumours. It also allows identification of at-risk family members and counselling regarding parenting options including preimplantation diagnosis. Institutional protocols regarding radiological screening for other tumours vary and include MR imaging and ^{123}I-metaiodobenzylguanidine (MIBG) radioisotope imaging. Our preferred modality is whole body MRI including coronal T1-weighted and STIR sequences and axial fat saturation T2-weighted sequences. Somatostatin receptor scintigraphy and positron emission tomography are also used in some centres for screening purposes.

Table 23.2 Lower cranial nerve syndromes

Syndrome	Nerve palsies
Vernet's	IX, X, XI
Collet-Sicard	IX, X, XI, XII
Villaret's	IX, X, XI, XII, sympathetics (Horner's)

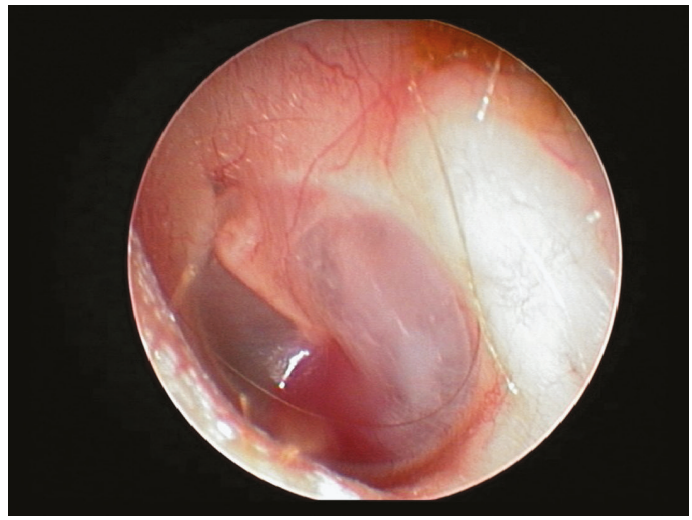

Fig. 23.1 Otoscopic photograph demonstrating the setting sun sign. A characteristic blood red glomus tumour is seen in the middle ear.

Pathology

Origin

Glomus tumours arise from extra-adrenal autonomic paraganglia. Paraganglia have been found to store and secrete catecholamines and are thought to play a homeostatic role, but their physiological purpose in health remains largely unknown (with the notable exception of carotid body oxygen chemoreceptors). They are small neuroendocrine clusters of chief cells derived from the neural crest during embryonic development (Heth, 2004). Neoplasms, including glomus tumours, that are derived from these cells are properly termed paragangliomas and are of the same lineage as phaeochromocytomas; they may retain functional catecholamine production and secretion (DeLellis, 2004). These tumours can be broadly divided into three subgroups:

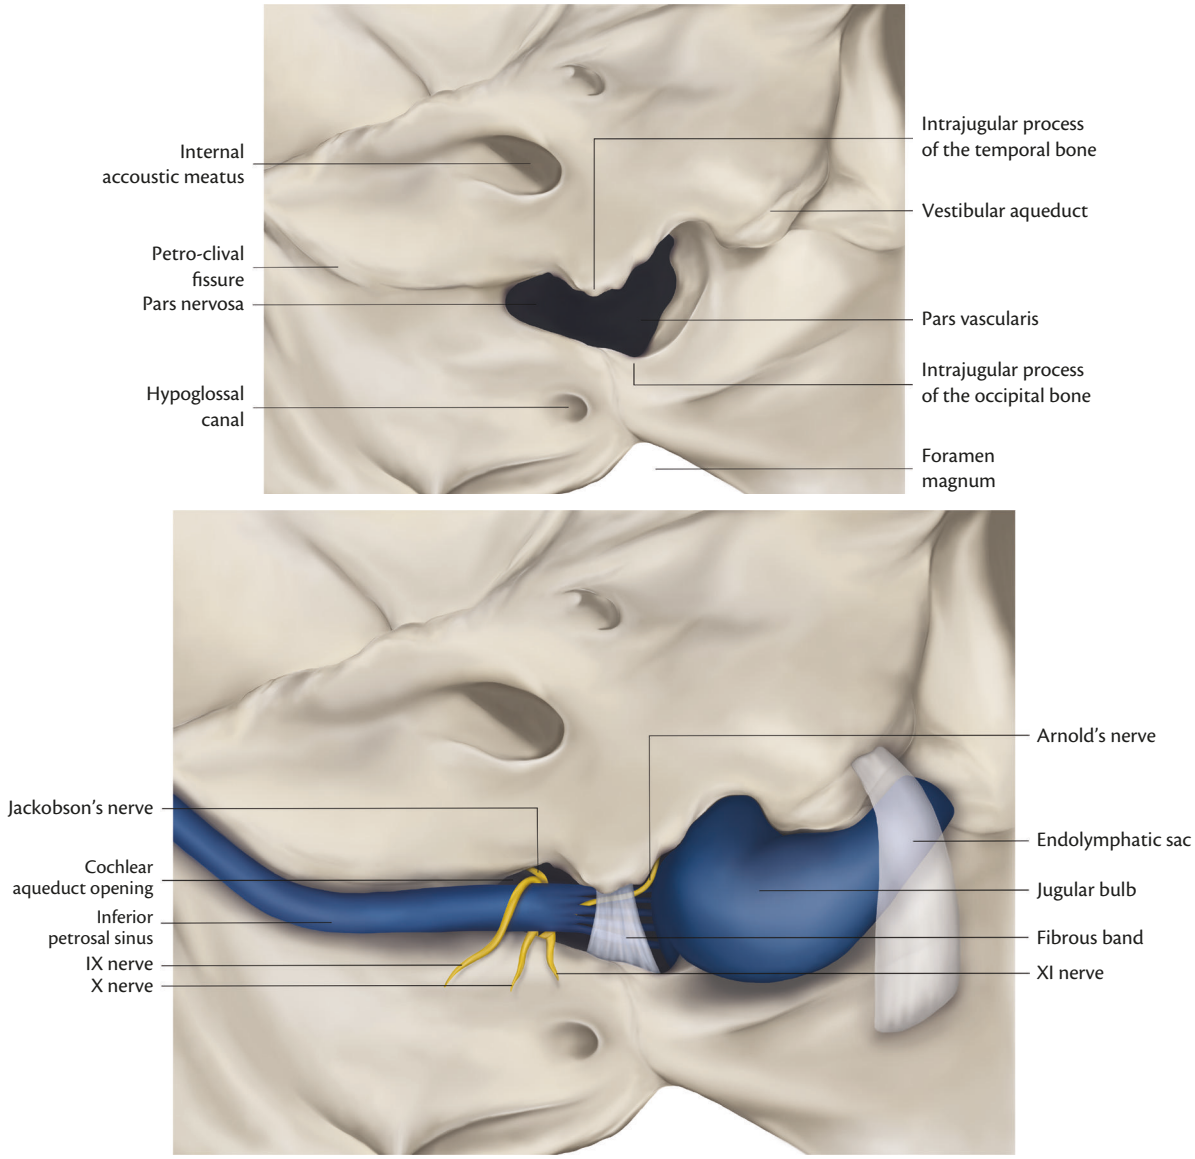

Fig. 23.2 (A) Two classifications exist for the subdivision of the jugular foramen. The traditional division is into pars vascularis containing the sigmoid sinus and CNs X and XI and pars nervosa containing CN IX. Some authors propose an additional subdivision of the pars vascularis into the compartment containing the sigmoid sinus alone lying posteriorly and a further intermediate compartment (the intrajugular compartment) bounded posteriorly by the petro-occipital ligament (a fibrous or osseous band connecting the jugular processes of the occipital and temporal bones) and anteriorly by a dural fold. This intrajugular compartment is described as containing CNs X and XI. There are three compartments of the jugular foramen with the sigmoid part posterolateral and the smaller petrosal anteromedial part harbours the inferior petrosal sinus—'pars vascularis'. The intrajugular processes of the temporal and occipital bones are joined by a fibrous and sometimes osseous band forming the intrajugular septum. The third compartment is intrajugular—'pars nervosa' is between the sigmoid and petrosal parts. [the pars nervosa includes the ninth nerve adjacent to the inferior petrosal sinus while the tenth and eleventh nerves runs with the sigmoid-internal jugular junction in the pars vascularis].
(B) The inferior petrosal sinus joins the sigmoid through openings in the medial wall of the jugular bulb. This connection lies between the ninth nerve anteriorly and the tenth and eleventh nerves posteriorly. These nerves penetrate the dura at the medial margin of the intrajugular process of the temporal bone and pass on the medial aspect of the internal jugular vein. The cochlear aqueduct opening is above the petrosal part near the ninth nerve in the interjugular part. The meningeal branches of the ascending pharyngeal and occipital arteries, the tympanic branch of CN IX 'Jacobson's nerve' entering the tympanic canaliculus to reach the tympanic cavity and the auricular branch of CN X 'Arnold's nerve' entering the mastoid canaliculus located in the anterior wall of the sigmoid part to exit at the tympanomastoid suture are the relevant structures within the jugular foramen with regards to glomus tumours.

- Phaeochromocytomas—intra-adrenal paragangliomas (functional)
- Sympathetic paragangliomas—extra-adrenal arising anywhere along sympathetic chain from cranial base to pelvis (usually functional; also known as chromaffin paragangliomas)
- Parasympathetic paragangliomas—extra-adrenal parasympathetically innervated tumours, which arise at the skull base and in the neck associated with the ninth and tenth cranial nerve branches (rarely functional; also known as non-chromaffin paragangliomas)

Table 23.3 Glasscock–Jackson classification[a]

I	Small tumour involving jugular bulb, middle ear, and mastoid
II	Tumour extending under internal auditory canal; may have intracranial canal extension
III	Tumour extending into petrous apex; may have intracranial canal extension
IV	Tumour extending beyond petrous apex into clivus or intratemporal fossa; may have intracranial canal extension

[a] Adapted from, Glasscock ME 3rd, Jackson CG, Dickins JR, Wiet RJ: Panel discussion: Glomus jugulare tumors of the temporal bone–The surgical management of glomus tumors. *Laryngoscope* 89: 1640–51, 1979 (16) and Willen SN, Einstein DB, Maciunas RJ, Megerian CA: Treatment of glomus jugulare tumors in patients with advanced age: Planned limited surgical resection followed by staged gamma knife radiosurgery—A preliminary report. *Otol Neurotol* 26:1229–34, 2005 (41).

Jugulotympanic glomus tumours belong to the parasympathetic non-chromaffin paraganglioma subgroup.

Histology

Histological sections of paragangliomas (Fig. 23.5) stained with haematoxylin and eosin (H&E) show a thin tumour capsule, a meshwork of fibrovascular stroma rich in thin walled capillary channels surrounding diagnostic nested balls of round or polygonal chief cells (zellballen) and spindle-shaped supporting or sustentacular cells at the periphery. Immunohistochemistry shows positive reaction for antibodies directed against synaptophysin in chief cells and S100 and GFAP in sustentacular cells (Branica et al., 1993). Electron microscopy is not a routine diagnostic investigation, but confirms the presence of neurosecretory granules in the chief cells (Warren et al., 1985). Determination of the grade of tumour is not possible histologically. Sustentacular cells are notably lost in high grade tumours with metastases (Kliewer and Cochran, 1989), but other microscopic features of malignancy such as mitotic figures and necrosis are not reliable and the WHO classification considers metastasis as the only diagnostic criteria for malignancy (DeLellis, 2004).

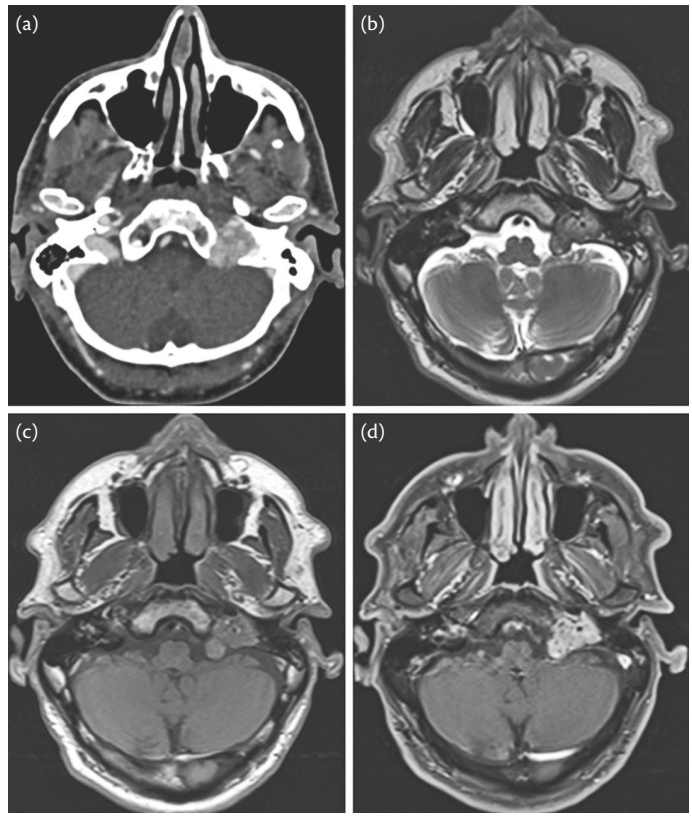

Fig. 23.3 Cross-sectional imaging at the level of the jugular foramen: postcontrast axial CT scan (A), T2-weighted axial MR (B), precontrast T1-weighted axial MR (C), and postcontrast T1-weighted axial MR (D) images demonstrate a typical enhancing glomus jugulare tumour on the left with bone destruction and vascular flow voids.

Table 23.4 Fisch classification

Class	Description
A	Limited to middle ear (glomus tympanicum)
B	Limited to middle ear/mastoid, jugular plate intact, no infralabyrinthine involvement
C	Involving infralabyrinthine part of temporal bone and petrous apex
C1	Carotid foramen involved, but limited vertical carotid canal destruction
C2	Invasion of the vertical section of the carotid canal
C3	Invasion of the horizontal portion of the carotid canal, foramen lacerum spared
C4	Invasion beyond foramen lacerum to cavernous portion of carotid artery
De	Intracranial extradural extension
De1	<2 cm posterior fossa extradural extension
De2	>2 cm posterior fossa extradural extension
Di	Intracranial intradural extension
Di1	<2 cm posterior fossa intradural component
Di2	2–4 cm posterior fossa intradural component
Di3	>4 cm posterior fossa intradural component

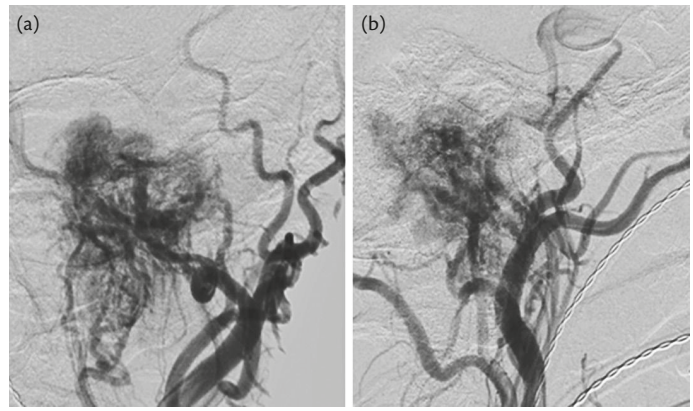

Fig. 23.4 Intra-arterial digital subtraction angiogram: selective catheter angiography of the left external carotid artery demonstrates a glomus jugulare tumour in frontal (A) and lateral (B) projections with a characteristic hypervascular appearance.

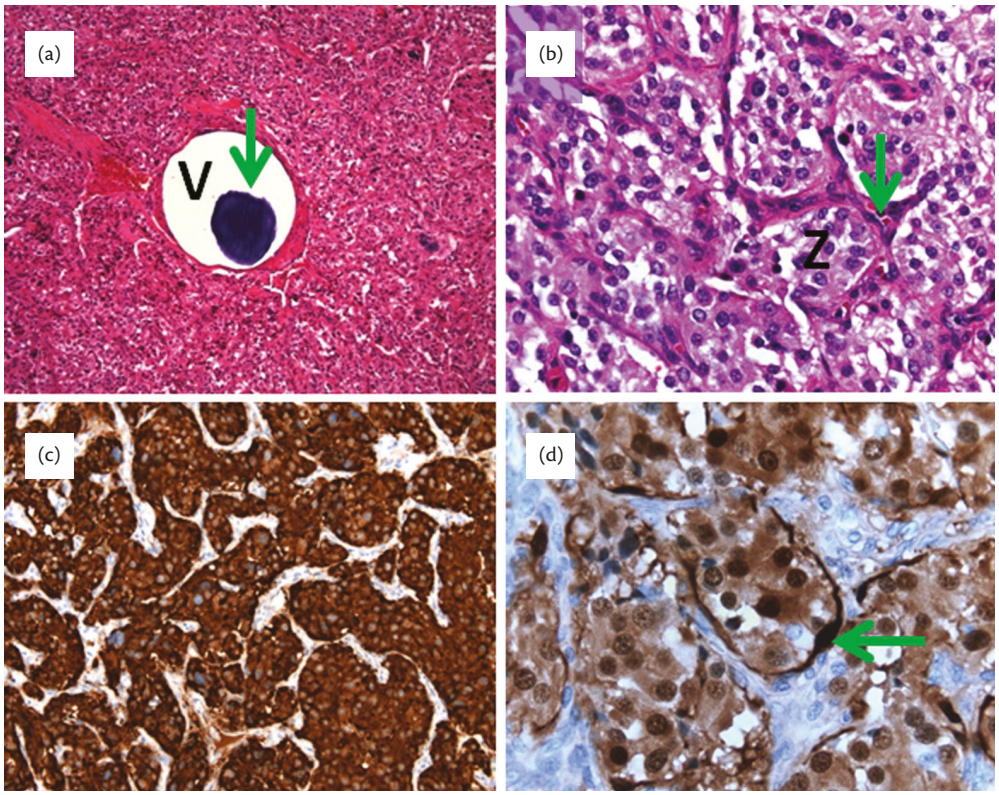

Fig. 23.5 Glomus jugulare histology: H&E stained section from a glomus jugulare tumour (panel A, ×100 original magnification) demonstrating a vessel (V) with endovascular embolization material evident (arrow). A higher power H&E photomicrograph (panel B, ×400 original magnification) showing the 'zellballen' arrangement of tumour cells (Z) with surrounding rich capillary networks (arrow). Immunohistochemistry using antibodies against synaptophysin (panel C, ×200 original magnification) demonstrates diffuse strong immunoreactivity of tumour cells confirming neuroendocrine cell lineage. S100 immunostaining (panel D, ×630 original magnification) demonstrating strong anti-S100 staining of sustentacular support cells surrounding tumour cell nests (nuclear and cytoplasmic staining of tumour cells represents unspecific staining). A bipolar densely staining sustentacular cell (arrow) is clearly seen in association with the centre cell nest as a densely brown staining cell with bipolar projections enveloping the cell ball. Photomicrographs courtesy of Dr Daniel du Plessis.

Epidemiology

These tumours are rare and as such an accurate incidence is not known, despite variable figures found in the published literature. The combined incidence of the phaeochromocytoma-paraganglioma spectrum of neuroendocrine tumours is 0.8 per 100, 000 per year (Beard et al., 1983). Women are affected more often, 4:1 F:M (Reddy et al., 1983). Malignant glomus tumours—defined by systemic metastases—are unusual and it is not clear what the specific incidence is for glomus tumours of the skull base; for paragangliomas at all sites, it has been estimated that the incidence is less than 100 persons per 400 million per year (Welander et al., 2011). Sporadic tumours are often diagnosed in the fifth decade of life, with hereditary disease tending to present earlier.

Risk factors

Environment

It is notable that carotid body hyperplasia is seen at high altitudes and sporadic paragangliomas at this site are more common at high altitudes, particularly in females. Glomus jugulare tumours are also more common in this setting, which may be due to chronic hypoxia, although this remains to be proven (Saldana et al., 1973).

Genetics and hereditary syndromes

Family history of paragangliomas and female sex confer a higher risk of paraganglioma tumorigenesis. Glomus tumours are either sporadic or familial, with recent data suggesting up to 50% of extra-adrenal paragangliomas are familial (Fishbein et al., 2013). In addition, paragangliomas are part of several other genetic syndromes: multiple endocrine neoplasia type 2 (*RET* gene), von Hippel Lindau syndrome (*VHL* gene), neurofibromatosis type 1 (*NF1* gene) and Carney triad/Carney-Stratakis syndrome (Galan and Kann, 2013). Young age, bilateral/multiple tumours, other stigmata of the various syndromes and family history may point to the diagnosis of a genetic syndrome, but it is important that all patients with paragangliomas are referred to a clinical genetics service for comprehensive workup. There are currently at least 15 known susceptibility genes and next-generation sequencing is now the method of choice for genetic testing. A recent consensus document recommends which genes should be included in the test panel (Toledo et al., 2017). Familial paragangliomas are autosomal dominant with variable penetrance and some are exclusively transmitted via paternal mutations due to maternal genetic imprinting. Inherited paragangliomas have been linked to mutations in the genes coding

the subunits of the succinate dehydrogenase (SDH) enzyme, which is important in the Krebs cycle and mitochondrial respiratory chain. There are four genes encoding separate enzyme subunits (*SDHA, SDHB, SDHC, SDHD*) and another coding a protein which flavinates the first subunit (*SDHAF2*). The *SDHx* genes are believed to have tumour suppressor functions. Although the mechanisms and mediators of this are not fully understood, *SDHx* mutations may interfere with cellular oxygen sensing and cause succinate and reactive oxygen ions and peroxides to accumulate, causing stabilization of hypoxia inducible factor-1α and consequent activation of hypoxia signalling cascades (Heth, 2004; Galan and Kann, 2013). Five hereditary *SDHx* paraganglioma syndromes have been discovered to date, each with a different gene mutation (Table 23.5). *SDHD* mutation is the most common and is associated with paraganglioma syndrome 1 (PGL1), which is particularly prevalent in Dutch familial skull base/head and neck paraganglioma patients due to a single founder mutation (Hensen et al., 2011).

Table 23.5 Familial paraganglioma syndromes

Syndrome	Chromosome	Gene	Description
PGL1	11q	*SDHD*	• Paragangliomas / pheochromocytomas • Paragangliomas more common • Multiple in more than half of cases • Usually parasympathetic • Malignancy reported, but uncommon • Paternal transmission (gene maternally imprinted) • High penetrance • Most common familial paraganglioma syndrome
PGL2	11q	*SDHAF2*	• Parasympathetic paragangliomas • Usually multiple • Paternal transmission (gene maternally imprinted) • High penetrance
PGL3	1q	*SDHC*	• Paragangliomas • Mainly parasympathetic • Multiple in a fifth of cases • Malignancy reported, but uncommon • Low penetrance
PGL4	1p	*SDHB*	• Paragangliomas/ pheomochromocytomas • Paragangliomas more common • Multiple in a fifth of cases • Most often sympathetic secreting tumours • Most commonly pelvic/ abdominal/thoracic • Skull base location reported, but unusual • Associated with renal cell carcinoma • Higher risk of malignancy • High penetrance • Relatively young age at diagnosis typical • Relatively poor prognosis • Second most common familial paraganglioma syndrome
PGL5	5P	*SDHA*	• Paragangliomas/ pheochromocytomas • Paragangliomas more common • Sympathetic or parasympathetic • Multiple not described • Malignancy not described • Low penetrance

Treatment and prognosis

Although skull base paragangliomas are generally benign, patients have reduced quality of life (Havekes et al., 2008). Optimal management of glomus tumours is both challenging and controversial (see 'Controversies' section), and requires a personalized approach administered by an experienced multidisciplinary team including neurosurgeons, neuro-otologists, endocrinologists, clinical geneticists, interventional neuroradiologists, radiation oncologists, and pathologists.

Conservative

Glomus tumours are normally slowly progressive and some are static over protracted follow-up. The risks of treatment can therefore exceed the risks of doing nothing in some cases, therefore a watch, wait, and rescan policy is often the first-line management strategy. Initially, a repeat scan at 6 months is performed. Static tumours and slow growing small tumours can be managed conservatively with further interval clinical and imaging review on an annual basis. This surveillance interval is often extended once the indolent behaviour of the tumour is established. A similar approach is sometimes appropriate with larger tumours in older people and those with significant comorbidities. Large tumours, faster growing smaller tumours (particularly in younger patients) and secreting tumours may require treatment with surgery and/or radiation therapy. Established lower cranial nerve deficits ipsilateral to the tumour lower the threshold for treatment, as it reduces the fear of iatrogenic deficits and tends to signal a more invasive tumour phenotype. Treatment decisions have to be made in the context of the patient's genetic status and synchronous tumours. This is most evidently important when there are bilateral tumours with risk of cranial nerve deficits on both sides. In such cases the decision of the team must aim at minimizing the risk of permanent tracheostomy and enteral feeding. The aim is to preserve function, while controlling the tumour.

Surgery

Surgery for glomus tumours has evolved significantly over the last few decades with widespread adoption of multidisciplinary teams, preoperative embolization, intraoperative cranial nerve monitoring, and advanced microsurgical techniques. Glomus tympanicum tumours can be excised totally using neuro-otological transcanal approaches with hearing preservation and minimal morbidity. Therefore, surgery is the treatment of choice in these cases and there is a limited role for radiotherapy. Total excision of glomus jugulare and jugulotympanic tumours can also be attempted via transmastoid-transcervical and infratemporal fossa approaches depending on size and the invaded structures. This is often suitable

when examination (including laryngoscopy) indicates the presence of established lower cranial nerve deficits on the side of the tumour, whereas partial excision (with adjuvant radiation therapy or further observation) is an option to discuss with the patient when lower cranial nerves are functional. The decisions regarding operative approach can be aided by use of the Fisch classification, but each patient is unique and the approach must be tailored. The details of surgical anatomy, approaches, and nuances of technique are dealt with in Chapter 24. These tumours are very vascular and intraoperative haemorrhage can be dramatic, preoperative catheter embolization should therefore be strongly considered in all cases. Carotid balloon occlusion test is indicated where there is internal carotid involvement and study of the contralateral venous sinuses should also be performed, when the jugular venous drainage will need to be sacrificed during surgery. In the hands of an experienced team with all treatment modalities and adjuncts available, there is the possibility of surgical cure, but the risk of postoperative morbidity is high, particularly cranial nerve deficits. Gross total tumour excision is achieved in roughly 80% of patients (even with large tumours) and long-term tumour control can be expected in over 85% of cases. Notably up to 7% of patients reported to have had gross total resection develop recurrence, but less than 1% of patients treated surgically go on to die as a result of tumour progression (Suárez et al., 2013). The most striking drawback to surgery is the high reported rate of new cranial nerve deficits (20–60%, although some will be temporary). Lower cranial nerve palsies can ultimately have fatal consequences, although peri-operative mortality is low, in the region of 1–3% (Makiese et al., 2012). As a result of the cranial nerve morbidity, treatment strategies are moving away from surgery for the majority of patients (excluding glomus tympanicum) and towards radiotherapy in many centres (see 'Controversies' section).

Radiotherapy/radiosurgery

Radiation treatment can be used as primary treatment, adjuvant treatment after partial excision, or as second-line treatment at the point of recurrence or growth of residual tumour. Conformal fractionated radiotherapy, stereotactic radiosurgery, or hypofractionated stereotactic radiotherapy are all used depending on the individual tumour characteristics, patient choice, and available resources. Generally, radiosurgery is suitable for smaller lesions less than 3 cm in diameter and larger lesions require fractionated radiotherapy. The aim of irradiation is to stop growth (control), rather than to eradicate the tumour and in most series, tumour control rates greater than 90% have been observed for all forms of radiation treatment with up to 10 years follow-up in some series. Cranial nerve morbidity is favourable when compared to surgery with some patients even improving after treatment (Tran Ba Huy, 2014). Deaths due to subsequent tumour progression have been reported in around 3% of cases treated with conventional radiotherapy. Treatment-related mortality is also less than 2%. Acute toxicity symptoms are common, but transient, and include headache, nausea, vomiting, mucositis, and weight loss. Long-term xerostomia, dysphagia, and inflammatory otitis media/externa can be problematic for some patients and iatrogenic sensorineural deafness continues to be seen in up to 5% of cases (Suárez et al., 2013; Tran Ba Huy, 2014). Osteonecrosis and brain necrosis were severe complications seen with external beam radiotherapy in the past, but this has been essentially eliminated with newer intensity-modulated conformal and stereotactic methods. Vascular sequelae including carotid stenosis with ischaemic complications can occur, but appear to be unusual, however as younger patients with longer lifespan are now treated, rates of late vascular complications will need to be assessed. Similarly, the rates of late radiation induced malignancy are thought to be low (less than 1/1000), but long-term follow-up, particularly in young patients with many decades to live is required (Tran Ba Huy, 2014).

Drugs

Alpha-blockers are routinely used in patients with secreting tumours, and medication should be commenced several weeks before planned intervention to reduce the risk of dangerous swings in blood pressure and cardiac arrhythmias. Beta-blockers are required less often as these tumours produce nor-adrenaline rather than adrenaline. There is no role for systemic chemotherapy in isolated glomus body tumours, but chemotherapy can induce remission or stability in some cases of metastatic paraganglioma (Patel et al., 1995).

Post-treatment management

All patients, regardless of treatment modality, should be followed up with interval MR scans. Specific post-treatment cranial nerve deficits should be addressed if they are present. Tracheostomy and nasogastric/gastrostomy feeding are usually required temporarily if the lower cranial nerves have been sacrificed. Dysphonia and swallowing problems can improve with speech therapy and where voice problems persist, laryngologists can offer a variety of injection and surgical treatments to help. Facial weakness requires physiotherapy, ophthalmic review, and sometimes reanimation surgery, and is best managed through a specialist facial function clinic. Hearing loss and balance problems can be addressed with hearing aids and vestibular rehabilitation, respectively. Reduced shoulder movement and consequent shoulder pain due to accessory nerve dysfunction should be treated with physiotherapy exercises. Tongue weakness and dysarthria require speech therapy support.

Controversies

There is variability in the management of temporal bone glomus tumours. In particular, the choice of radiation or surgery as the primary treatment has been controversial. Surgery is the mainstay of benign tumour management in essentially all other areas of the body. However, the skull base is unique due to its complex anatomy and delicate neurovascular structures. Despite significant advances in surgery, excision is associated with relatively high cranial nerve morbidity. Cranial nerve function can be protected to some degree by a policy of accepting partial excision, leaving a small amount of tumour over cranial nerves if need be (Wanna et al., 2014). While this was once controversial, this is now seen as a good strategy by most of the skull base community. At the same time, targeted radiotherapy and radiosurgery methodology has evolved to minimize risks, while achieving tumour control in most cases. The severe complications such as osteoradionecrosis and brain necrosis, which used to reinforce the surgical paradigm, are now extremely rarely encountered. As a consequence, radiation treatment has become the

mainstay in many units in recent years. Nevertheless, surgery is still indicated in selected cases:

- Sustained growth after radiotherapy/radiosurgery
- Tumours with CPA or petroclival extension and brainstem compression
- Symptomatic catecholamine secreting tumours (chief cell secretion is radioresistant)

Additionally, there is debate to be had regarding primary treatment modality in the following scenarios:

- Young patients
- Small growing tumours
- Patients with established cranial nerve deficits before treatment

Young patients should therefore be offered the options of surgery or radiosurgery with a discussion about the risks of both including the possibilities of late radiation effects and the lack of quality follow-up data beyond ten years. The risk of cranial nerve injury with surgery is proportional to the size of the tumour (Moe et al., 1999) and so it is also appropriate to have this discussion with patients who have small growing tumours, where the risk of postoperative cranial nerve deficits is likely to be low. Finally, with regards to patients who have established cranial neuropathies before treatment, the main morbidity associated with surgery—cranial nerve injury—is factored out of the equation to some extent, although new deficits such as facial weakness should not be underestimated. Moreover, apparent lower cranial neuropathies found preoperatively are often incomplete and sacrifice during surgery can produce unanticipated swallowing problems by converting to complete impairment. Nevertheless, while a proportion of patients may gain some subjective improvement in nerve function after radiation therapy, most will not and radiation denies them the chance of surgical cure, while still exposing them to the standard risks of radiation. There is undoubtedly therefore still a role for surgery in select cases, but most will be treated with radiation.

It would not be possible to undertake randomized controlled trials to answer these questions because of rarity, need for prolonged follow-up over decades, complex anatomical tumour variability and mixed populations, including older people with comorbidities and patients with and without a variety of germline tumorigenic mutations. Retrospective reviews of published case series, expert opinion and patient choice are therefore all that is available to guide management and it is likely that these complex scenarios will remain controversial for the foreseeable future.

Conclusions

Skull base glomus tumours (paragangliomas) are slow growing benign neuroendocrine tumours, which are locally invasive, but demonstrate low rates of malignant transformation. They are sporadic or familial, in which case *SDHx* mutations are usually implicated. Many patients can be managed with observation and serial imaging alone. When treatment is indicated, radiation and surgery are options, with a recent swing towards radiation treatment for most cases.

Surgical management of cerebellopontine angle and petrous lesions

Nicholas Hall, Yuval Sufaro, and Andrew H. Kaye

Introduction

At the turn of the twentieth century, Harvey Cushing, the father of neurosurgery, described the cerebellopontine angle (CPA) region of the brain as 'the gloomy corner of neurosurgery', famously comparing this anatomical region with the bloody fence corner of the Gettysburg. With limited magnification and illumination, a modern skull base subspecialist neurosurgeon can understand the huge technical challenges that pioneers such as Cushing would have faced treating large tumours with major pre-existing morbidity in this location. At that stage Cushing advocated subtotal tumour debulking as the only rational strategy, however, shortly after that Dandy began to advocate safe total removal of CP angle tumours.

Since these early days introduction of more sophisticated anaesthesia, perioperative antibiotic prophylaxis, the operating microscope, and cranial nerve monitoring techniques have all resulted in significant advances in CP angle surgery. The concentration of cases in subspecialty centres and the recognition of the importance of experience and meticulous technique has transformed skull base surgery into a subspecialty field with consequent reductions in mortality and morbidity. Although fragile and tenuous anatomical structures, supplying critical function, will always make treatment of pathology in this region a high-risk challenge, frequently, curative outcomes are now achieved with minimal morbidity for patients.

This chapter aims to outline the anatomy and pathology of the CP angle. The chapter describes the presentation of patients and investigations needed to make diagnoses for the different pathologies in this region, and the surgical techniques, approaches, and outcomes that we use to treat these lesions.

Anatomy

An intimate understanding of the complex anatomical relationships, anatomical variants and how the anatomy is distorted by pathological processes is critical to the surgeon's ability to access and treat pathologies located in this beautiful but treacherous angle.

An angular cerebellopontine fissure is formed by the petrosal cerebellar surface folding around the pons and the middle cerebellar peduncle with superior and inferior limbs extending from the angle. Within the angle are three subcompartments: superior, middle, and inferior. Each of the compartments contains an arterial supply, a portion of the brainstem, part of the fissure, and a series of cranial nerves.

The superior compartment contains the superior cerebellar artery (SCA), midbrain surface, cranial nerves III, IV, and V, the superior cerebellar peduncle, and the cerebellomesencephalic fissure. The neurovascular complex runs across the cerebellomesencephalic cistern.

The middle compartment contains the anterior inferior cerebellar artery (AICA), the seventh and eighth nerve complex, the anterolateral surface of the pons, the middle cerebellar peduncle, and the cerebellopontine fissure. At the apex of the middle compartment lies the foramen of Lushka medial to which is the lateral recess of the fourth ventricle. The flocculus of the cerebellum lies rostral and slightly posterior to the lateral recess out of which choroid plexus runs.

The inferior CPA contains the lower cranial nerves IX–XII, the posterior inferior cerebellar artery, and the lateral surface of the medulla, the inferior cerebellar peduncle, and the cerebellomedullary fissure. The sixth cranial nerve runs near the base of the fissure in a line containing the superior and inferior limbs of the fissure. The complex anatomy of the cranial nerves, arteries, veins, and cerebrospinal fluid (CSF) arachnoid cisterns, as well as the anatomical variations of these structures, is described comprehensively by Albert Rhoton (Rhoton, 2007).

The cranial nerves traverse across the arachnoid cisterns to enter their respective foraminae within the skull. The hypoglossal nerve runs from the medulla, in a line continuous with the ventral spine nerve roots and anterior to the olive, to enter the hypoglossal foramen in the occipital condyle. The accessory nerve is formed from both spinal and cranial components from the medulla on the inferior third, anterior to the olive and the upper cervical cord. These multiple rootlets are immediately below the brainstem origin of the inferior rootlets of the vagus, which may be indistinguishable as they all run forwards as multiple rootlets to enter the pars vascularis of the jugular foramen. The glossopharyngeal nerve is composed of one or two more substantial trunks that leave the brainstem posterior to the olive, coursing ventral to the choroid plexus and entering the jugular foramen separately to the vagus and accessory nerves within the

pars nervosa. The facial nerve arises from the brainstem at the lateral end of the pontomedullary sulcus 1–2 mm anterior to where the vestibulocochlear nerve enters the brainstem at the lateral end of the sulcus. At the brainstem, the facial and vestibulocochlear nerves are most widely separated joining and running almost together in the pontocerebellar cistern. The AICA frequently passes below or between the brainstem origin of the VII and VIII nerves. The V cranial nerve arises at the midpoint of the pons and runs obliquely forwards from the lateral pons towards Meckel's cave, sitting in the trigeminal impression on the apex of the petrous temporal bone. There is considerable variability of the rotational axis of the trigeminal nerve as it runs across the cistern in close proximity to the superior cerebellar artery.

Presentation of cerebellopontine angle lesions

The different pathologies and their size result in considerable variability of clinical presentation. Smaller lesions may be found either incidentally, as part of the work up for common ailments such as headache, or with specific symptoms related to the location of the lesion and its surrounding structures such as hearing loss and dysequilibrium in the case of vestibular schwannomas. The tempo of onset and the specific neurological symptoms, respectively, give important clues to the type of pathology and the location of the lesion. Vascular, ischaemic pathology and haemorrhage present with hyperacute symptoms over a period of seconds and minutes. Rapidly growing lesions such as metastasis may cause acute hydrocephalus and typically present over days to weeks, but the vast majority of CP angle lesions are slow growing and present more insidiously over months or even years.

The specific neurological features give important clues to the location and type of pathology. Lesions in the upper CP angle often present with trigeminal hypoaesthesia or occasionally facial pain or diplopia. Anterior petroclival lesions may present with diplopia from sixth nerve palsies. Mid-CP angle lesions present with symptoms affecting the seventh and eighth cranial nerve complex, more commonly with dysequilibrium and hearing loss than facial weakness, which may be a sign of a facial neuroma. Lower CP angle lesions may present with a hoarse voice, cough, or recurrent chest infection from aspiration. Larger lesions present with symptoms consistent with hydrocephalus these ranging from headache, nausea, vomiting, and visual deterioration to memory and gait disturbance. Brainstem and cerebellar compression in the largest lesions may present with progressive gait deterioration, weakness, and spasticity followed ultimately by coma and death.

The most common lesion arising within the CP angle is the acoustic neuroma, accounting, over multiple case series, for between 78 and 85% of CP angle lesions (House, 1964; Moffat and Ballagh, 1995). The second most common tumour in this region is the meningioma accounting in Moffat's 1993 series of 305 tumours from Addenbrookes, Cambridge, for 6.5% of tumours (Moffat et al., 1993) and in Revilla's seminal 1947 series for 6%. The third most common lesion within this region is the epidermoid cyst accounting for 4.6 and 6%, respectively. Other lesions in this location have been described but in total account for only 2.7% of lesions. Rare differentials include glomus jugulare lesions 1.7%; other schwannomas: facial 1%, trigeminal 1%, arachnoid cyst 0.7%, and metastasis 0.7%. Other very rare, differential diagnoses include: aneurysm, arteriovenous malformation, choroid plexus papilloma, lipoma, lymphoma, ependymoma, medulloblastoma, chordoma, chondrosarcoma,

Fig. 24.1 Anatomical representation of posterior fossa components. Colours correlate with Table 24.1.

endolymphatic sac tumour, and cholesterol granuloma. The imaging characteristics on MRI and CT can lend considerable help to differentiation of many of these diagnoses and many of the lesions have characteristic appearances. Bonneville elegantly described a segmental approach to the radiological diagnosis of rare CP angle lesions (Fig. 24.1 and Table 24.1) (Bonneville et al., 2001).

The presenting features of differential diagnosis may lend clues to the type of lesion with sparing of hearing and involvement of facial or trigeminal nerves seen more commonly in both the presentation of meningioma and other cranial nerve schwannomas. Other particularly pertinent imaging characteristics for differentiation of lesions include the expansion and remodelling of the internal auditory meatus (IAM) in schwannomas of the VII/VIII nerve complex, the presence of a dural tail and flat base in meningiomas and the presence of CSF-like signal properties, low T1, high T2, in epidermoid tumours with concurrent gross diffusion restriction (high-signal DWI, low-signal ADC map) (Bonneville et al., 2001).

Presentation of patients with vestibular schwannomas

Although the typical presenting symptoms for acoustic neuroma are unilateral hearing loss, tinnitus, and dysequilibrium, there is emerging an increasing group of patients representing 5–12% of presentations with asymptomatic tumours identified incidentally on MRI (Selesnick et al., 1999).

Hearing loss is the most common presenting symptom with numerous historical case series reporting rates of hearing loss at 94–96% (Tos and Thomsen, 1984; Hardy et al., 1989; Kentala and Pyykkö, 2001). Typically, patients experience difficulty with speech discrimination and high-frequency sensorineural loss (Johnson, 1977). The duration of symptoms prior to presentation has been

reported as 3–8 years (Thomsen et al., 1983). Dysequilibrium or vertigo is another common finding in patients with an acoustic neuroma secondary to involvement of the vestibular nerve. This symptom is reported in 50–77% of patients (Hardy et al., 1989; Kentala and Pyykkö, 2001) though it is unusual for this to be the major presenting feature. 47% of patients experience brief episodes of giddiness lasting between 2 seconds and 5 minutes, while 32% of patients had longer attacks lasting up to a few hours. Subtle abnormalities of balance may be detected in patients using the Unterberger's stepping test. In this test, the patient is asked to stand upright with eyes closed and arms outstretched at 90 degrees to the trunk, and to march on the spot. The result is positive if the patient deviates more than 50 cm or in excess of 30 degrees from the spot. More severe ataxia may be found in association with larger tumours and cerebellar dysfunction.

Tinnitus is another common feature at presentation being found in 57–83% of patients. Tinnitus is rarely found in isolation, accounting as the sole presenting complaint in 3% of patients. In his series of 1000 patients, Samii evaluated the preoperative symptoms and found that tinnitus became less common as tumour size increased from 86% in pure intrameatal tumours to 51% in tumours with brainstem compression (Matthies and Samii, 1997).

Cerebellar dysfunction is a common presenting feature in larger tumours, present in 58% of patients if the tumour is more than 4 cm in diameter. Cerebellar dysfunction is commonly picked up with an abnormal finger to nose test and abnormal gait.

Nystagmus is a common sign at the time of presentation and may be of different types depending on the location of compression. Large tumours causing significant compression of the pontine gaze centre may present with opticokinetic nystagmus or Bruns' nystagmus. Bruns' nystagmus comprises coarse ipsilateral horizontal nystagmus and high-frequency fine nystagmus to contralateral gaze. Vestibular nystagmus in smaller tumours manifests as fine horizontal nystagmus beating away from the lesion (Kaye and Laws, 2012).

Cranial neuropathy is found more rarely presenting with subtle trigeminal hypoesthesia often in the V2 distribution in Samii's series in 18% of patients. Rates increase with larger tumours to up to 32% (Matthies and Samii, 1997). Facial weakness is also unusual but can be identified with absence or delay of the blink reflex. This sign may be found in up to 17% of patients (Matthies and Samii, 1997). Loss of sensation in the posterior aspect of the external auditory meatus is common and is secondary to nervus intermedius involvement.

Headache is another common presenting feature found in 20–85% of patients (Stucken et al., 2012). Headache is often the cause for investigations leading to the finding of an incidental acoustic neuroma on MRI or CT brain scans.

Raised intracranial pressure was common in early reports of acoustic neuroma causing the constellation of symptoms of headache, nausea, vomiting, decreased vision, diplopia, papilloedema, and altered consciousness. In Cushing's 1917 series, 66% of patients were reported to have diplopia (Cushing, 1917) compared to only 3% in a more recent study published from UCSF (Selesnick et al., 1993).

Less commonly (1.8%), the abducent nerve is involved producing lateral gaze diplopia (Matthies and Samii, 1997). Rare cases have been described of trigeminal neuralgia, hemifacial spasm, and sudden hearing loss in relation to acoustic neuroma presentation (Matthies and Samii, 1997).

Further evaluation of cerebellopontine angle lesions

Radiological evaluation

Advances in the radiological tools available to clinicians have undoubtedly changed the landscape of diagnosis of skull base and CP angle lesions. From the early days of the use of plain radiographs to image the 'petrous pyramid' in 1910, through the era of pneumoencephalography and contrast myelography, we have moved on to the combination of CT and MRI as our gold standard tools. In diagnostic terms the sensitivity and specificity of MRI in the diagnosis of acoustic neuroma has been reported to be as high as 100% (Brackmann and Kwartler, 1990; Newton et al., 2010). The addition of gadolinium contrast sequences and fine slice acquisition sequences such as heavily saturated T2 fast spin echo and 3DFT-CISS, allow vestibular schwannomas as small as 3 mm to be detected with sensitivity and specificity rates of 97 and 96% (Stuckey et al., 1996; Naganawa et al., 1998).

The typical MRI appearance of vestibular schwannoma is that of a tumour within and usually expanding the IAM, extending variably into the CP angle. The tumour is low signal on T1 sequences and on T2 is low signal compared to CSF and high signal compared to the

pons. Meningiomas in comparison to schwannomas have a broad dural base, are more likely to be isointense to brain on T1 and T2 images precontrast and vividly enhance with gadolinium. CP angle meningiomas are rarely centred on the IAM and when they are do not usually expand the IAM. The shape of meningiomas is typically said to be more oval in the CP angle than the rounder vestibular schwannoma and the meningioma may also have a dural tail sign, not present with schwannomas. Epidermoid tumours have a characteristic MRI appearance, isointense to CSF on T1 and T2 sequences with no gadolinium enhancement but strong diffusion restriction on DWI and ADC map sequences.

Though not necessary in diagnostic terms, CT scans may be useful in the evaluation of CP angle lesions. Expansion of the IAM is better visualized on CT than MRI and calcification is well identified on CT and seen in approximately 25% of meningiomas. We routinely use CT as an adjunct to surgical planning as it provides valuable information regarding the extent of aeration of the petrous temporal bone, the presence of perimeatal air cells and the bony anatomy of the jugular bulb. We use this information to determine the suitability for the translabyrinthine approach and for the extent of drilling of the lateral internal auditory canal in a retrosigmoid approach for removal of a tumour invaginating the canal. In the presence of CP angle tumours involving the petrous temporal bone such as cholesteatoma or glomus jugulare tumours, anatomical information regarding the bony anatomy of the fallopian canal, the medial wall of the jugular foramen and the middle ear is also crucial for surgical planning during exposure.

Audiometry

Given that vestibular schwannomas represent 75–85% of CP angle lesions and characteristically present with hearing loss, the use of audiometry is an important part of the preoperative evaluation of CP angle lesions. As all CP angle surgery has a risk of hearing deterioration it is also important to have a hearing baseline evaluation. In addition, some approaches which may optimize tumour access and resection such as the translabyrinthine approach, result in unilateral deafness. The improved access and subsequent minimization of operative morbidity may make this a preferred approach but the presence of pre-existing contralateral normal hearing must be determined so as to ensure the approach does not render the patient deaf.

Pure-tone audiogram (PTA) thresholds in patients with acoustic neuroma range from 5 to 130 dB with a mean threshold of 66.5 dB. Some 16% of patients have complete loss of hearing precluding testing. 65% of patients have high-frequency loss and 22% have flat type loss (Johnson, 1977; Stucken et al., 2012). Poor speech discrimination is a typical feature of retrocochlear pathology. In Johnson's 1977 study, 24% of 500 patients with acoustic neuroma had no speech discrimination, while 56% had speech discrimination scores (SDS) of 60% or less.

The combination of PTA and SDS form the basis of several definitions for 'serviceable' and 'salvageable' hearing, which are used to assess patients with acoustic neuroma for potential hearing preservation surgery. The Gardner Robertson scale for hearing function classifies patients into excellent, serviceable, non-serviceable, poor, and non-hearing (Table 24.2) with 0–30 dB on PTA and 70–100% SDS being associated with the best chances of hearing preservation.

Auditory brainstem responses (ABRs) measure the synchronized response of neurons in the lower auditory pathways in response to a stimulus. The ABR became an established tool to screen patients for acoustic neuromas after expansion of their application from a research to clinical application in 1977 by Selters and Brackmann (Selters and Brackmann, 1977). ABR involves generating a stimulus and measuring the evoked response. The most commonly used stimulus is the 100 μs click. The response is recorded from scalp electrodes and is displayed as a predictable series of waves that are labelled waves I to V. Waves I and V are the most predictable and respectively demonstrate activity from the cochlear nerve and the neurons of the inferior colliculus. The most reliable latency between waves is the interaural wave I to V latency difference known as IT5. A test latency difference of more than 0.2 ms is abnormal (Selesnick and Jackler, 1992). The sensitivity of the test for diagnosing acoustic neuromas was initially reported as being excellent, with sensitivity reported between 93 and 100% and specificity of 90% (Stucken et al., 2012). Since the introduction of MRI, these figures have been shown to be less accurate with sensitivity of 63–95%; this is particularly the case with small tumours of less than 1 cm where accuracy rates of 58% are cited (Schmidt et al., 2001). The discovery that ABRs were not as sensitive as previously thought led to the development of stacked ABRs. These represent a measurement of essentially all of the VIII CN fibres not just a part and so does not depend so much on size and location of the tumour. In 2005, Don et al. published a series of 54 patients with small tumours demonstrating 95% sensitivity and 88% specificity (Don et al., 2005).

Facial nerve function

Preoperative evaluation of facial nerve function is an important part of diagnostic evaluation. The presence of subtle weakness in vestibular schwannomas is cited in up to 17% of patients though only

Table 24.2 Gardner Robertson hearing classification

Gardner Robertson class	Description	Speech discrimination score (SDS)	Maximum pure-tone audiogram (PTA)
I	Good	70–100%	0–30 dB
II	Serviceable	50–69%	31–50 dB
III	Non-Serviceable	5–49%	51–90 dB
IV	Poor	1–4%	91 dB to max
V	Non	0%	Not testable

one-third of patients have awareness of symptoms (Matthies and Samii, 1997). Larger tumours causing displacement of the brainstem and fourth ventricle have reported rates of 26% (Matthies and Samii, 1997). Subtle weakness may be detected as slowing in the efferent arc of the blink reflex, a small proportion of patients will have altered taste and a larger proportion of patients will demonstrate hypoaesthesia in the posterior external auditory meatus.

Pre- and postoperative facial nerve function should be documented and numerous scales exist to assess facial nerve function. The long-recognized system devised by House in 1985 has widespread acceptance and most postoperative outcomes to date have been reported based on this scale (House and Brackmann, 1985; also see Chapter 22). This scale though has received widespread criticism as it does not allow individual assessment of each area of the face. Of the 19 validated facial nerve assessment tools, only the Sunnybrook system (Ross et al., 1996) scores each facial nerve territory, examines static and dynamic activity and synkinesis with good interobserver reliability (Fattah et al., 2015).

Patients with significant preoperative facial weakness and a CP angle lesion may be suspected of having a facial neuroma. Facial neuromas typically extend laterally beyond the internal auditory meatus and into or beyond the fundus of the IAM.

Operative treatment of CP angle lesions

The complex algorithm for determining the optimal surgical approach for CP angle and petrous lesions must take into account a multitude of factors such as the anatomical location of the lesion, its size, hearing status on the approached side, bony and sinus anatomy of the patient, and the imaging characteristics of the lesion.

The surgical approaches to the posterior fossa can be categorized into the presigmoid and retrosigmoid approaches. While the retrosigmoid approach involves a craniotomy or craniectomy of the occipital bone, the presigmoid approaches mandates drilling out of the petrous bone to allow access to the dura and posterior fossa pathology, anterior to the sigmoid sinus, with minimal brain retraction. The term presigmoid usually refers to posterior petrosal approaches, which are all extensions of the basic mastoidectomy. Included under this category with a progressively increasing extent of petrous bone resection from posterior to anterior are the retrolabyrinthine, translabyrinthine, and the transcochlear approaches. These allow a surgical corridor into the CPA, specifically to the middle and upper thirds of the clivus. The more anterior the petrous bone resection, the wider the surgical corridor into the posterior fossa (Fig. 24.2). The retrolabyrinthine approach, almost never used in isolation, spares the vestibular organ, thus being the least morbid of the three approaches, while the translabyrinthine approach involves its resection therefore inevitably resulting in hearing loss. Further resection of the cochlea requires transposition of the facial nerve and the possibility of at least partial facial nerve injury, thus increasing approach related morbidity significantly. Some modifications to the transpetrosal approaches have been described, aimed to address the high associated cranial nerve morbidity while allowing improved surgical exposure. In the trancrusal approach, selective resection of the posterior and superior semicircular canals from ampulla to common crus, allows for exposure in the range close to that of the translabyrinthine approach while providing a substantial chance of preserving hearing. Hearing preservation outcome reports with this approach are scant, mainly owing to its infrequent use due to the highly specific skills

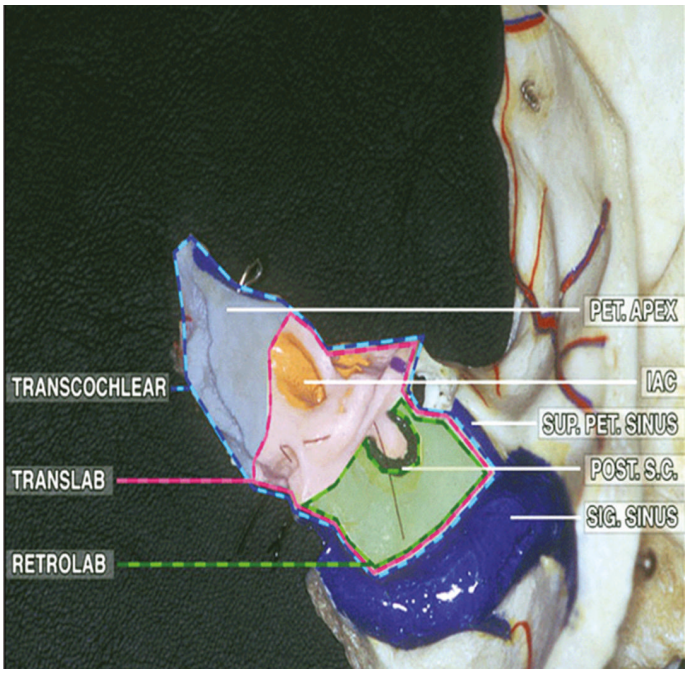

Fig. 24.2 Three-dimensional demonstration of the bone resection for the transpetrosal approaches.

needed. However, it is reported to be 58–100% (Sekhar et al., 1999; Horgan et al., 2001; Kaylie et al., 2004; Brandt et al., 2010). In the transotic approach, the otic capsule is entered with complete removal of the semicircular canals and skeletonization of the facial nerve. As in the transcochlear approach, hearing is lost but facial nerve morbidity is reduced. Similarly to the transcrusal approach, outcome data for the transotic approach is not robust. The reporting of facial nerve functional outcome is often equivocal. Most of the studies available refer to HB I–II as good facial functional outcome. Reports of HB I-II at long-term follow-up vary from 27% to 90%. The type of pathology also plays a role. When the transotic approach was applied for resection of petroclival meningiomas, functional results of the facial nerve differed to a greater degree (De la Cruz and Teufert, 2009; Gurgel et al., 2012; Miller et al., 2015).

In general terms the retrosigmoid approach offers wide access to the CP angle. With this approach lesions are resectable across the whole of the CP angle from tentorium to foramen magnum. If smaller lesions lie medial to the petro-occipital synchondrosis the retrosigmoid approach allows limited access without unacceptable morbidity from brainstem retraction. Larger clival and petroclival lesions enable anterior access as the tumour has effectively opened a dissection corridor by displacing the brainstem during its slow growth. The retrosigmoid approach is limited superiorly by the tentorium and lesions that extend above the tentorial hiatus or beyond the petrous apex into the middle fossa are difficult to resect completely using this approach alone. In this circumstance either a staged or combined middle fossa–presigmoid approach allows access above the tentorium and the petrous apex.

In larger lesions centred around the IAM such as large vestibular schwannomas we prefer to utilize the translabyrinthine approach. This has the advantage of minimizing cerebellar retraction by rotating the angle of approach to the tumour buried into the cerebellar hemisphere, it also shortens the working distance between surgeon

and tumour allowing greater instrument control. With adequate exposure by an experienced surgeon the translabyrinthine approach allows even the largest schwannomas to be removed. Anatomical factors that may make this approach less desirable include a high dominant jugular bulb, a poorly pneumatized mastoid, and an anteriorly placed sigmoid sinus. These factors all reduce the working space within this approach and reduce the angle available for visualization particularly of the inferior and brainstem aspects of a larger tumour.

A combined presigmoid middle fossa approach gives excellent exposure for lesions located anterior to the cranial nerves, but with increased morbidity related to the approach. The commonest is the combined retrolabyrinthine middle fossa craniotomy which allows visualization of tumours antero-lateral to the upper pons and lower midbrain especially if there is extension into the middle fossa.

For lesions predominantly at the petrous apex and within the middle fossa, such as many trigeminal schwannomas, the widest access for optimal resection would usually be provided via a predominantly middle fossa, subtemporal approach with the possibility of further petrous apex removal via approaches such as the Kawase approach. The borders of the Kawase triangle are defined by the V3 division of the trigeminal nerve anteriorly, the greater superficial petrosal nerve laterally, the arcuate eminence posteriorly, and the superior petrosal sinus medially. This approach is also referred to as the anterior petrosal approach. In these lesions it is common for much of the bone to be already eroded by the tumour itself. In the case of intracanalicular tumours with minimal CP angle extension and intact hearing a middle fossa approach to the IAM also facilitates removal.

While the anatomical location and size of the lesion play a major part in the decision-making algorithm, temperance must be exercised. In patients with significant comorbidities or advanced age, the optimal choice of approach may be simply the least invasive approach. In this situation the goal of surgery might change from complete excision of the tumour to decompression of the brainstem and cerebellum with a limited debulking procedure via a retrosigmoid approach. The surgeon's hubris for complete tumour excision must be constrained in situations of high morbidity such as in facial or lower cranial nerve schwannomas or in patients with NF2 where hearing preservation is a maxim.

In addition, the expected tumour consistency and vascularity of the lesion play a part in determining the ideal approach. Tumours with high T2 signal might be expected to be less firm and allow intracapsular debulking and mobilization from surrounding neurovascular structures with greater ease. Conversely a tumour with an expected high vascularity or firm consistency may require a more elaborate approach to maximize access and give the operator shorter, better angles for tumour removal.

In some cases, particularly where a tumour extends widely from anterior to posterior cranial fossae multiple staged approaches are required.

Retrosigmoid approach

The retrosigmoid approach is ideal for vestibular schwannomas where hearing preservation is being attempted. We also favour this approach for many other tumours centred on the petrous temporal bone. This approach also lends itself to access larger more anterior lesions such as petroclival meningiomas, and is especially useful in the older and more medically frail population where extended anaesthetic duration or temporal lobe manipulation may be less well tolerated. For the majority of epidermoid tumours this approach allows safe removal of the tumour and the angled endoscope can facilitate complete removal.

Positioning: Although numerous positions are described for this approach, we favour the lateral or park-bench position. The patient is placed laterally on the operating table with the operative side up. The contralateral axilla with an axillary roll is at the uppermost end of the table with the contralateral arm held in a sling attached to the arm gutter for the ipsilateral arm. Both legs are flexed and two pillows placed transversely between them. The hips are taped to the table and a back support placed mid-torso to which the ipsilateral shoulder is taped gently. The head is held in a three-pin head holder, and flexed and rotated 10–15° towards the floor. At this time, a lumbar CSF drain is usually placed. Continuous electrophysiological monitoring for facial nerve function during the operation is essential. For tumours low within the CP angle we also favour monitoring of lower cranial nerves using an endotracheal tube with vocal cord monitoring, a soft palate electrode, and trapezius electrode. We occasionally utilize the semi-sitting position for large patients with short necks.

Incision and exposure. A slightly sigmoid incision is made 1 cm posterior to the mastoid from approximately 2.5 cm above the transverse sigmoid junction to below the level of the mastoid tip. The inferior end of the incision is curved away from the mastoid tip so as to avoid the deeply placed vertebral artery coursing around the transverse process of C1 (**Fig. 24.3**). The muscles and fascia are reflected from the suboccipital region, lateral to the digastric groove. A burr hole is then made at the level of the asterion and the hole widened to expose the transverse sigmoid junction. Further burr holes are made posteriorly to expose the transverse sinus and inferiorly over the thin occipital bone and the craniotomy is completed. Care must be taken to preserve the dura and ensure the more superficially placed sinuses are not damaged during exposure and that the frequently placed mastoid emissary vein is skeletonized away from the sinus and coagulated and divided away from the sinus wall. We find the use of a 5 mm coarse diamond burr helpful to safely skeletonize the sinus. The dura is opened in an asymmetrical Y shape, basing the edges of the opening on the sigmoid and transverse sinuses. Prior to opening the dura 5–10 ml of CSF is drained via the lumbar catheter. This relaxes the dura and the contents of the posterior fossa. The presence of a very large tumour with untreated hydrocephalus would be a contraindication to a spinal drain, in which case the cisterna magna needs to be accessed for CSF drainage through a small durotomy. After opening dura, the basal cisterns can be accessed utilizing the operating microscope for further drainage of CSF.

At this stage, a Greenberg retractor system is attached and the retractor blade may, only if necessary, be used to very gently retract the cerebellum. Following identification of the tumour, the arachnoid plane overlying the posterior capsule is identified and opened. This greatly facilitates dissection of the tumour capsule away from surrounding structures all of which must be preserved. Inferiorly, the CN IX–XI complex and loop of AICA are identified and preserved. Branches of AICA are frequently associated with the posterior capsule of vestibular schwannomas and tumours in the mid-CP angle, and these must be preserved. However, smaller branches that are seen to enter the tumour capsule may be coagulated and divided.

Fig. 24.3 Positioning and incision for retrosigmoid craniotomy. (A) Skin incision; (B) lateral positioning; (C) lateral positioning noting the arrangement of axillary roll, contralateral slung arm, and ipsilateral arm gutter.

Superiorly, CN V and IV are identified along with the superior petrosal vein of Dandy. The vein is preserved if possible but occasionally may need to be coagulated and divided, especially if thought to be at risk of being avulsed from the superior petrosal sinus. Care should be taken to ensure no branches of the SCA are inadvertently coagulated at this time, which may account for some of the reports of morbidity associated with coagulation of this vein.

In most CP angle tumours, it is possible to enter the arachnoid plane between tumour capsule and cerebellum and dissect the plane to visualize the brainstem and respective cranial nerves at their root entry zones. In larger tumours, with more gross brainstem compression, internal debulking of the tumour must precede this step utilizing a combination of bipolar coagulation, sharp dissection, and a suction aspirator to perform internal debulking. The bipolar forceps must be used at the lowest voltage settings to minimize the risk of heat transmission and injury to the nerves. In the case of vestibular schwannomas, following internal debulking, the tumour can be further mobilized inferiorly allowing dissection of CN V from the superior tumour capsule, and laterally allowing full visualization of the eighth nerve root entry zone and AICA. If hearing preservation is not being attempted, the vestibular and cochlear fibres can be divided sharply with care taken to ensure that CN VII lying immediately adjacent is preserved. Frequently, AICA runs between the two nerves. The facial nerve may also be identified by its white colour and close proximity to the root entry zone of the glossopharyngeal nerve and confirmed by gentle electrical stimulation. Following identification of the VII CN, the tumour can then be further debulked and the tumour brainstem interface sharply and carefully opened. The VII nerve is dissected from the capsule meticulously using microscissors or a sharp arachnoid knife in a side-to-side direction. Where hearing preservation is a goal, the cochlear nerve is not divided but similarly dissected free of the tumour capsule with a meticulous sharp technique.

In the case of other CP angle tumours, the principles remain the same, with internal debulking creating room for the tumour capsule to be rolled away from surrounding vessels and cranial nerves as well as the cerebellum and brainstem. The layering of the arachnoid planes around a vestibular schwannoma mean that the facial nerve lies stretched, directly on the surface of the tumour capsule. In contrast meningiomas usually demonstrate a layer of arachnoid between the capsule and the overlying neurovascular structures which facilitate the identification of meticulous dissection planes. Where tumours extend into the IAM or jugular foramen, further bone removal may be necessary to remove this tumour bulk safely. Once the dura of the IAM has been opened and arachnoid dissected between the tumour capsule and the margins of the IAM the tumour may be further debulked to allow mobilization. Following excision of the lesion, the lateral extent of the IAM is inspected using a 70° endoscope to ensure that no small volume tumour residual remains beyond the lateral extent of the drilled canal.

Translabyrinthine approach

This approach sacrifices hearing so particularly lends itself to treatment of larger vestibular schwannomas where hearing is already diminished. It is particularly useful for these tumours as the exposure

opens the posterior and superior walls of the IAM allowing exposure of the facial nerve at the fundus of the IAM, thus allowing good visualization of the most lateral part of the tumour for gross total resection. In addition, the exposure provides a more direct approach to the CP angle and negates the need for cerebellar retraction. The approach when combined with a middle fossa craniotomy and division of the tentorium also provides panoramic access to anteriorly located tumours high within the CP angle and extending into the middle fossa. Care must be taken during this approach to evaluate and preserve the insertion of the vein of Labbe and to minimize elevation of the temporal lobe, damage to either of these structures can result in significant morbidity.

In a typical translabyrinthine approach, the posterior fossa dura is opened in Trautmann's triangle bounded by the sigmoid sinus, jugular bulb, and superior petrosal sinus. The presence of an anteriorly placed sigmoid sinus or superiorly placed jugular bulb may restrict the access of this approach. The high-riding jugular bulb may be found in 9–18% of temporal bones and is predicted by poor pneumatization of the temporal bone.

We perform most CP angle surgery requiring skull base specialist exposure as a skull base team together with highly experienced and skilled neuro-otologists. We prefer to use the supine position for this procedure with the head placed in three-pin fixation and rotated to approximately 45°. Lateral flexion should be used to widen the angle between the shoulder and the exposure to better visualize the tentorium in larger superior lesions. The head of the table should be raised to 30 degrees to improve venous return and the neck should slightly extended so the fallopian canal is parallel to the floor. Fat is harvested from the abdomen and if tentorial reconstruction is needed fat and fascia lata are harvested from the lateral thigh. We use a generous C-shaped incision, placed well behind the mastoid and sigmoid sinus. Following elevation of a scalp flap, fibroperiosteal flaps are elevated after performing a T-shaped incision exposing the cortical mastoid bone. The neuro-otologist then performs an extensive cortical mastoidectomy.

The lateral cortical mastoidectomy is completed exposing anteriorly the thinned bone overlying the external auditory canal. Superiorly the dura of the middle fossa and superior petrosal sinus is exposed and posteriorly the sigmoid sinus is exposed and the mastoid decorticated to show the digastric notch and followed towards the jugular bulb. The mastoid antrum and aditus is opened and the incus removed to demonstrate the lateral semicircular canal on the medial wall of the epitympanic recess, deep and anterior to which lies the horizontal portion of the facial nerve. The semicircular canals are then identified and opened, removing the lateral canal to open the vestibule and the posterior and superior canals to demonstrate the common crus deep to which lies the second genu of the facial nerve. The fallopian canal is skeletonized. Deep to the vestibule the internal auditory canal (IAC) is then opened to 270° and laterally to the fundus where the transverse crest is identified. CSF can usually be partially drained via the cochlear aqueduct to allow some cerebellar relaxation. Technical aspects we consider to be particularly pertinent with this approach include removing occipital bone approximately 1 cm behind the sigmoid sinus to allow posterior retraction of the sinus thus increasing exposure. We also take pains to minimize compression of the sigmoid sinus or aggressive lowering of a high-riding jugular bulb in the case of a dominant venous sinus complex. In some circumstances this influences the decision to perform this approach versus a retrosigmoid approach. We also consider maximal exposure of the IAM helpful, particularly in larger, more anterior tumours where 270° opening of the IAM achieves improved access to this portion of the tumour (**Fig. 24.4**).

In cases of vestibular schwannoma, the IAC dura is opened allowing identification and stimulation of the facial, vestibular, and cochlea nerves at the fundus. In our team the neurosurgeon then opens the dura, releases CSF, and identifies the arachnoid planes surrounding the tumour. The tumour capsule is stimulated and safely opened, allowing internal debulking of the lesion using scissors, suction, and cavitronic suction aspiration. This debulking allows the edges to be rolled away from the cerebellum, superior petrosal vein, lower cranial nerves, and traversing SCA branches. Once the tumour is debulked enough to identify CN VIII and VII at the brainstem, the lesion is further debulked and rolled off these nerves laterally. Arachnoid dissection and removal of the thinned capsule usually allows lateral displacement and resection of the tumour until the nerve becomes more adherent towards the porous of the IAM. Where the nerve spreads widely and becomes attenuated in calibre the most meticulous dissection must occur to preserve facial function. The IAM component of the tumour is often reduced until just this part remains. We then remove this and the IAM component in a medial to lateral direction with the aim to achieve complete tumour extirpation. If the facial nerve is particularly adherent and thinned, we may elect to leave a small volume of residual capsule at this point alone, though this is rarely necessary. Constant electromyography (EMG) monitoring during tumour debulking and facial nerve dissection is essential to reduce injury to the nerve. Proximal stimulation can be used to assess functional integrity both during dissection and at the completion of the tumour removal.

Following meticulous haemostasis, the opened dura is closed under magnification to the dura of the porus acusticus. The middle ear cavity is then packed with a combination of small pieces of fat and muscle, and after filling the CP angle with irrigation solution an antibiotic fat graft is placed in the mastoid cavity. The temporalis fascia is closed in a watertight fashion and the skin closed in layers with a mastoid bandage and dressing to reinforce the closure.

Retrolabyrinthine approach

The retrolabyrinthine approach allows access to middle clival region. On its own, the amount of petroclival region and CPA exposure is limited. However, in patients with serviceable hearing, as part of a combined transtentorial, middle fossa approach, this technique has an important role in the resection of lesions spanning the posterior and middle fossae. A detailed description of the approach can be found in the surgical literature (Brackmann, 1979; McElveen et al., 1988; Glasscock et al., 1991; Ortiz Armenta, 1992). Positioning of the patient is similar to that described for the translabyrinthine approach. After completing the mastoidectomy, further medial resection of the temporal bone is performed using the high-speed drill in order to expose Trautmann's triangle, which corresponds to the area of cerebellar dura limited by the jugular bulb inferiorly, the middle fossa dura superiorly, the superior petrosal sinus and sigmoid sinus posteriorly, and the otic capsule anteriorly. The endolymphatic sac can be seen along the inferior portion of Trautmann's triangle, inferior to the posterior semicircular canal. Great care should be taken not to dissect the endolymphatic sac or drilling into the semicircular canals as this may well result in permanent hearing loss. The dural

(C) Extended mastoidectomy completed with skeletonization of the semicircular canals and descending facial nerve. (D) Temporal bone and internal auditory canal dissection complete: lines for dural incision shown. (E) Initial tumour exposure following dural incision and retraction. (F) The tumour bed at completion of the resection. The facial nerve is shown in its most usual position displaced medially and upwards. (G) Postoperative CT demonstrating the left temporal bone defect following translabyrinthine removal of a large acoustic neurinoma. Exposure of the cerebellopontine angle and internal auditory meatus is more direct than via a suboccipital approach.

(A–F) This article was published in *Brain Tumors: An Encyclopedic Approach*, Third edition, Kaye, Andrew H. II. Laws, Edward R., pp. 535 to 553, 614, Copyright Elsevier 2012.

flap is then elevated with an anterior base in parallel with the otic capsule.

Transcochlear approach

Of the posterior transpetrosal approaches, this provides the maximum amount of petrous bone removal and the most anterior exposure. It offers a wide corridor to the middle and upper thirds of the clivus as well as to the anterior brainstem. This approach is not very useful for the resection of acoustic neuromas and is associated with intrinsic associated morbidity, such as facial paralysis and potential CSF leakage. There is a transotic variation where the bony facial canal is left intact and remains as a bridge within the approach field. There are two variations of the transcochlear approach. The original, as described by House and Hitselberger, involves facial nerve transposition (Hitselberger, 1966; House and Luetje, 1979). It involves complete skeletonization of the facial nerve to mobilize the nerve posteriorly and to obtain a flat exposure. The greater superficial petrosal nerve is cut where it emerges from the geniculate ganglion so that the facial nerve can be released and mobilized. Once the facial nerve is mobilized posteriorly, the cochlea is entered. In the transotic approach described by Fisch, the facial nerve is not mobilized, but the external auditory canal is occluded and resected. Drilling continues to the petrous apex along the inferior petrosal sinus. The petrous portion of the internal carotid artery constitutes the lateral aspect of the exposure.

Combined middle fossa and transpetrosal approach

Tumours involving the petroclival region with extension into the perimesencephalic or peripontine structures can be approached using the petrosal approach. For more extensive lesions extending anteriorly to the clinoidal and carotid cisterns, the extended petrosal approach should be considered. To access these regions, the petrosal approach offers a number of advantages. The surgeon's operative distance to these regions is shorter than with the retrosigmoid approaches, there is minimal retraction of the cerebellum and temporal lobe, the neural structures (i.e. cranial nerves VII and VIII) are preserved, the otologic structures (i.e. cochlea, labyrinth, and semicircular canals) are preserved, the major venous sinuses (i.e. transverse and sigmoid), along with the vein of Labbe and other temporal and basal veins, are preserved.

The patient is positioned in much the same manner as for a translabyrinthine approach. The incision starts at the zygoma, anterior to the tragus, and extends posteriorly approximately 2–3 cm above and encircling the ear, where it descends behind the mastoid process. The skin flap is sharply dissected from the underlying pericranium and fascia. The temporalis fascia is reflected sharply and is kept in continuity with the sternocleidomastoid muscle then the temporalis muscle itself is sharply dissected off the bone and reflected anteriorly and inferiorly. Four burr holes, two on each side of the transverse sinus, are made. The first burr hole is placed just medial and inferior to the asterion, which is located at the inferior junction of the transverse and sigmoid sinuses. The second burr hole is placed at the squamous and mastoid junction of the temporal bone, along the projection of the superior temporal line, which opens into the supratentorial compartment. The final two holes are placed approximately 2–3 cm more medially and closer together on either side of the transverse sinus. A temporoparietal craniotomy and lateral occipital craniotomy are performed without connecting the burr holes across the sinus. The holes across the sinus are then connected. After meticulous separation of the wall of the sinus from the flap, the bone plate is elevated. The surgeon next performs a posterior petrous temporal bone removal, either retrolabyrinthine or translabyrinthine depending on the extent of tumour and the patient's preoperative hearing status. Once the bone removal has been completed, the dura of the posterior fossa is opened. Superiorly, the dura overlying the temporal lobe is also opened and these are joined ligating the superior petrosal sinus anterior to the insertion of the vein of Labbe, which must be preserved. The tentorium is then divided under microscopic visualization with a loosely placed retractor sitting under the temporal lobe for support. At the tentorial hiatus deep retraction sutures are placed before careful completion of the medial tentorial division posterior to the point where the IV CN enters the medial aspect of the tentorium. The IV can be seen traversing the perimesencephalic cistern beneath the arachnoid prior to this step. The dural edges are retracted forwards revealing this panoramic exposure. (Fig. 24.5).

Surgical outcomes for CP angle lesions

Vestibular schwannoma

For the purposes of assessing efficacy of removal of vestibular schwannomas both the retrosigmoid and translabyrinthine approaches have comparable outcomes. There are advantages and disadvantages of either approach and in practical terms most teams develop an approach that they are most familiar and comfortable with.

The single biggest determinant of outcome in terms of mortality, facial nerve function, and hearing preservation has been documented across multiple series as the size of the tumour (King and Morrison, 1980; Ruth et al., 1985; Hardy et al., 1989; Anderson et al., 2005; Samii et al., 2010; Sughrue et al., 2011). Though debate continues regarding the approach associated with the least morbidity,

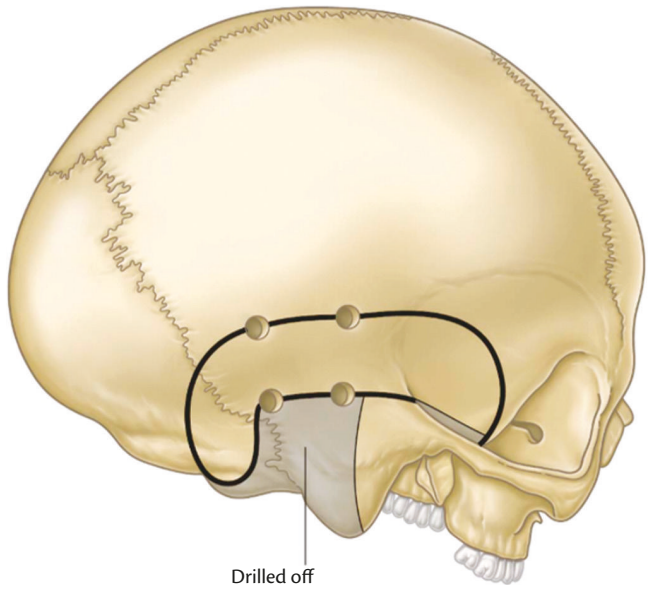

Fig. 24.5 Craniotomy for combined presigmoid middle fossa approach.
This article was published in *Brain Tumors: An Encyclopedic Approach*, Third edition, Kaye, Andrew H. II. Laws, Edward R., pp. 535 to 553, 614, Copyright Elsevier 2012.

there have been many studies highlighting good results for each of the approaches.

When considering the choice of approach for a given lesion, we consider that other than in the case of bilateral tumours or pre-existing contralateral hearing loss, most patients' primary concerns are the issues of postoperative facial weakness and completeness of resection of the lesion, rather than preservation of hearing (Kaye and Laws, 2012). The psychological impact of facial weakness in terms of a patient's perceptions of outcome should not be underestimated and is a major determinant of postoperative quality of life (Ryzenman et al., 2005; Nicoucar et al., 2006; Browne et al., 2008).

Sughrue from UCSF recently comprehensively reviewed the outcome of facial nerve preservation across the acoustic neuroma literature evaluating 296 studies with 25 000 patients and reporting on 11 873 patients across 79 studies (Sughrue et al., 2010b). This analysis defined facial nerve preservation as an outcome of House–Brackmann score of I or II, and demonstrated outcomes of 85% via the middle fossa approach, 81% via the translabyrinthine approach, and 78% for the retrosigmoid approach. Patients with tumours less than 2 cm had facial preservation rates of 90% versus 67% in tumours more than 2 cm. Patients less than 65 years old had lower facial preservation rates 71% versus 84% and intraoperative monitoring was associated with improved facial nerve outcomes. The presence of preoperative facial weakness is an independent predictor of postoperative facial weakness with rates being as high as 33%. Preoperative facial weakness is associated with large tumours and may also be associated with involvement of tumour invested within the nerve rather than displacing it (Lye et al., 1982).

If gross weakness exists preoperatively, or if the facial nerve is severed during surgery, consideration should be given to facial nerve reconstruction options intraoperatively. Facial nerve cable grafting using sural or greater auricular nerve grafts have been shown to have outcome rates of House–Brackmann III or better in 45–75% of cases (Fisch et al., 1987; Stephanian et al., 1992; Gidley et al., 1999; Bacciu et al., 2009). In this event microsurgical repair follows standard microsurgical techniques, with delicate and minimal nerve handling and tensionless apposition of the epineurium.

Auditory monitoring techniques: As surgical techniques have developed and the rates of functional and anatomical preservation of the CN VII have improved, attention has been focussed towards the goal of hearing preservation surgery. Adjuncts developed to assist in the monitoring and preservation of VIII nerve function are based on either 'far field' or 'near field' techniques. Far field intraoperative auditory monitoring techniques were first used and described in 1978 by Levine (Levine et al., 1988). There are several techniques currently used to monitor auditory function.

Brainstem auditory evoked potentials (BAEPs) represent the bioelectric neural activity that occurs in response to the stimulation of the vestibulocochlear nerve. This is produced by placing scalp and ear electrodes, and monitoring averaged responses from an auditory stimulator placed in the operated ear. The BAEPs have to be distinguished from background noise requiring averaging of several thousand responses and thus have a significant time lag. This delay in response of seconds to minutes means it may be difficult to determine the cause of a change in waveform. The prognostic significance of BAEPs is based solely on the preservation of waves and is thus of limited value (Oh et al., 2012). Setting up and monitoring intraoperatively requires expertise and should be performed by an expert technician.

The electrocochleogram (EcoG) and direct compound near action potentials (dCNAPs) record electrical response close to the origin of stimulus on the cochlear nerve. This means that the averaging needed to detect a stimulus is reduced and a more rapid assessment of nerve function is achieved. In this technique, reference and ground electrodes are placed on the ipsilateral earlobe forehead, respectively. A foam ear plug not only holds the electrode in place but also reduces external sound interference. The stimulating electrode administers click impulses and responses are averaged for a wave pattern to emerge. In dCNAP, the action potential is measured directly from the acoustic nerve itself after placing an electrode on the nerve proximal to the tumour. These near-field techniques have the advantage of being more rapidly attained and thus more reflective of an intraoperative change. The utility of dCNAP is also increased by its higher predictive value in postoperative function with improved sensitivity and specificity (Yamakami et al., 2009). The near-field techniques do have specific disadvantages with EcoG providing only functional information about the lateral part of the auditory pathway. A proximal division of the nerve may not be identified using this technique (Colletti et al., 1998). dCNAP recording may also present technical difficulties with placement of the CN VIII electrode made difficult in moderate or large sized tumours, thus, generally limiting the use of this technique to removal of smaller tumours where some groups have reported improved outcomes in terms of hearing preservation (Danner et al., 2004) at rates of up to 71% in small tumours.

Hearing preservation outcomes: Results relating to the efficacy of performing surgery with hearing preservation as a goal have been widely reported and the success rates of this approach are significantly different across the board. Quotes range from 17–100% with regards to hearing preservation and a clear relationship between the size of the tumour and hearing preservation rates. Although many authors would argue that hearing preservation rates are negligible in larger tumours, some authors have published data showing hearing preservation rates of 43% in very large tumours (Matthies and Samii, 2002). Sughrue recently reviewed the literature regarding hearing preservation rates and identified 123 studies, 49 of which detailed data that could be extracted (Sughrue et al., 2010a). Of 998 patients included in their analysis, hearing preservation was most significantly dependent upon the size of the tumour, preoperative hearing levels, and the age of the patient. Overall hearing rates were 52% over a follow-up period of 6 months to 7 years. Hearing rates in patients less than 30 years of age were 53% versus 29% in patients more than 60 years. Tumours smaller than 1 cm had hearing preservation rates of 64% compared to 32% in tumours larger than 3 cm.

Long-term durability of hearing preservation surgery also remains a contentious issue with the House group reporting delayed hearing loss in 56% of their patients (Shelton et al., 1990). Theories for the mechanism of delayed hearing loss include scar tissue formation around the cochlear or microvascular injury to the cochlear blood supply (Chee et al., 2003). Since then, a number of other studies have shown ongoing durability of long-term hearing preservation with maintenance of rates of 85–96% (Betchen et al., 2005; Woodson et al., 2010; Mazzoni et al., 2012).

Acute hearing loss in the contralateral ear has been reported as a complication of acoustic neuroma surgery, and mild hearing

loss is common following posterior fossa surgery. The mechanism behind this phenomenon is poorly understood but may relate to low CSF pressure in the perilymph and perilymphatic hypotonia. This may also improve spontaneously (Clemis et al., 1982; Walsted et al., 1991).

Brainstem and cochlear implants

The presence of an intact and functional cochlear nerve and cochlear allows placement of a cochlear implant. In the case of vestibular neuroma surgery this may be utilized if a translabyrinthine approach is used for technical considerations and the cochlear nerve is preserved.

Auditory brainstem implants (ABI) are typically used in a situation where hearing is threatened bilaterally. This situation arises most commonly in patients with Neurofibromatosis type 2 (NF-2) where the patient has bilateral vestibular schwannomas. The implant can be placed either following first tumour removal where a gross total removal is expected as hearing on this side has already significantly diminished or been lost, or after removal of a second schwannoma where hearing has been lost. Patients with preserved hearing gain little benefit from an ABI as it is rare to get more hearing quality than environmental sounds and closed-set words. If an ABI is placed at first side surgery with hearing intact it is not usually used until hearing on the contralateral side has been lost. Although detailed discussion is beyond the scope of this chapter, if possible, we favour debulking of tumours in patients with NF-2 with attempt to preserve hearing and minimize the morbidity of deafness. Placement of an ABI is feasible with either a retrosigmoid or translabyrinthine approach. The surgical technique is well described (Toh and Luxford, 2008) but essentially involves placement of an electrode on the ventral cochlear nucleus. This is not visible directly and so must be placed using indirect surface landmarks within the lateral recess adjacent to the dorsal nucleus and the inferior aspect of the ventral nucleus between the roots of the facial and glossopharyngeal nerves. Once placed, an electrode array is used to test the response of the implant and adjacent nerves and structures. The array is secured using Teflon or fat within the opening of the lateral recess and the electrode lead positioned in the mastoid cavity and the ground electrode under the temporalis muscle.

Results for the ABIs indicate that 85% of patients receive auditory sensations. Combined with lip reading, 93% of patients demonstrated improved sentence understanding at 3–6 months. Most patients have awareness of environmental sounds as well as closed-set words, consonants, and vowels. Results continue to improve for 8 years (Ebinger et al., 2000; Maini et al., 2009).

Petroclival meningioma

Petroclival meningiomas arise from the upper two-thirds of the clivus, medial to the fifth cranial nerve. These tumours typically displace the brain stem, but may displace or engulf the basilar artery, cranial nerves III–XI as well as extend into Meckel's cave, the cavernous sinus, Dorello's canal, the internal auditory meatus, or the jugular foramen. Surgical removal is frequently challenging and as such, operative morbidity may be correspondingly significant.

Published series examining extent and morbidity of resection have varied greatly, mainly being influenced by the philosophy of the treating team. The substantial morbidity of petroclival meningioma resection certainly urges weighing aggressiveness versus outcome. Factors including improvements in microscope technology, preoperative imaging, and the development of radiosurgical techniques have resulted in improved patient outcomes. In larger tumours microsurgery remains the only viable treatment option. The resection of these tumours is undoubtedly associated with significant morbidity. Feng Xu et al. reviewed 840 cases of patients that underwent surgical resection for petroclival meningioma. Mortality ranged from 0 to 9%, new cranial nerves deficits ranged from 20.3% to 76%. Gross total resection was 28–85% (Xu et al., 2013). Almefty et al. reported the results of 64 patients of whom 54 had long-term follow-up, 39% had persistent cranial nerve deficits, mainly cranial nerves V–VIII. Notably CN V and VIII were more likely to improve from preoperative status while CN VI is the most at risk for permanent deficit (Almefty et al., 2014). Brain stem compression is frequent with large tumours. Dissection of tumours that have brainstem pial or basilar artery encasement may lead to catastrophic brain stem infarct. Preoperative indicators that may be helpful to identify are tumour consistency as measured by T2 signal, presence of a CSF cleft between tumour and brainstem on MRI, or MRI evidence of brainstem oedema, which suggests increased adhesiveness to the brain stem (Uede et al., 1996; Carvalho et al., 2000).

Extent of resection does play a role in recurrence rate. Following gross total resection, recurrence rates of 6–9.8% have been reported. Following subtotal resection recurrence is reported to be as high as 26–41% (Seifert, 2010; Li et al., 2013; Almefty et al., 2014). In patients where GTR is precluded by expected severe neurological morbidity, radiation therapy may be initiated following evidence of progression of tumour growth.

Trigeminal schwannoma

With modern microsurgical techniques mortalities have been drastically reduced. Chen's review of 459 patients described five operative deaths and a mortality rate of 1% (Chen et al., 2014). Additional morbidity includes cranial nerve injury, CSF leak, meningitis, and hydrocephalus. Many patients will be left with some degree of permanent trigeminal dysfunction, most commonly the persistence of trigeminal hypoesthesia (Fukaya et al., 2010), which patients should be informed may never resolve. The combination of this with facial nerve injury often necessitates eyelid closure techniques to prevent neurotropic keratitis. New onset postoperative cranial nerve dysfunction, such as abducens and oculomotor palsies, usually resolve within 4 months. Some preoperative neurologic deficits, such as cerebellar and brainstem compression syndromes, diplopia, facial pain and weakness, and hearing loss may improve postoperatively. CSF leak and/or hydrocephalus may require shunt placement.

Jugular foramen schwannoma

Complications following surgical removal of these tumours potentially include dysphagia, hoarseness, aspiration, and stridor. Most recent reports have demonstrated a remarkably low incidence of serious dysphagia and aspiration (Bakar, 2008; Bulsara et al., 2008; Cavalcanti et al., 2011). In some persistent cases of serious dysphagia, tracheostomy or vocal cord medialization techniques may be needed. Many patients though can be managed with temporary nasogastric feeding and meticulous pulmonary toilet in order to reduce the chance of aspiration pneumonia. Most will eventually adapt and tolerate a regular diet.

Dermoid and epidermoid tumours

With the development of microsurgery, the mortality and morbidity of dermoid and epidermoid tumour surgery have dropped dramatically. Yaşargil et al. were able to obtain an improvement in 86% of their patients, with a 9% neurologic morbidity and 5% mortality. In this same series the rate of meningitis (including chemical) was described to be 19%, and hydrocephalus was present in 19% of the patients (Yaşargil et al., 1989).

The primary complications from management of these lesions are aseptic meningitis, septic meningitis, hydrocephalus, and neurological dysfunction related to the position of the lesion. The neurological deficits of concern follow involvement of the lower cranial nerves and subsequent difficulty with swallowing, aspiration pneumonia, and death.

Both dermoid and epidermoid cysts can recur after many years, although symptomatic recurrence is rare. The recurrence potential is related to the volume of capsule that remains unresected. This capsule will produce cells at the normal rate of cell transformation (Alvord, 1977) and thus a symptomatic recurrence is uncommon. A recurrent tumour is still likely to be benign though malignant change has been reported in both dermoid and epidermoid cysts.

Dissemination can only occur if there has been rupture of the cyst contents into the CSF spaces. Maravilla (1977) described this pattern of dissemination associated with multiple secondary satellites nodule.

Controversies

The management of small vestibular schwannomas: Observation vs. stereotactic radiosurgery vs. microsurgical excision

For many lesions smaller than 1.5 cm in middle aged and older patients, initial management with observation and close radiological and clinical follow-up is appropriate. Growth in these patients should trigger intervention.

The treatment of tumours less than 2 cm in size can be either microsurgery or radiosurgery. Surgery for small tumours performed in high volume subspecialty centres offers excellent rates of gross total resection with rates of good facial nerve outcome typically more than 90%. Radiosurgery offers a viable alternative in small tumours, with good control of growth and typically excellent, low rates of facial nerve dysfunction. Salvage microsurgery following failed radiosurgery is typically associated with more challenging nerve dissection and higher rates of facial nerve morbidity.

Radiosurgery in anticoagulated patients is relatively contraindicated with a significantly increased rate of intratumoural haemorrhage.

The timing and extent of intervention and tumour excision in patients with NF-2

Given the high priority in this patient group of hearing preservation, the management of vestibular schwannomas is inherently more conservative. Growing tumours associated with poor hearing or a deaf ear should be managed with microsurgical excision. While hearing remains intact we adopt a strategy of maximal debulking while placing the intraoperative priority on preservation of the cochlear nerve. This situation frequently means that residual tumour remains and patients may require multiple retrosigmoid craniotomies. We typically reserve treatment in patients with NF-2 until the size of the lesion is compressive on the cerebellum. Radiosurgery in this patient group is less effective at controlling growth and is typically not advised except as a salvage strategy.

The choice of approach in patients with large tumours and serviceable hearing

Excepting the NF-2 patient population, and the small proportion of idiopathic patients with poor hearing on the side contralateral to the tumour, we would generally advocate that in the case of a large tumour the primary goal of surgery remains safety to both the brainstem and cerebellum. We feel that minimizing cerebellar retraction and maximizing the angle for safe brainstem dissection of the tumour with a translabyrinthine approach optimizes the surgical outcome for the patient. In large tumours we believe that the possibility of useful hearing preservation is low in any approach and thus our choice is typically translabyrinthine.

The pituitary gland: Essential anatomy

The pituitary gland occupies the sella turcica, approximately 5 cm posterior to the tip of the nose in the midline of the skull base (Fig. 25.1A). It is closely related to the hypothalamus and third ventricle superiorly, chiasm and lamina terminalis antero-superiorly, sphenoid sinus antero-inferiorly, cavernous sinus and cavernous segment of the carotid artery laterally, the posterior clinoids and clivus posteriorly.

There are two distinct components to the pituitary gland, the anterior and posterior lobe, which are derived from the ectoderm and neuroectoderm respectively (Fig. 25.1B). The anterior pituitary constitutes 80% of the gland mass and in the horizontal plane it is distributed into two lateral wings. The hormones produced by the anterior pituitary are adrenocorticotropic hormone (ACTH), prolactin (PRL), growth hormone (GH), thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The normal endocrine cells have a distinct distribution with GH and PRL producing cells being abundant in the anterior and posterior parts of the lateral wings respectively; TSH and ACTH producing cells most represented in the anterior and posterior part of the central wedge respectively and gonadotropin cells being scattered throughout the anterior lobe (Fig. 25.1C).

Blood supply to the pituitary is integral to its hormone-producing function (Fig. 25.1D). The superior and inferior hypophyseal arteries, direct branches of the supraclinoid and cavernous carotid, respectively, supply the pituitary gland and ventral hypothalamus. The superior hypophyseal artery forms the hypophyseal portal system by branching into the primary plexus circumventing the ventral hypothalamus and the pituitary stalk. This plexus drains towards the anterior lobe via the hypophyseal portal veins to form the secondary plexus around the anterior lobe. This second plexus is then collected in the anterior hypophyseal veins and drains into the cavernous sinus. The importance of this plexus is that it couples the trophic factors released from the arcuate nucleus of the hypothalamus to the anterior lobe to control its hormone secretion. The posterior lobe is supplied by the inferior hypophyseal artery and drained towards the posterior hypophyseal veins. The gland is connected to the hypothalamus superiorly via the pituitary stalk, which harbours the axons of the paraventricular and supraoptic nuclei. These axons transport oxytocin and vasopressin into the posterior pituitary and are released into the posterior hypophyseal vein (Fig. 25.1).

Epidemiology of pituitary tumours

Pituitary gland abnormalities are relatively common, the majority being pituitary adenomas. Their estimated prevalence as an incidental finding is approximately 17% according to a meta-analysis from radiological and post-mortem studies with no gender predilection (Ezzat et al., 2004). However, most these pituitary lesions are very small, incidental, and do not require clinical intervention.

Symptomatic pituitary adenomas have an incidence of 19–28/million/year which peaks between the third and sixth decade of life with an overall predominance in premenopausal women. The exact prevalence varies based on the study population; surgical series are biased by focus on lesions causing mass effect, whereas medical series may capture more of functioning adenomas such as prolactin-secreting adenomas that are typically medically managed. Up to 20% of pituitary adenomas, depending on series are discovered incidentally and many remain asymptomatic.

Pituitary adenomas requiring intervention represent 10–15% of all intracranial tumours, ranking them the third most common tumours after gliomas and meningiomas. Their classification is based on pathological and immunohistochemical features. Seven types and 13 subtypes are currently recognized in the WHO Classification of Tumours to Endocrine Organs (WHO, 2017). The types include a predominant lactotroph (prolactin immunostaining, 39%), gonadotroph (LH/FSH immunostaining, 27%), somatotroph (GH immunostaining, 16%), corticotroph (ACTH immunostaining, 16%) and thyrotroph (TSH immunostaining, 1%) cell type, and the rest include null cell and plurihormonal adenomas (WHO, 2017).

Pituitary adenomas in children are about ten times less common than adults contributing to 2–6% of all intracranial paediatric tumours (Keil and Stratakis, 2008). Only 3.5–8.5% of pituitary adenomas are diagnosed before the age of 20. Paediatric adenomas can have a dramatic impact on the critical period of development in childhood.

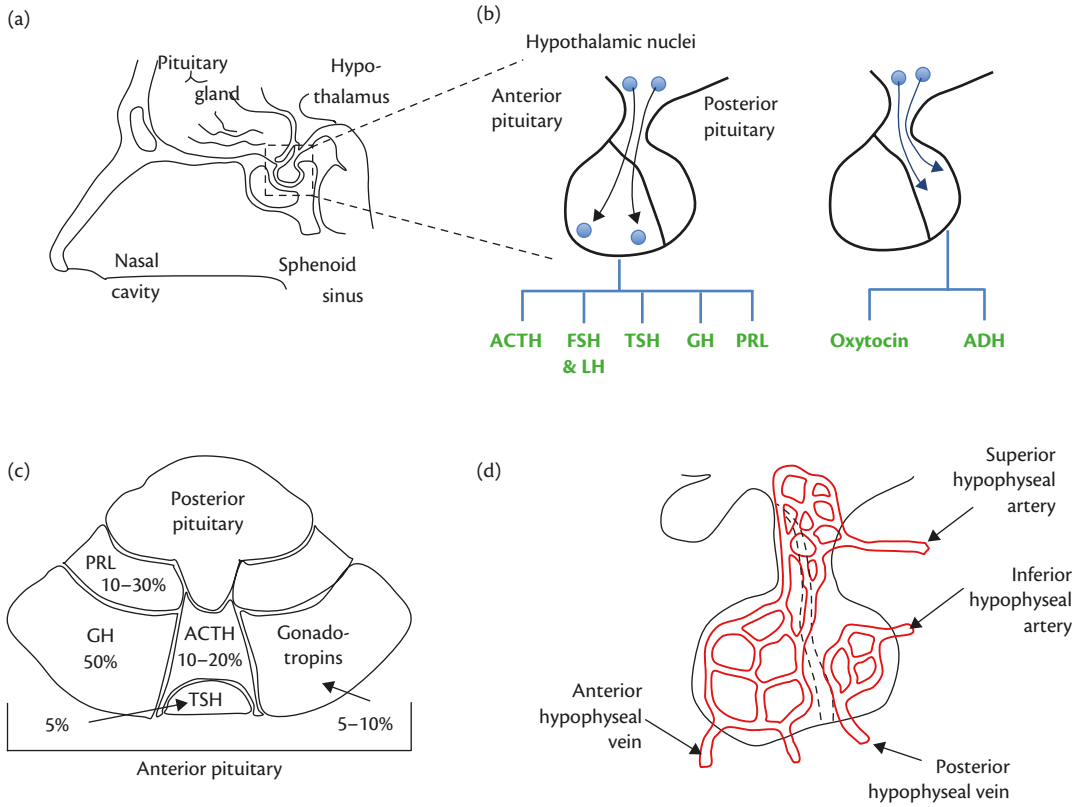

Fig. 25.1 Panel A: regional anatomy of the pituitary gland, panel B: pituitary gland structures and hormonal secretion panel C: topographic distribution of hormone-producing cells within the pituitary gland. Panel D: pituitary blood supply, the hypophyseal portal system.

Genetics

The classical concept of disruption in the oncogene proto-oncogene balance that regulates cell proliferation and leads to clonal expansion of tumour cells may provide some explanation, but the pathogenesis of pituitary adenomas remains unclear (Daly et al., 2009; Marques and Korbonits, 2017). Several lines of evidence support the monoclonality of pituitary tumours, however there are also evidence for multiple foci of monoclonal expansion.

The majority of pituitary tumours are sporadic (95%). A small minority are familial (5%) and occur either as isolated (i.e. familial isolated pituitary adenomas, FIPA), or as part of a familial genetic syndromes, including multiple endocrine neoplasia type 1 (MEN 1), MEN type 4, McCune–Albright syndrome, Carney complex (CNC), X-linked acrogigantism (XLAG syndrome), SDH mutations, and mutations of *DICER* gene (Vandeva et al., 2010; Marques and Korbonits, 2017).

Sporadic pituitary adenomas

There are multiple oncogenes identified to promote pituitary tumour formation (Daly et al., 2009; Marques and Korbonits, 2017). One of the first identified was the *gsp* oncogene, where a gain of function mutation is detectable in 40% of somatotrophinomas. *Gsp* codes the $G\alpha_s$ subunit of a GTPase and the mutation results in persistently elevated cAMP levels. This constitutes a constant stimulation from the growth hormone release hormone (GHRH) and may lead to the development of somatotrophinomas. Other relatively common mutational events involve the genes encoding USP8 (ubiquitin-specific protease 8) and P13K (phosphatidylinositol 3-kinase). Altered expression of cell cycle protein abnormalities have been noted in up to 80% of pituitary adenomas and these include the cyclin-dependent kinases (CDK), pituitary tumour transforming gene 1 (*PTTG1*), and various growth factors.

Familial pituitary adenomas

Familial isolated pituitary adenoma (FIPA): This condition was defined as the occurrence of two or more cases of pituitary adenomas in a family, but not associated with other tumours. The majority (~60%) of FIPA are macroadenomas with somatotroph and lactotroph adenomas being the dominant tumour types. Mutations in the aryl hydrocarbon receptor-interacting protein gene (*AIP*) have been identified as the cause in 15–30% of FIPA families (Marques and Korbonits, 2017). The *AIP* gene is located at chromosomal region 11q13.2 and it is suggested that in *AIP*-mutated FIPA, *AIP* loses its ability to bind its partners, and therefore, loses its activity as a tumour suppressor. The penetrance of pituitary adenomas among AIP mutation-positive carriers is around 12–30%.

MEN1 (Multiple endocrine neoplasia): The estimated incidence of MEN1 is 1–10/100 000/year. The syndrome is caused by a loss of function mutation in the *MEN 1* tumour suppressor gene on chromosome 11q13 (Balogh et al., 2006; Daly et al., 2009; Marques and Korbonits, 2017). The mutation is dominantly inherited with a penetrance of up to 90%. *MEN1* gene encodes

Menin, which has a complex regulatory interaction with a series of further proteins and gene expression. The spectrum of the condition includes primary hyperparathyroidism, pancreatic neuroendocrine tumours, and pituitary adenomas. The latter develop in 40% of cases. The distribution of histotypes is similar to sporadic adenomas. Lactotroph adenomas in *MEN1* show much lower response rate to dopamine agonist (approximately 40% normalization rate) and tend to be more invasive. The majority of *MEN1*-related pituitary tumours are macroadenomas. These patients therefore present twice as frequently with mass effect (approximately 80% vs. 40% in sporadic cases) compared to non-*MEN1* cases.

MEN4 (multiple endocrine neoplasia): This is a very rare inherited syndrome with autosomal dominant transmission and caused by mutations in the *CDKN1B* gene encoding the cyclin dependent inhibitor p27. The syndrome was first identified in rats with a frameshift mutation causing the synthesis of an unstable protein (MENX) (Pellegata et al., 2006). Both homozygous and heterozygous animals develop gonadotroph adenomas and phaeochromocytoma with 100% penetrance. Patients can present with acromegaly, primary hyperparathyroidism, renal angiomyolipoma, testicular cancer, and cervical carcinoid tumour.

McCune–Albright syndrome: This syndrome first described in 1937 is characterized by café-au-lait spots, fibrous dysplasia, hormonal abnormalities such as precocious puberty, excess GH production and prolactin hypersecretion (Albright et al., 1937; McCune and Bruch, 1937). It is caused by postzygotic somatic mutations in the *GNAS1* gene (guanine nucleotide binding protein, alpha-stimulating activity polypeptide 1) on chromosome 20q13.2-q13.3. Such postzygotic mutations lead to the mosaic-like phenotype typical of the disease and cause a variable clinical picture, which depend on the cell lineage affected. The specific tissue types affected are the pituitary gland, notably GH and prolactin-producing adenomas, skin, proximal femur, and facial bones.

Carney complex (CNC): This rare syndrome was first described in 1985 and consists of myxomas (cutaneous and cardiac), spotty pigmentations and endocrine overactivity, including pituitary adenomas (Casey et al., 1998). Pituitary adenomas are part of the phenotype in only 10% of cases with 75% of patients having subclinical elevation of GH, IGF-1, and prolactin. The genetic basis of Carney complex is heterogeneous. Associated germline mutations include CNC1 loci at 17q22-24, which encodes protein kinase A regulatory subunit Ia (PRKAR1A) and a site at 2p16, proposed to code the CNC2 gene.

X-linked acrogigantism: Sporadic and germline microduplications of the GPR101 on Xq26.3 account for about 10% of cases of gigantism. Abnormal growth occurs by the first four years of life. Mammosomatotroph hyperplasia and mixed lactrotroph/somatotroph adenomas are the underlying pathology in XLAG patients. The clinical features are striking but genetic diagnosis can be challenging, particularly in patients with somatic mosaicism. Surgery can be curative (Marques and Korbonits, 2017).

Mutations of succinate dehydrogenases: Patients with mutations in one of four subunits of SDH and its associated assembly factor can develop pituitary macroadenomas, which occur more commonly in familial cases, tend to be more aggressive than their sporadic counterpart and to be resistant to treatment (Marques and Korbonits, 2017).

DICER1: Heterozygous germline mutation in the *DICER1* gene cause pleuro-pulmonary blastoma familial tumour and dysplasia syndrome that is characterized by the occurrence of several tumours including cystic nephroma, Sertoli-Leydig cell tumours, goitre, and sarcomas. Children with *DICER1* mutations can also develop pituitary blastoma at very low penetrance

Radiology

Skull X-ray

X-rays are now mostly of historical interest (Fig. 25.2A). Prior to the advent of computed tomography (CT) and MR, plain X-rays were useful in detecting enlarged sella, erosion of the posterior clinoid or clivus for craniopharyngiomas, enlarged sphenoid sinus with tuberculum sella meningiomas and a 'J' shaped sella for optic nerve gliomas. Abnormal thickening of the skull is a feature of acromegaly.

CT head

CT scan can reveal an enlarged sellar and the associated pituitary mass (Fig. 25.2B). CT is also useful to identify calcification, which is more commonly seen in craniopharyngiomas and tuberculum sellar meningiomas. Pituitary apoplexy may be first seen on CT brain as a hyperdense lesion within the sella. The vascular relations of the pituitary can be assessed with contrast enhanced CT or CT angiogram. The most widely used application of CT however is for assessment of sinus characteristics as part of operative planning and/or intraoperative neuronavigation for endonasal approaches. Coronal and sagittal reconstructions are used to assess skull base/sinus anatomy.

MRI head

This is the standard modality for evaluating the tumour size, enhancement characteristics and neurovascular relationships of pituitary lesions in different planes (Fig. 25.2 C, D). The pituitary gland enhances compared to normal brain after administration of gadolinium due to the absence of the blood brain barrier (Fig. 25.2D). The posterior lobe accumulates contrast first followed by the anterior gland.

There are age- and sex-dependent variations in the size of the normal pituitary gland with an upper limit of 9–10 mm. However, it is important to be aware that physiological enlargement can occur at puberty and pregnancy resulting in a bulbous appearance on coronal MRI and dimensions of up to 12 mm.

On T1-weighted imaging, the posterior pituitary shows high signal also referred to as the 'bright spot'. Relations to adjacent neurovascular structures are better assessed with MRI than CT. Of particular importance are the relations of the optic apparatus and internal carotid artery to the pituitary tumour. Pituitary microadenomas can cause unilateral enlargement of the gland, with displacement of the pituitary stalk to the contralateral side.

Dynamic MR

Most pituitary adenomas can be detected by conventional imaging. However, small adenomas may be less obvious. Dynamic MRI

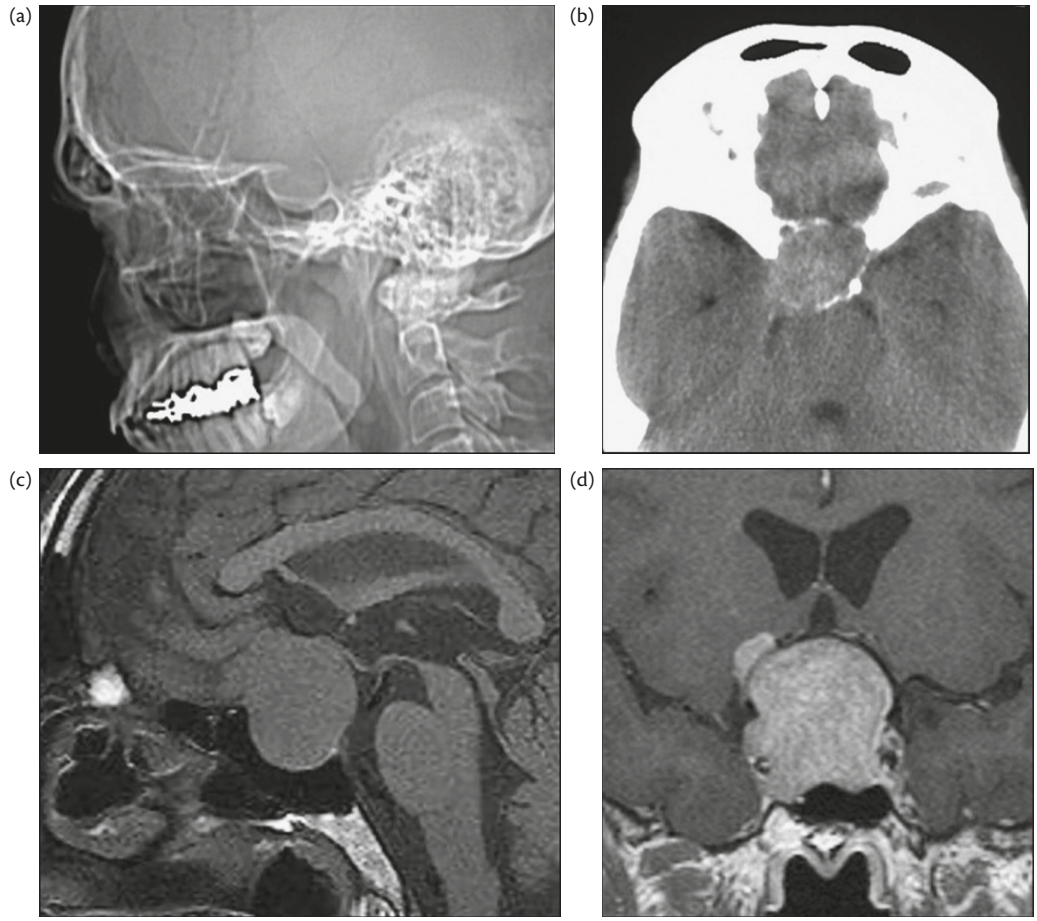

Fig. 25.2 Lateral skull X-ray (A) depicting an expanded pituitary fossa secondary to the adenoma. Axial CT scan (B) depicting a pituitary mass. Sagittal T1-weighted MR (C) and coronal T1-weighted MR with enhancement (D) reveal a pituitary macroadenoma with chiasmal compression.

imaging relies upon the altered contrast enhancement of pituitary microadenomas in relation to the normal gland (Figs. 25.3A–C). The technique involves intravenous administration of gadolinium followed by sequential rapid acquisition of T1-weighted MRI images for approximately 2–3 minutes from the time of contrast administration. Tumours usually enhance at a later (or sometimes earlier) time point compared to the normal pituitary gland. The timing correlates with tumour size, vascularity, integrity of blood brain barrier and also physical consistency (Kanou et al., 2002).

Other specialised MR sequences such as the spoiled gradient recalled acquisition in the steady state (SPGR) may also have value in identifying small microadenomas not seen with conventional MR sequences.

Inferior petrosal vein sampling (IPSS)

This is a useful test in determining the site of ACTH overproduction in Cushing disease (Deipolyi et al., 2011) (Figs. 25.3D, E). It is an invasive procedure with small risks of stroke, haemorrhage, and puncture site haematomas, and therefore currently used as an adjunct to the remaining diagnostics. The procedure involves guiding an intravenous catheter into the petrosal veins and measuring ACTH levels directly from the venous aspirate before and/or after corticotrophin factor (CRF) administration. Hormonal levels from within the inferior petrosal sinuses are interpreted in conjunction to peripheral samples. Sensitivity of IPSS reaches 80–90%, but IPSS is more useful in confirming the central (ie pituitary) origin of ACTH rather than the laterality of the microadenoma within the pituitary fossa.

Grading systems for pituitary adenomas

Grading systems of pituitary adenomas are typically based on anatomical and imaging information. The most widespread classification is the distinction between maximum tumour diameter above 1 cm (macroadenomas) or diameter below 1 cm (microadenomas).

Sophisticated classifications were developed to describe the involvement of adjacent structures such as extension into the para- or suprasellar area with the degree of spread into the sella floor, sphenoid, and distant spread. The main aim of these classifications was to assess difficulty of excision, probability of residual tumour, predict recurrence, and hormonal remission.

The initial radiological concept of grading pituitary adenomas was established by Hardy and Wilson in the 1970s (Hardy and Vezina, 1976; Fig. 25.4). In this scheme pituitary adenomas that do not breach the sella floor are classified as non-invasive, whereas sellar destruction qualifies the adenoma as invasive (Fig. 25.4A). The second feature is suprasellar extension of the tumour with distinction between intradural lesions and extradural spread (Fig. 25.4B).

The Knosp classification (Knosp et al., 1993) primarily assesses the extent tumour extending across into the cavernous sinus with focus on relations to the cavernous carotid (Fig. 25.5)

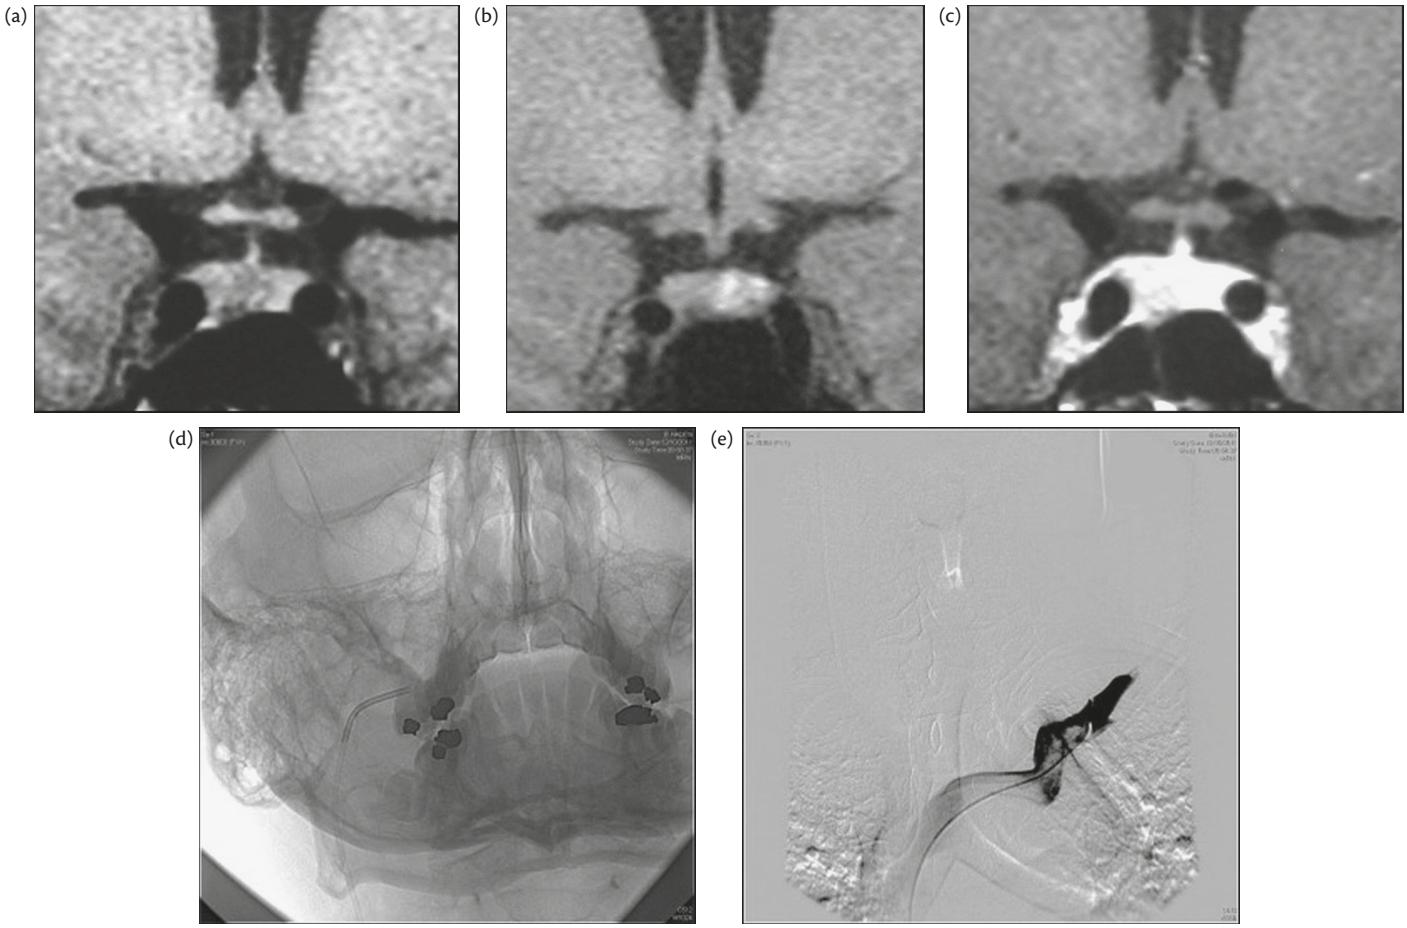

Fig. 25.3 Different phases of the dynamic MRI scan (A–C) demonstrating a right sided microadenoma, that shows less enhancement than the normal pituitary gland to the left at 5 seconds (B), but not later at 3 mins (C) in a patient with Cushing's disease. Anteroposterior (AP) skull X-rays showing endovascular catheter (arrow, D) placed into the right petrosal sinus that is then out lined by contrast (E).

Pathology

Histopathology

Historically pituitary tumours were classified according to the tintorial properties of their cytoplasm into acidophil, basophil and chromophobe (Kernohan and Sayre, 1956). Staining properties correlate with adenoma function: acidophil tumours are generally GH producing and linked with gigantism and acromegaly, basophil tumours were more likely to secrete ACTH, and chromophobe adenomas were thought to be hormonally inactive (Fig. 25.6). The introduction of electron microscopy has improved the classification and allowed the identification of subtypes such as densely and sparsely granulated somatotroph adenomas, but it was with the advent of immunohistochemistry that the spectrum of types and subtypes was recognized (Kovacs et al., 2001).

Morpho-functional classification

The current classification of pituitary adenoma includes seven major morphological and functional types (WHO, 2017) each of which is divided into subtypes with distinct histological and ultrastructural features, immune-phenotype, and function. Immunohistochemistry for pituitary hormones is the mainstream technique for the classification of adenomas; immunohistochemical stains for cytokeratins and transcription factors SF1, pit-1, and T-pit are also helpful to further define adenomas. Much less commonly, adenoma can be stained with antibodies directed against epidermal growth factor receptor (EGFR), oestrogen receptor, e-cadherin, VEGF, and mitochondria. A broader panel of antibodies is used when light microscopic features of a sellar tumour are not typical of adenoma and the lesion has to be differentiated from other primary, non-adenomatous tumours, or metastatic deposits.

Pathological features must always be correlated with clinical phenotype and biochemical evidence of hormone overproduction. Adenomas that are immunohistochemically positive for one or more pituitary hormones in the absence of clinical features of hormone hypersecretion are defined as clinical silent or clinically non-functioning. The lack of function may depend on several factors including defect in hormone release or synthesis of a biologically inactive hormone. In fact, immunohistochemistry detects the hormonal storage within the tumour cell cytoplasm and is not an indicator of secretory activity. Finally, adenomas such as lactotroph and gonadotroph adenomas can release active hormones but occur in postmenopausal women and therefore appear as clinically non-functioning and present with signs and symptoms of mass effect.

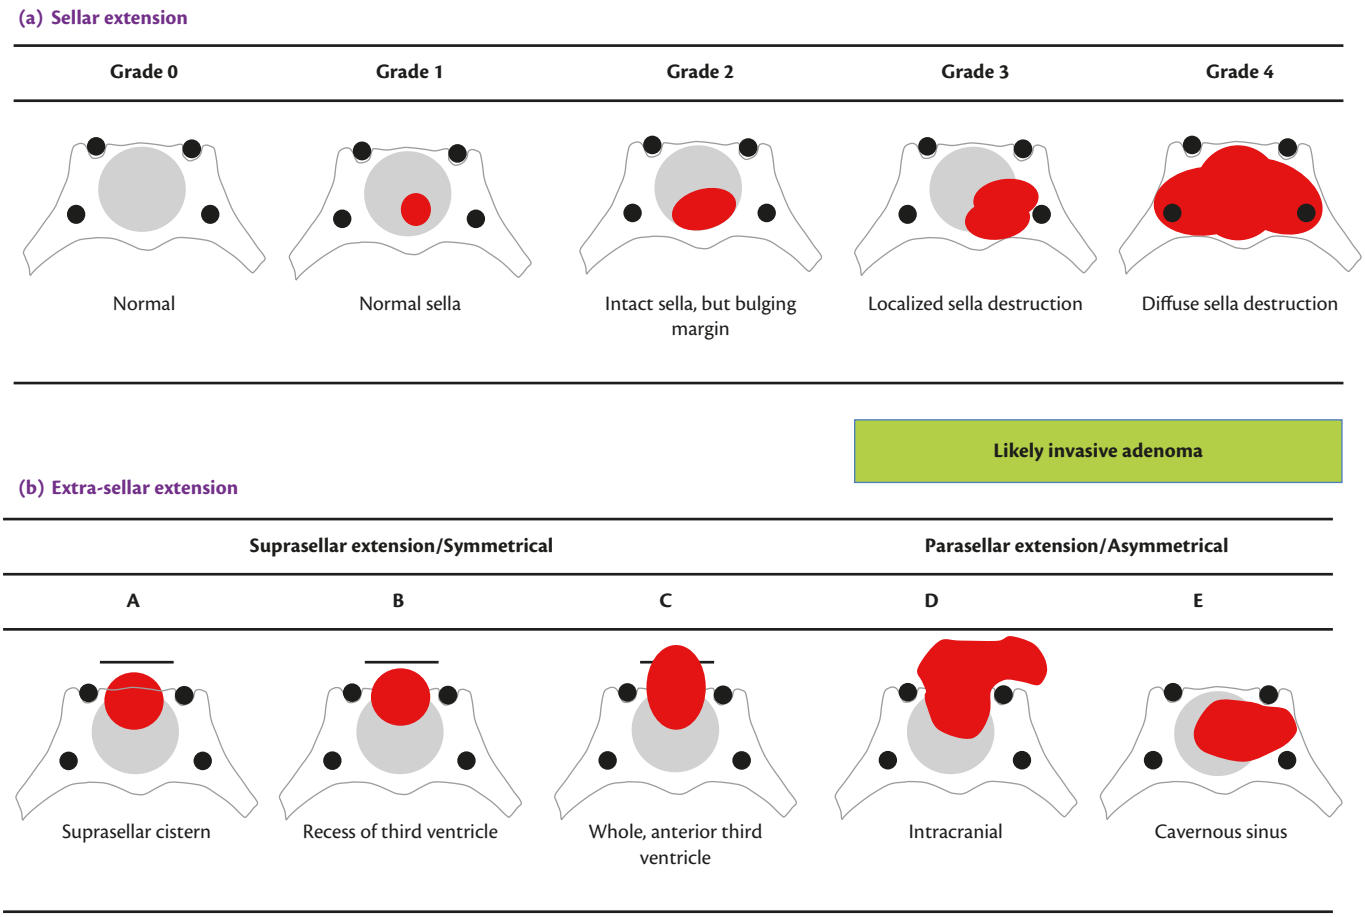

Fig. 25.4 Modified Hardy grading for pituitary adenomas. Grades 3, 4, D, and E reflect likely cavernous sinus invasion.
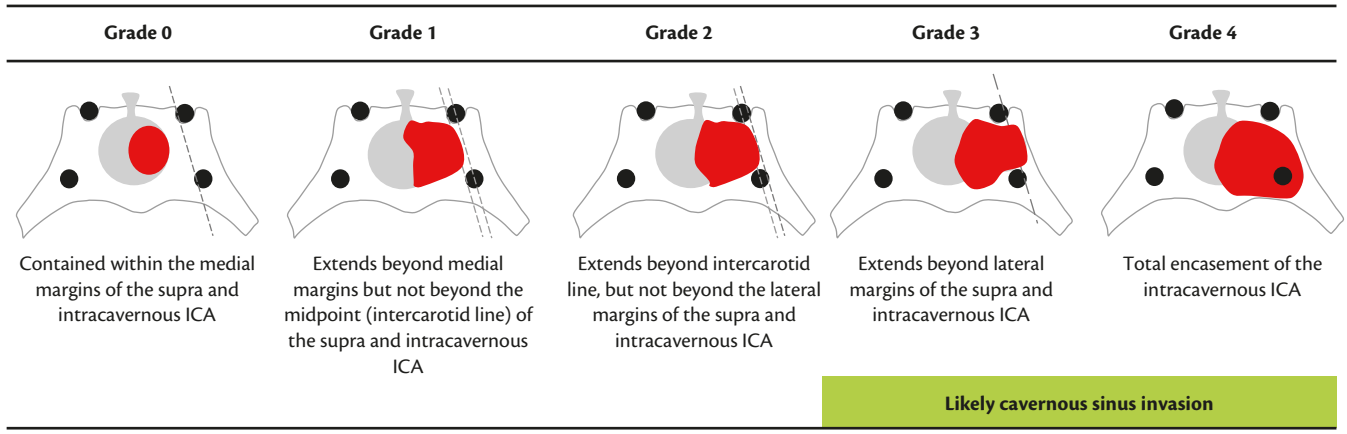
Hardy J, Vezina JL: Transsphenoidal neurosurgery of intracranial neoplasm, in Tompson RA, Green JR (eds): *Advances in Neurology*. New York, Raven Press, 1976, vol 15, pp 261–75.

The application of electron microscopy is limited to rare cases where light microscopic features and immunophenotype are not diagnostic. Ultrastructural features such as number, location, and size of secretory granules, location and aggregation of intermediate filaments, and presence of nuclear inclusions are those usually considered in the diagnosis.

Prediction of behaviour and response to treatment

Histotype, proliferative activity and tumour invasiveness are predictors of outcome for pituitary adenomas. The recent European Society of Endocrinology guidelines propose an integrated clinico-pathological approach to define aggressive adenomas that includes invasion, rapid growth, lack of response to treatment and



Grade 0
Grade 1

increased proliferation (Raverot et al., 2018). The definition of atypical adenoma that was introduced in the 2004 version of the WHO classification is no longer contemplated in the 2017 edition (WHO, 2017).

Assessment of mitotic activity can be helpful to predict recurrence, particularly in adenomas that extend outside the sella and where complete excision is not possible.

The prognostic value of Ki-67 proliferation index is not universally accepted given the interlaboratory variability of immunostains and the lack of a consensus for quantification. Nevertheless Ki 67 values ≥3% should raise concerns as they may predict aggressive behaviour.

Expression of the enzyme O6-methyl-guanine-DNA methyltransferase (MGMT) can routinely be assessed by immunohistochemistry to help predict the response to temozolomide (TMZ). Low-level MGMT immunoexpression was correlated with a favourable response but MGMT immunoexpression is not always concordant with methylation of the MGMT gene promoter. Nuclear expression of the DNA Mismatch Repair Protein (MSH6) seen on immunohistochemistry can also contribute to assess response to chemotherapy.

The value of immunostains for somatostatin receptors 2, 3, and 5 in predicting the response to somatostatin analogues is still under debate.

The definition of pituitary carcinoma is still restricted to a tumour of adenohypophyseal cells that metastasize within and outside the cranio-spinal axis. Pituitary carcinoma is exceedingly rare representing about 0.12% of adenohypophyseal tumours collected in German Pituitary Registry and accounting for 6% of invasive adenomas in the SEER (Surveillance, Epidemiology, and End Results programme) database. Pituitary carcinomas in children are exceptional.

Endocrine aspects

Pituitary hormones and homeostatic feedback loops

Hormone secretion of the pituitary gland is regulated via multiple feedback loops involving the hypothalamus, pituitary gland, and target organs. A summary of these feedback loops is depicted in Figure 25.7.

The arcuate nucleus of the hypothalamus secretes (growth hormone releasing hormone (GHRH) growth hormone-inhibiting hormone (GHIH, usually referred to as somatostatin); thyrotropin-releasing hormone (TRH); gonadotropin-releasing hormone (GnRH); prolactin-releasing hormone (PRH); prolactin-inhibiting hormone (PIH, dopamine); and corticotrophin-releasing hormone (CRH). These factors are secreted into the hypophyseal portal system and transported to the anterior pituitary.

There are six hormones produced by the anterior pituitary: adrenocorticotrophic hormone (ACTH), prolactin (PRL), growth hormone (GH), thyroid stimulating hormone (TSH), follicle stimulating hormone (FSH) and luteinizing hormone (LH) (Figs. 25.1 and 25.7).

Oxytocin and anti-diuretic hormones (ADH, also known as vasopressin) are hormones secreted by the posterior pituitary. They are synthesized by neurons of the paraventricular and

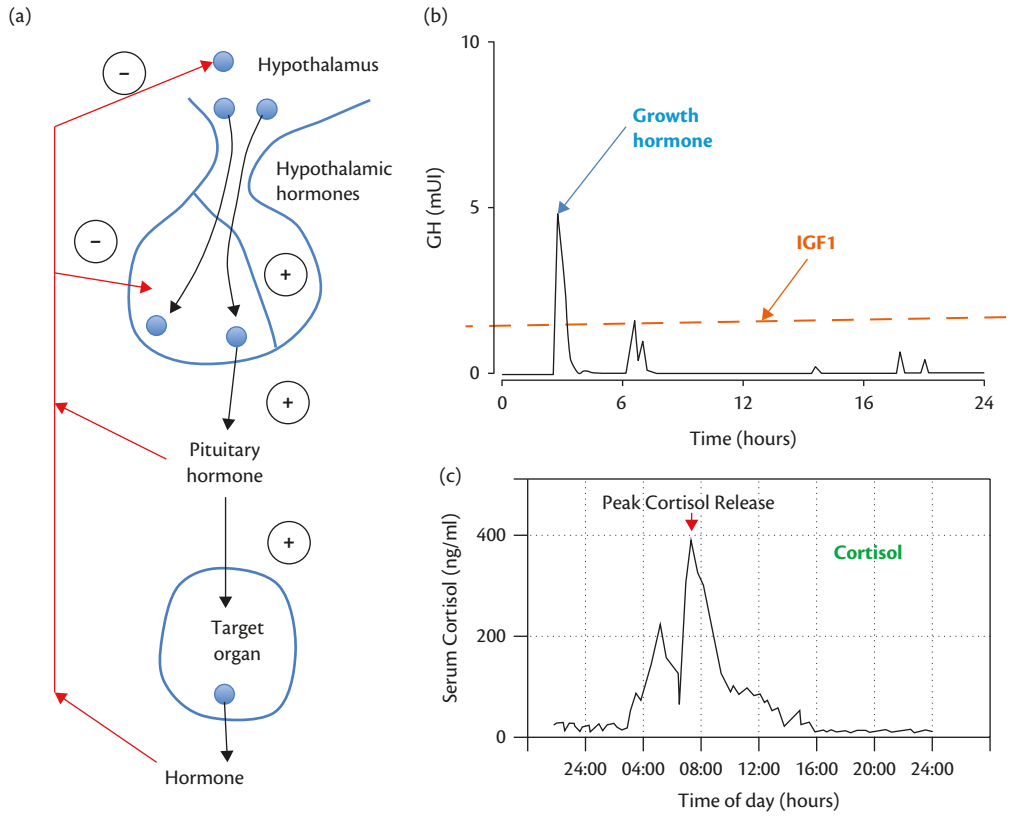

Fig. 25.7 Schematic depicting the hormonal feedback loop (A), pulsatile growth hormone release (B) and the circadian rhythm of serum cortisol release during the day (C).

supraoptic nuclei of the hypothalamus and are transported via the axons coursing through the pituitary stalk in to the posterior lobe.

Several hormones are dynamically secreted and cycles vary over days or months. For example, GH is released in a pulsatile fashion throughout the day. GH stimulates the production of IGF1 in the liver, which has more stable blood levels (Fig. 25.7B). Cortisol release peaks in the morning and reaches a trough by midnight (Fig. 25.7C). Other hormones such as LH and FSH follow a monthly cyclical pattern.

The primary target organs of the pituitary hormones include the adrenal glands (ACTH), thyroid gland (TSH), reproductive organs (FSH and LH) and breasts (PRL). Other hormones such as GH have a more widespread systemic effects, including impact on bone and muscle growth.

Basal, stimulation, and suppression endocrine tests

Pituitary hormone profile can be considered as basal endocrine tests. Basic profile includes prolactin levels, thyroid function, IGF-1, 9am or random cortisol, ACTH, LH, FSH, oestradiol, or testosterone. Prolactin is an important test for the management of patients because prolactin-secreting adenomas can be managed medically in the vast majority and surgery be avoided.

Stimulation tests are used to investigate diminished function of the pituitary or the target organ. A common example is the insulin stress test which is used to assess cortisol or GH deficiency by inducing hypoglycaemia which stimulates glucostatic counter-regulatory hormones ACTH, cortisol, or GH production (Fig. 25.8A). An alternative to this test is the glucagon stress test, which is better tolerated by patients. Glucagon stress test raises glucose to above normal and then the drop in glucose levels back down to normal stimulates glucostatic counter-regulatory hormones GH and ACTH.

Suppression tests investigate hormone overproduction. For example, the dexamethasone suppression test is used to suppress ACTH and cortisol responses and thus confirm Cushing's syndrome (Fig. 25.8B). The oral glucose tolerance test is used to confirm the diagnosis of growth hormone excess. In acromegaly, it demonstrates the lack of GH suppression by the raised serum glucose. The clinical use of these tests is detailed under the specific conditions later.

Occasionally the Short Synacthen Test (SST) can be used as a surrogate marker of ACTH production by the pituitary. Synacthen assesses the adrenal response to exogenous ACTH, but does not confirm that the patient has endogenous ACTH secretion. However, if the patient has been chronically ACTH deficient it is likely that they will have adrenal atrophy and so the SST can be used as an indirect assessment of chronic ACTH deficiency. It cannot be used to assess recent onset ACTH deficiency as inadequate time will have ensued to cause adrenal atrophy and hence they will still respond to exogenous ACTH while being deficient endogenously.

Treatment options

Surgical options

Surgery is undertaken to treat tumour-related mass effect and/or normalize excessive hormonal secretion. A diagnostic biopsy is required in cases where neuroimaging features are not clear.

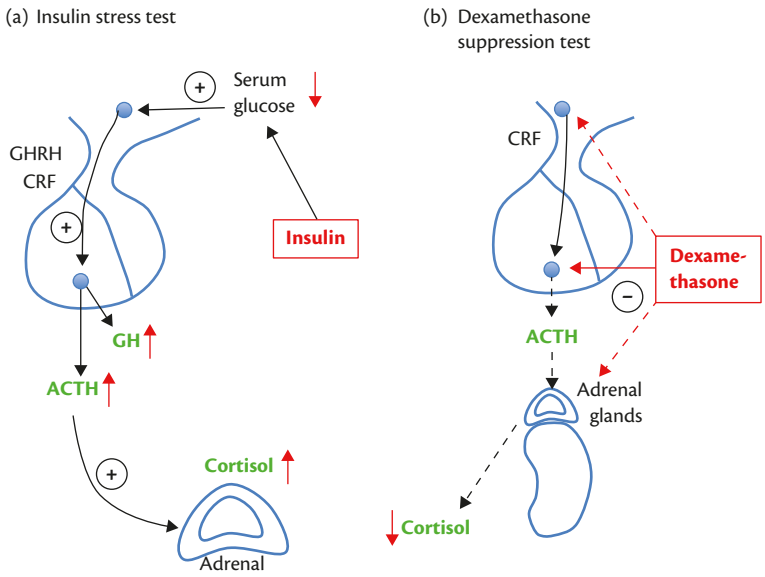

Fig. 25.8 Schematic examples of stimulation (A—insulin stress test) and suppression tests (B—dexamethasone suppression test).

The surgical techniques are described in the accompanying chapters. The general considerations of surgical approaches are dictated by the central location of the pituitary gland. Consequently, there are several approaches to the pituitary region. However, the vast majority of cases are tackled using the endoscopic transnasal approaches. See Figure 25.9.

Medical management

There are several aspects to medical management. At a simple level it involves replacing the missing hormones to treat hormone deficiencies and medically treating excess hormone production by pituitary tumours.

Common causes of hypopituitarism in the case of pituitary tumours are due to (1) tumour mass effect on the normal pituitary tissue; (2) postoperative impairment in pituitary function; and (3) hypopituitarism following radiotherapy. ACTH and ADH deficiency can be life-threatening and require urgent replacement. Other hormones can be replaced at a later date.

Hormone excess and the associated mass effect in some functioning adenomas could be successfully controlled medically. The most frequently encountered example is using dopamine agonists for prolactin-secreting adenomas. For other hormone active tumours medical options also exist although not as effective (e.g. somatostatins for GH-producing adenomas).

Radiotherapy

Radiotherapy is mainly used as an adjuvant therapy to reduce tumour growth in the postsurgical residuum, which could not be removed safely. Very occasionally, it can also be used as a first-line treatment in those patients where surgical intervention is contraindicated or ill advised.

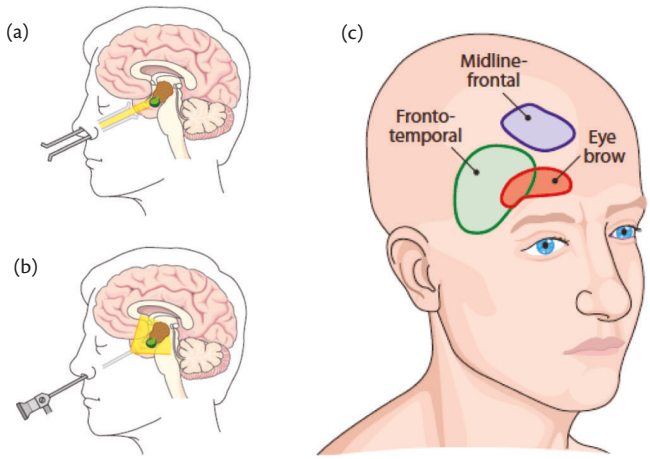

Fig. 25.9 Schematic overview of surgical approaches to pituitary tumours. Endonasal transsphenoidal approach with microscopic (A) and endoscopic (B) techniques. Transcranial options (panel C) include the eyebrow, pterional, and frontal craniotomies.

Modalities of radiotherapy include conventional linear accelerators where radiation is delivered from multiple ports in daily fractions over a period of 5–6 weeks constituting a total dose of 40–50 Gy. Fractionated radiotherapy carries the advantage of allowing adjacent normal neuronal tissue to recover between doses (Kanner et al., 2009). It is reported to be effective at disease control in 93% of cases at 10 years follow-up (Darzy and Shalet, 2009).

Complications include the gradual development of hypopituitarism over the course of several years following treatment. Hypopituitarism following radiotherapy to the sellar region is progressive and irreversible and therefore requires regular monitoring and adjustments in treatment. The risk is influenced by the radiation dose and there is a difference in the susceptibility of each hormonal system (Darzy and Shalet, 2009). Production of GH is the most vulnerable, deficiencies occur even with a radiation dose below 24 Gy and exposures between 40 and 50 Gy cause insufficiency in up to 50–100% of cases. TSH and ACTH production is less susceptible. Gonadotropin deficiency differs among genders: precocious puberty occurs in girls at a dose below 30 Gy and deficiency occurs in both genders at 30–50 Gy. Hyperprolactinaemia due to loss of hypothalamic inhibition is usually subclinical.

Radiotherapy is guided by face mask head fixation and high-resolution three-dimensional MRI to allow more accurate target delineation. Conformal planning with linear accelerators is standard in the modern era **Figures 25.10A & 25.10B**. Intensity-modulated radiotherapy (IMRT) and volumetric modulated arc therapy (VMAT) help plan a steep dose fall outside the target and thus better sparing the normal tissue.

The most frequently used stereotactic radiosurgery systems are Gamma knife and Linear accelerator (LINAC) **Figures 25.10C & 25.10D**. They are either used to deliver a single dose (15–20 Gy) or in 2–5 fractions in some cases. Tumour control rates range from 88–97% and morbidity ranges from 0% to 12% for optic nerve function, and 0% to 41% for the pituitary function.

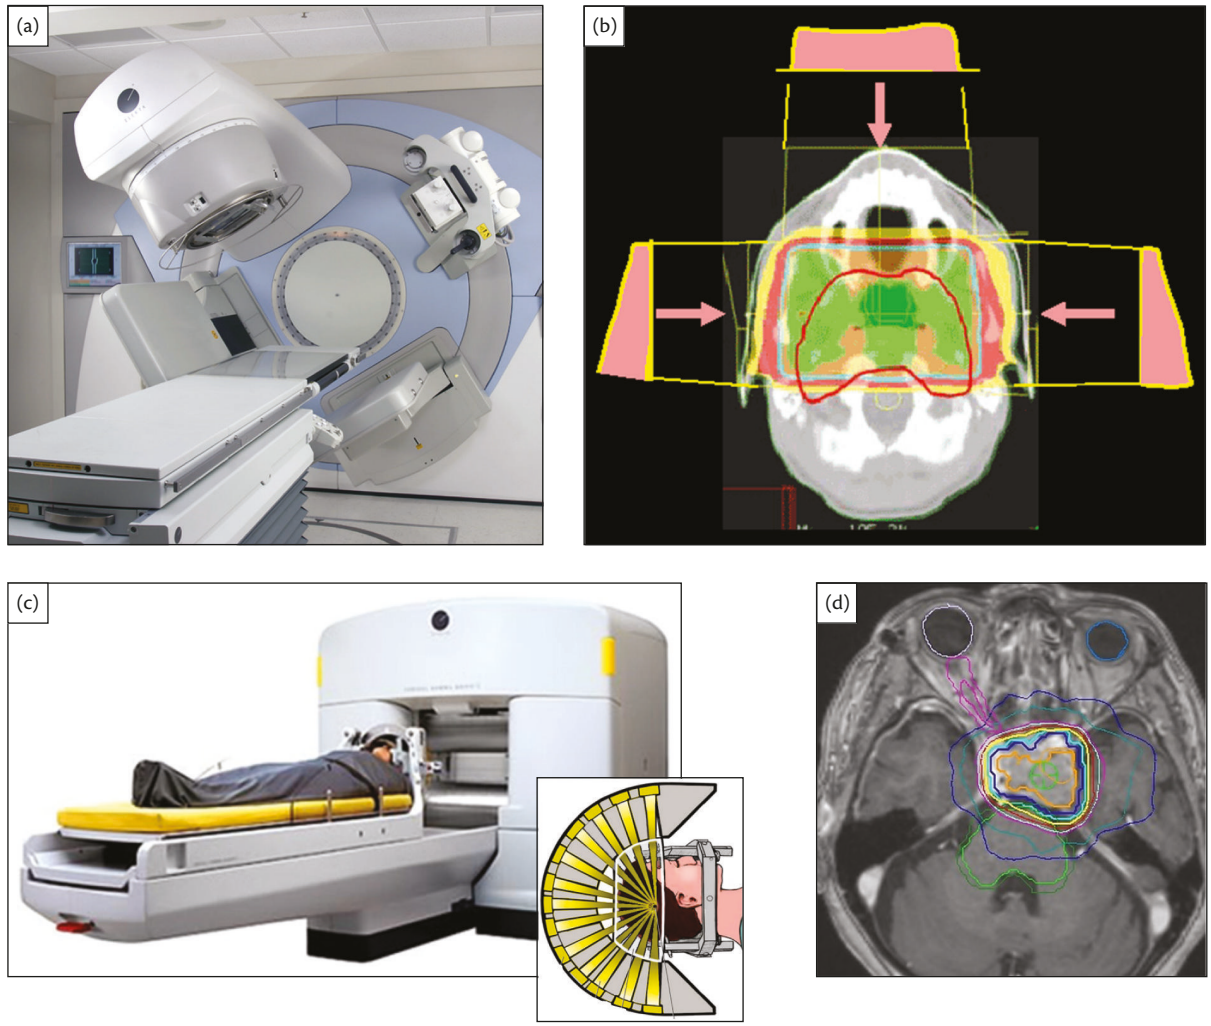

Fig. 25.10 Modalities of radiotherapy. Panel A: conventional radiotherapy with multileaf collimators targeting the beam. Panel B: radiotherapy dose planning. Panel C: stereotactic radiosurgery (Leksell Gamma Knife). Panel D: schematic of radiosurgical planning.

Choice between these modalities depends on the size and shape of residual tumour: stereotactic radiosurgery is recommended for small and focal targets that are more than 3 mm distance from the optic apparatus, whereas larger targets can be candidates for more conventional fractionated radiotherapy.

Proton beam is an emerging option to treat some skull base lesions and carries the advantage of a sharp drop out of radiation (i.e. the 'Bragg-Peak' effect). This enables higher doses of radiotherapy to be administered to the tumour with relative sparing of adjacent normal tissue. Proton beam therapy is not routinely recommended for pituitary adenomas. It is more reserved for treatment of residual skull base chordomas and chondrosarcomas which require a higher dose of radiotherapy with sparing of normal brainstem and optic chiasm.

Chemotherapy

Chemotherapy is rarely used in pituitary tumours except as a salvage treatment for very aggressive pituitary adenomas, where other treatment modalities have been exhausted. Oral temozolomide, a second-generation alkylating agent has been used in the treatment of pituitary adenomas and carcinomas with favourable response (Syro et al., 2011). Results of a Phase I trial suggested a possible role for placement of Gliadel (Carmustine wafers) into the resection cavity of pituitary tumours (Laws et al., 2003).

Management of tumour subtypes

Non-functioning pituitary adenomas (NFPA)

NFPA represent about 20% of all pituitary tumours and are the most frequent tumour type in terms of surgical caseload. About 80% belong to the gonadotroph cell lineage. They usually do not secrete active hormones. As a result, they remain clinically silent and continue to grow until they cause symptoms from mass effect or hypopituitarism by compression of the normal gland. By the same token NFPA are mostly macroadenomas.

These most frequently present with visual field defects, detected in 60–80% of cases. The chiasm is typically compressed from below in the midline, initially affecting the upper temporal quadrant, then progressing to bitemporal hemianopia (Fig. 25.11B). Contralateral homonymous hemianopia is also possible if the lesion is more posterior and with greater compromise of the proximal optic tract and involvement of Wilbrand's knee. Headaches are part of the presentation in up to 70% of cases, endocrine deficit in 8–20% of cases, apoplexy in approximately 2–7%, while cranial nerve palsies are less frequently seen (3%).

With the increasing availability of MRI and CT scans these lesions are also increasingly being discovered as incidental findings. A full set of pituitary function test should be performed as part of the workup.

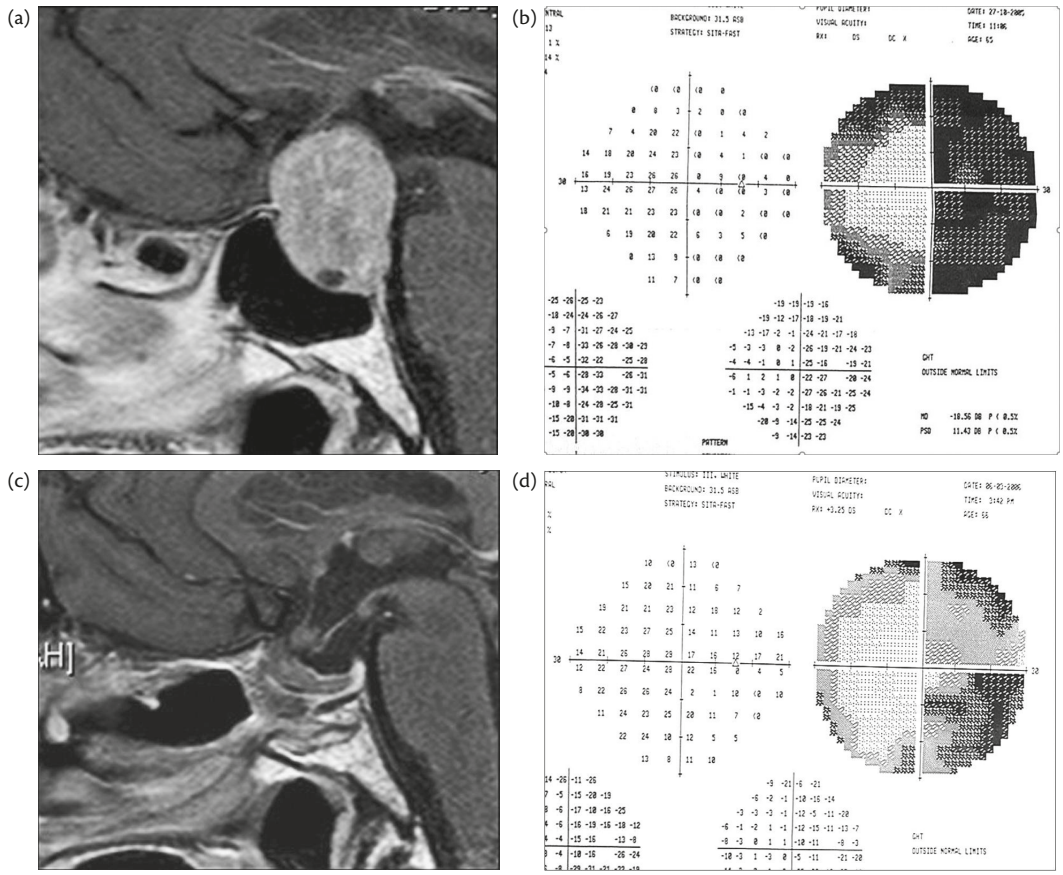

Fig. 25.11 Case example of a NFPA. Panel A: sagittal T1 gadolinium enhanced MRI scan a NFPA, displacing the optic chiasm upwards. Panel B: preoperative visual field assessment of the right eye for the same patient, showing right temporal hemianopia. Panel C: postoperative MRI appearances, with the descent of the optic chiasm following tumour debulking. Panel D: visual field assessment 6 months postoperatively with substantial improvement of the previously demonstrated deficit.

Primary treatment is surgical debulking with the aim to relieve compression on surrounding structures. The most commonly used surgical technique is endoscopic transsphenoidal approach.

Postoperatively vision improves in the majority with return to normal in 35%, partial improvement in 60% and there is no improvement or worsening vision in only around 5% (Gnanalingham et al., 2005). Postoperative visual improvement is typically progressive and over several years, but 50% of the eventual improvement in visual field deficits is apparent within the first 6 months (Fig. 25.11D).

Pituitary tumours being managed non-surgically can show spontaneous regression in about 10% of cases, but 50% of cases will progress and ultimately require surgery. Residual tumours can be targeted with fractionated radiotherapy or stereotactic radiosurgery.

Prolactin-producing adenomas

Incidence of prolactinomas ranges from 6 to 8 million/year. There are gender differences. Microprolactinomas are diagnosed 20 times more frequently in women of childbearing age, presumably because of the impact this has on fertility and the menstrual cycle, which prompts earlier investigation. Macroprolactinomas however occur with equal frequency for both genders. Furthermore, for women suffering from microadenomas, frequent symptoms are oligo or amenorrhoea, infertility, and galactorrhoea due to tumours secretory activity rather than mass effect. Hyperprolactinaemia in men can cause decreased libido, erectile dysfunction, gynaecomastia, and rarely galactorrhoea. See Figure 25.12.

Baseline prolactin levels are the first line of investigation, but several factors can affect serum prolactin levels. For example, the stress of a vein puncture can be associated with raised prolactin and thus blood samples taken from a cannula are preferred. Other extrapituitary causes of hyperprolactinaemia include neurogenic stimulation, drugs such as antidepressants, antipsychotics, and decreased serum clearance secondary to renal or hepatic insufficiency. Non-secreting pituitary lesions can also cause a modest increase in serum prolactin (typically 500–1000 mU/litre) due to pressure on the pituitary stalk. Values during pregnancy and breastfeeding can be around 3000–6000 mU/litre). In general, Prolactin levels greater than 2000 mU/litre are likely to be associated with prolactinomas and there is also a correlation between the prolactin level and the tumour size.

Two biochemical caveats to consider are the hook effect and the presence of macroprolactin. With the hook effect, high levels of prolactin are detected as falsely low due to the signal quenching effect of very high prolactin. This artefact can be corrected using serial sample dilution (St-Jean et al., 1996). Macroprolactin is a physiologically inactive form of prolactin found in a small proportion of people. It is in fact prolactin bound to IgG and some laboratory assays will detect it as prolactin, leading to a falsely elevated result.

The majority of prolactin-secreting adenomas can be managed medically with dopamine agonists such as cabergoline, bromocriptine, or pergolide. These agents are usually effective in approximately 90% of patients in suppressing the serum prolactin levels and inducing tumour shrinkage. Long-term clinical follow-up is recommended in patients managed medically with dopamine agonists. Some studies have reported that the dopamine agonists in some patients may be successfully weaned off longer term when no detectable tumour is seen on MR imaging and prolactin is completely suppressed, although this is not a universal finding (Schlechte, 2007).

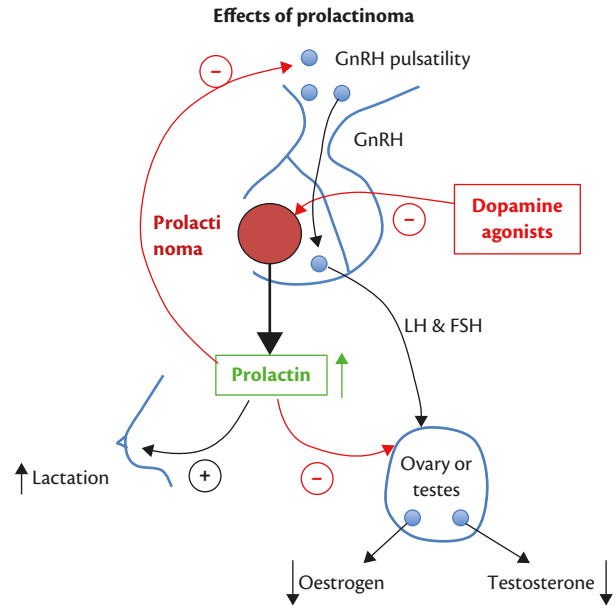

Fig. 25.12 Effect of prolactin-producing adenomas and medial management.

A rare but important side effect of cabergoline is cardiac valve abnormalities, which occurs secondary to fibroblast proliferation within the valve due to dopaminergic stimulation. Therefore, an echocardiogram is recommended prior to starting cabergoline and these patients should be monitored for this side effect. Dopamine agonists, notably cabergoline can be used to treat prolactinomas during pregnancy, with minimal risk of spontaneous abortion and congenital malformations.

About 10% of patients do not respond to treatment or are unable to tolerate the side effects of dopamine agonists such as nausea or depression. Thus only a minority of patients who are unable to tolerate the various dopamine agonists or fail to respond, warrant surgery. Surgical treatment is initially effective in 80–90% of microprolactinomas and in only about 50% of macroprolactinomas. Hyperprolactinaemia can persist and even recur after initial normalization. Radiotherapy can also be considered for inoperable tumours if medical therapy is not an option.

Growth hormone-producing tumours

GH-producing tumours constitute 20% of all pituitary adenomas with an incidence of 3–4 million/year. The source of growth hormone excess is a pituitary adenoma in 99% of cases with ectopic sources being exceptionally rare (Endocrine Society guidelines, Giustina et al., 2010).

Clinical presentation is often a combination of symptoms secondary to GH excess and/or mass effect from the tumour presenting as headaches and visual disturbance (Figs. 25.13B, C). In children and adolescents when the epiphyseal growth plates are active, GH excess causes gigantism, while in adults GH excess causes acromegaly. The constellation of signs and symptoms in acromegaly include swelling of soft tissues and internal organs, and pronounced jaw and frontal protuberances. Furthermore, excess GH production has a broad impact on body physiology affecting the following systems: musculoskeletal

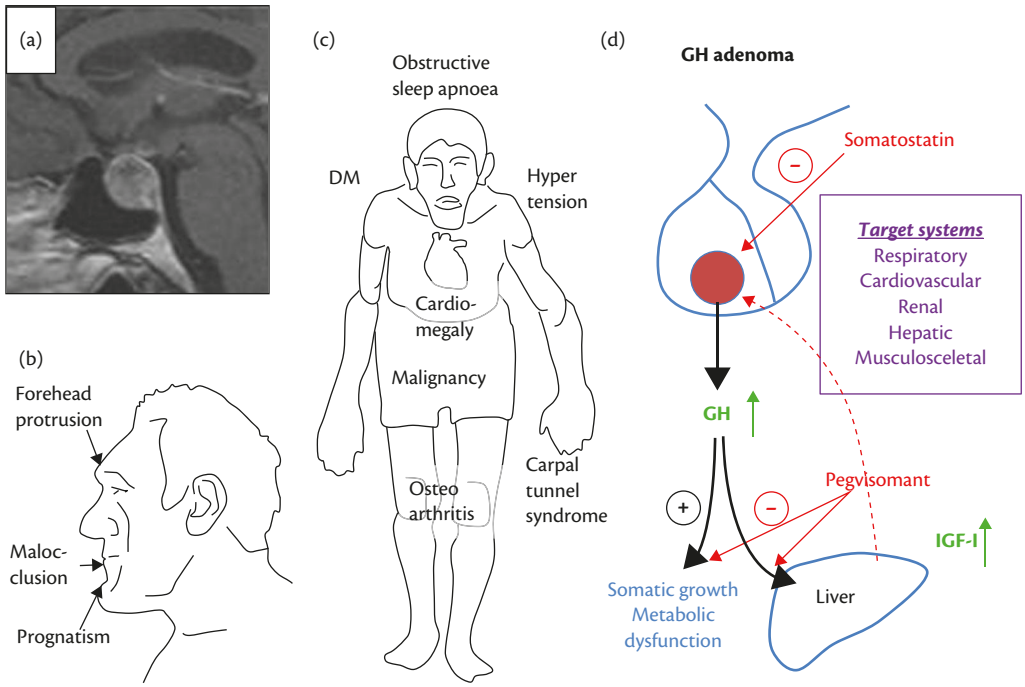

Fig. 25.13 (A) T1-weighted MRI scans of a growth hormone-producing macroadenoma. Presenting features of acromegaly (B) with typical involvement of multiple organ systems (C). Feedback loops and targets of medical management in growth hormone-producing adenomas (D).

in 70% of cases (e.g. arthropathy, degenerative osteoarthritis, vertebral fractures and compression neuropathy), cardiovascular in 60% of cases (e.g. cardiomyopathy, arrhythmia, hypertension and valvular disease) and respiratory in more than 50% of cases (e.g. obstructive sleep apnoea and nasal polyps). There are also pronounced metabolic effects such as diabetes, hypertension, dyslipidaemia and gout. There is a twofold risk of colon cancer in acromegaly. Compared to the general population, overall there is a twofold risk of mortality for untreated acromegaly due to the aforementioned cardiovascular, respiratory, and also neoplastic conditions.

Gender and age adjusted IGF-1 levels are the first line of investigation. As GH levels follow a pulsatile secretion pattern, random GH levels are difficult to interpret. IGF-1 is used as a surrogate marker of GH secretion and is usually raised in people with acromegaly. Confirmation of excessive GH secretion is obtained by the oral glucose tolerance test, which assesses adequate feedback of glucose on serum GH levels. Suppression of GH below 0.4 μg/litre with normal IGF1 levels rules out acromegaly (Giustina et al., 2010). Further confirmation can be obtained by demonstrating a raised mean GH level of greater than 1 μg/litre during a GH day curve. Coproduction of prolactin is also evident in 30–50% of cases.

MRI brain is warranted to delineate the pituitary adenoma prior to surgery. With negative MRI findings extrapituitary sources of GH/GHRH production should be investigated with further imaging (e.g. CT chest and abdomen).

Surgery is the most effective treatment for acromegaly with the goal of normalizing hormonal levels (i.e. both GH and IGF1) and decompressing surrounding structures. Endonasal transsphenoidal surgery generally achieves good outcomes with an average remission rate of 50–90% (Giustina et al., 2010). However, outcome is dependent upon several factors including surgeon experience, tumour size, tumour invasiveness, and preoperative GH levels. Predictors of good outcome include microadenomas (i.e. tumours smaller than 1 cm), non-invasive adenomas on MR and preoperative GH levels below 10 μg/litre. Early re-exploration may be considered for residual tumours and patients who are not in remission by the first operation to minimize surgical scarring.

Medical management consists of somatostatin analogues (eg. octreotide), which are successful at reducing GH levels in about half of the patients and partially shrink tumour size in about 30% of cases (Fig. 25.13D). GH receptor antagonists (e.g. pegvisomant) can reduce IGF1 levels in 95% of cases, but due to relative lack of feedback, there is an increase in adenoma size in about 5% of patients. In GH adenomas cosecreting prolactin, dopamine agonists can also be utilized. In practice, medical treatment serves as a postoperative adjunct in improving hormone levels in those not cured by surgery and for patients who are not medically fit for surgical intervention. Some centres also use pre-op medical treatment to help treat diabetes hypertension and to shrink tumour size.

Radiotherapy and radiosurgery are usually considered for residual tumour and are associated with a remission rate of 40–50, but there is a time delay of several years to achieve this (Castinetti et al., 2009).

Cushing's disease

Cushing's disease is a subtype of the greater category of Cushing's syndrome, which is defined as excess of serum cortisol. The most frequent cause of Cushing's syndrome is iatrogenic, where patients are kept on prolonged course of steroids for chronic conditions such as chronic obstructive pulmonary disease (COPD) or cerebral tumours. In the remaining cases glucocorticoid excess can be due to overproduction of ACTH either from a pituitary adenoma (~85% of cases) or other ectopic sources (~1%). Excess cortisol production by adrenal adenomas account for the remainder (approx. 15%).

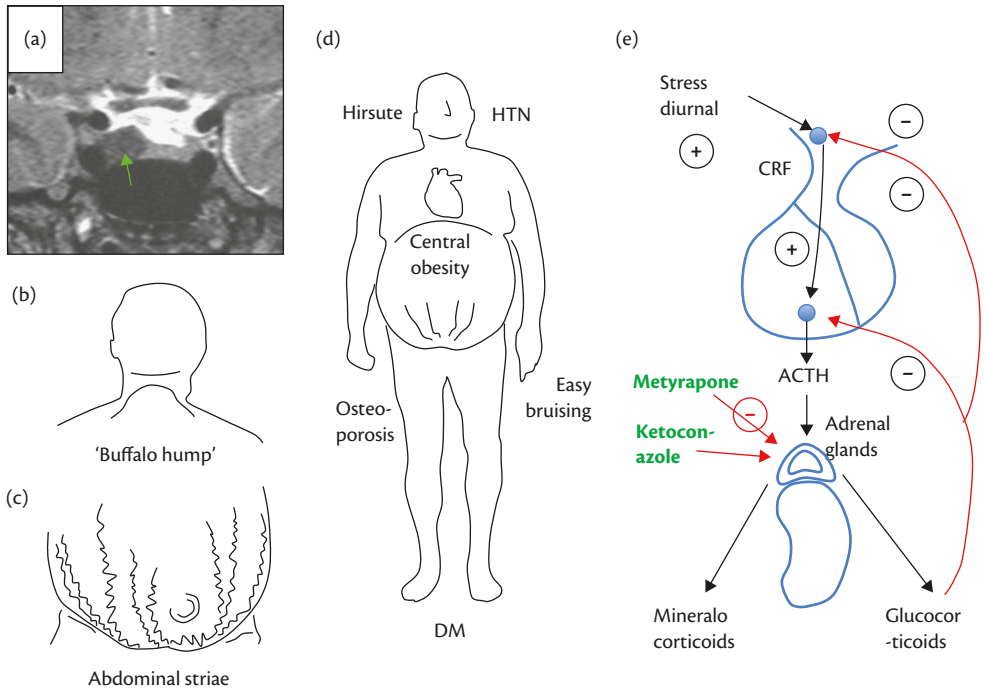

Fig. 25.14 MRI demonstrating right pituitary microadenoma causing Cushing's disease (A). Clinical features of Cushing's disease, including 'buffalo hump' (B), abdominal striate (C) and central obesity and involvement of multiple organ systems (D).

Pituitary adenomas associated with Cushing's disease are rare and carry an incidence of 1–2 million/year. Excessive exposure to glucocorticoids causes symptoms such as central obesity, facial plethora, rounded face, decreased libido, thin skin, decreased linear growth, hypertension, hirsutism, mood disorders, easy bruising, glucose intolerance, weakness, osteopenia, and nephrolithiasis (Figs. 25.14 B–D). Patients are often diagnosed in a delayed fashion, on grounds of the associated conditions such as difficult to control diabetes, hypertension, or obesity after a lengthy clinical journey.

In Cushing's disease the diagnostic pathway can also be complicated as no single diagnostic test has absolute sensitivity and specificity. Serum cortisol levels follow a circadian pattern and are influenced by several factors such as stress, depression, alcoholism, anorexia nervosa, or pregnancy.

Initial screening tests include early morning cortisol and ACTH levels, 24-hour urine free cortisol or midnight and 9am salivary cortisol levels. Late night salivary cortisol measurements have a sensitivity and specificity between 95 and 98% and can be used in the outpatient setting. The overnight dexamethasone suppression test involves giving 1 mg of oral dexamethasone at 23:00 hrs followed by measurement of serum cortisol at 9am the next day. Serum cortisol below 50 nmol/litre excludes Cushing's syndrome. In general, with pituitary and ectopic sources of Cushing's syndrome, both cortisol and ACTH levels are elevated. In Cushing's syndrome secondary to adrenal tumours, the cortisol levels but not the ACTH levels are high (Table 25.1).

Diagnostic dynamic tests are then undertaken and include the low-dose dexamethasone suppression test (LDDST). This involves the administration of dexamethasone (0.5 mg every 6 hours for 48 hours) following which 9am cortisol levels should suppress to below 50 nmol/litre. Failure to do so should be considered diagnostic of Cushing's, however in 3–8% of cases the sensitivity to dexamethasone is retained.

Table 25.1 Comparison of basal serum ACTH and cortisol levels in different causes for Cushing's syndrome. In Cushing's disease the diagnostic pathway can also be complicated as no single diagnostic test has absolute sensitivity and specificity. The typical changes seen with low-dose (LDDST) and high-dose dexamethasone suppression tests (HDDST) are shown

Tumour	ACTH	Cortisol	LDDST	HDDST
Normal	→	→	↓	↓
Pituitary adenoma	↑	↑	↑	→ or ↓
Ectopic ACTH	↑↑	↑	↑	↑
Adrenal tumours	↓	↑	↑	↑

The high dose dexamethasone involves administration of 8 mg of dexamethasone at 23:00 hrs and suppresses cortisol production in 50% of people with pituitary-dependent Cushing's, but its low sensitivity means that it is no longer commonly used (Table 25.1).

A dedicated MRI scan of the pituitary with contrast is used to look for the pituitary adenoma. Cushing's related tumours are largely microadenomas. However, in approximately 20–40% of cases, standard MRI scans fail to identify an adenoma in suspected cases of Cushing's disease. In such cases a dynamic MR scan is the next port of call (see radiology section, earlier on in this chapter).

If the adenoma is not clearly visible on the MR scan and/or if the biochemistry is equivocal then IPSS should be considered (Deipolyi et al., 2011). Despite it being an invasive investigation with potential morbidity, IPSS can help verify if the ACTH source is central (i.e. a CRF stimulated central to peripheral ratio of ACTH more than 3:1 is almost 100% sensitive and specific). Moreover, with IPSS a greater than 1.5-fold difference in CRF stimulated ACTH levels between the left and right sides can correctly identify the side of the lesion in the pituitary gland in approximately 70% of cases.

Suspected cases of ectopic tumours and adrenal adenomas are investigated with CT of the chest, abdomen, and pelvis.

For Cushing's disease secondary to a pituitary adenoma, surgical excision via a transnasal approach remains the most effective form of treatment. For non-invasive tumours selective microadenectomy can produce an initial remission rate of 70–80% but a relapse rate of up to 20% is quoted on longer follow-up. Remission rate is lower for macroadenomas, especially when invasive.

Medical treatment includes agents that inhibit steroid synthesis in the adrenal gland (e.g. metyrapone, ketoconazole, aminoglutethimide, and mitotane) (Fig. 25.14E). Medical therapy is also indicated for preoperative optimization and also reserved for patients where surgical treatment was not successful. Pituitary radiotherapy/radiosurgery is also generally reserved for when pituitary surgery has been unsuccessful.

In patients with ongoing disease after pituitary surgery, bilateral adrenalectomy is a salvage option to eliminate glucocorticoid excess. This treatment can result in Nelson's syndrome where due to the lack of negative feedback from glucocorticoids the increased ACTH production is associated with increase in melanocyte stimulating hormone (MSH), as both ACTH and MSH are derived from the same precursor, pro- opiomelanocortin. Increased MSH levels which stimulates melanocytes and causes excessive skin pigmentation. Furthermore, the remaining pituitary tumour can hypertrophy leading to mass effect.

Clinically 'silent' corticotroph adenomas may also become symptomatic due to mass effect or more rarely with conversion to Cushing`s disease in some patients.

Other functioning tumours

Thyrotropin-releasing pituitary tumours are much rarer and account for about 0.5–1% of all pituitary adenomas with an incidence of 1 per million population per year, limiting our experience to relatively small case series (Sanno et al., 2001). The majority of these tumours are macroadenomas presenting with signs secondary to mass effect and/or symptoms secondary to thyroxine excess including weight loss, palpitations, sleep disorders, and fatigue. TSHomas can be clinically indistinguishable from other causes of thyrotoxicosis.

Elevated serum T4 in association with raised or inappropriately normal TSH levels that do not suppress appropriately are the key biochemical findings. A MR scan to identify a pituitary mass is the other essential test.

Primary treatment is surgical excision, but preoperative medical control of hyperthyroidism is advised using beta-blockers and antithyroid agents (e.g. carbimazole or propylthiouracil). With transsphenoidal surgery, hormonal remission is achieved in about 80% of cases, but the ultimate cure rate is approximately 30%. Second-line treatment is radiotherapy, somatostatin analogues, or dopamine agonists.

Adenomas that produce biologically active gonadotropins (i.e. LH and FSH) are extremely rare. These patients usually present with signs of hypogonadism (e.g. irregular menstrual cycle or low libido), as the circadian rhythm is lost and testosterone levels are low. These patients can get large testes although this is extremely rare. On the other hand LH and FSH immunostaining adenomas that produce biologically inactive form of LH and FSH are common. This is apparent in the vast majority of non-functioning pituitary adenomas (Chaidarun and Klibanski, 2002).

Pituitary apoplexy

Pituitary apoplexy is an acute clinical condition secondary to infarction and/or haemorrhage within a pituitary adenoma (British Endocrine Society guidelines, Rajasekaran et al., 2011). Due to their rich vascular supply, tumours of the pituitary are approximately five times more likely to bleed or infarct than other brain tumours (Fig. 25.15). Overall, about 2–7% of pituitary adenomas can result in pituitary apoplexy. Risk factors include, anticoagulation, dopamine agonist therapy, pregnancy, hypertension, although most cases of apoplexy occur spontaneously.

The rapid expansion of the adenoma causes local mass effect with (1) visual field deficit; (2) endocrine disturbances due to compression of adjacent pituitary gland and hypothalamus; (3) cranial nerve deficits due to cavernous sinus compression; and/or (4) signs of raised intracranial pressure secondary to obstructive hydrocephalus. Headache is the most frequent presenting symptom occurring in 80–90% of cases. Headache is relatively acute in onset mimicking intracerebral or subarachnoid bleeds. Visual deficits, ocular paresis, and vomiting occur in 30–40% of patients. Altered consciousness is noted in approximately 20% of cases while meningism is seen less frequently.

Endocrine disturbances of one or more pituitary hormones are present in most (~80–90%) patients with pituitary apoplexy, with growth hormone and ACTH deficiency being the most common (65–80%). Pituitary apoplexy score (0–10) is based on the hierarchical consideration of deranged conscious level, visual acuity, visual field defect, and ocular paresis (Rajasekaran et al., 2011).

Management of pituitary apoplexy is dependent upon the severity of presenting symptoms. Factors to consider include decreased conscious level, severity of visual impairment, MR findings, endocrine and electrolyte disturbances. The initial medical management includes replacement of steroids (i.e. IV hydrocortisone) and fluid resuscitation.

Urgent surgery is advised in most patients with visual disturbance and corresponding mass effect and chiasmal compromise on MR. Moreover the timing of surgical decompression is subject to ongoing debate. In general, early surgery is considered for patients with severe visual deficits and those with less visual defect being treated conservatively. As a general rule, surgical decompression should take place within 1–2 days and once the patient has been medically stabilized. Transsphenoidal approach is favoured for most patients and the presence of hydrocephalus requires insertion of an external ventricular drain. Visual outcomes generally improve following surgery. However, the majority of patients with hypopituitarism at the outset do not recover from the hormone deficit. Moreover, even with conservative management, studies have shown that tumour shrinkage can happen over time with recovery in visual disturbances.

Craniopharyngioma

Craniopharyngioma is a rare suprasellar tumour with an incidence of 0.5–2.5 million/year. It is an epithelial-squamous, calcified, and cystic tumour arising from remnants of the craniopharyngeal duct and/or Rathke's cleft. Adamantinomatous and papillary variants are recognized histologically and intraoperatively the presence of dark brown 'machine oil' fluid with speckles of calcification and cholesterol clefts are pathognomonic.

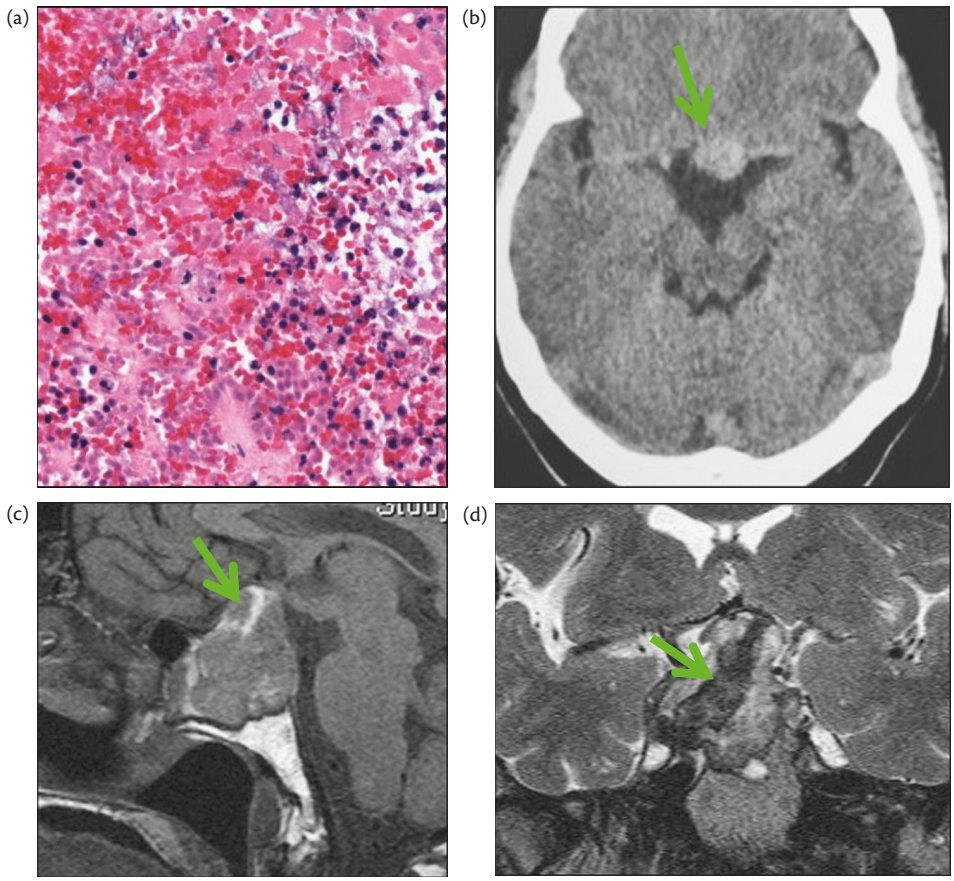

Fig. 25.15 In a case of pituitary apoplexy CT brain (panel B) and sagittal T1 (panel C) and coronal T2-weighted (panel D) MR images demonstrating haemorrhage (arrow) into a pituitary macroadenoma. Haematoxylin and eosin stain confirming evidence of haemorrhage and inflammatory cell infiltrate (A).

Endocrine deficits occur in 80–90% of cases and are associated with signs of mass effect such as visual field defect (20–25%). Diabetes insipidus is seen in 8–35% of cases at presentation.

MR and CT imaging usually differentiates craniopharyngiomas from pituitary adenomas based on the presence of calcification (80–90%), suprasellar position, cystic components, and patchy enhancement (Fig. 25.16A). Lesions can arise from the sellar, stalk, and suprasellar region extending into the third ventricle.

Principles of treatment consist of maximal and safe surgical resection and to decompress the optic chiasm, while taking care to minimize operative morbidity, notably hypothalamic injury. Cystic recurrence can be a troublesome problem and is usually managed by insertion of an Omaya reservoir. Radiotherapy and stereotactic radiosurgery are reserved for residual tumours and for patients who are not fit for surgery. With these measures, tumour control rates can reach up to 80%.

Rathke's cleft cyst

This is a non-neoplastic epithelium-lined cystic lesion arising from the embryologic remnants of Rathke's pouch in the sellar or suprasellar area. The majority of Rathke's cleft cysts are asymptomatic and are incidentally discovered. The cystic content is usually proteinaceous fluid, that appears high signal of T1-weighted MR imaging (Fig. 25.16B).

Management can be conservative if the cystic lesion is small and radiologically shown to be stable. With relatively large lesions or especially if increasing in size, the goal of surgery is drainage of the cyst and consequent decompression of the optic chiasm. Cyst recurrence may require further surgical drainage (e.g. transsphenoidal or transcranial approaches) and/or insertion of an Omaya reservoir to aid future percutaneous drainage in the event of recollections.

Inflammatory conditions

Lymphocytic hypophysitis: This is a rare inflammatory autoimmune condition (incidence 1/million/year). Most frequently it occurs in the peripartum period in women and acute, subacute, and chronic subtypes are recognized. In acute hypophysitis, the most frequent presentation is related to the mass effect from a rapidly expanding inflammatory mass. In the subacute or chronic setting, the symptoms of mass effect and hormonal deficits are more subtle.

This diagnosis can be suspected from clinical history and MRI findings, however if there is uncertainty a surgical biopsy is warranted. On MR imaging there is symmetric enlargement of the gland, with uniform enhancement and thickening of the pituitary stalk (Fig. 25.16C).

Treatment is determined by how fast the symptoms develop: surgical decompression is indicated for cases with acute deterioration and with no response to medical management. Expectant management (including steroids and hormone replacement) where there is little mass effect can be successful with progressive reduction in the size of the lesion (Falorni et al., 2014).

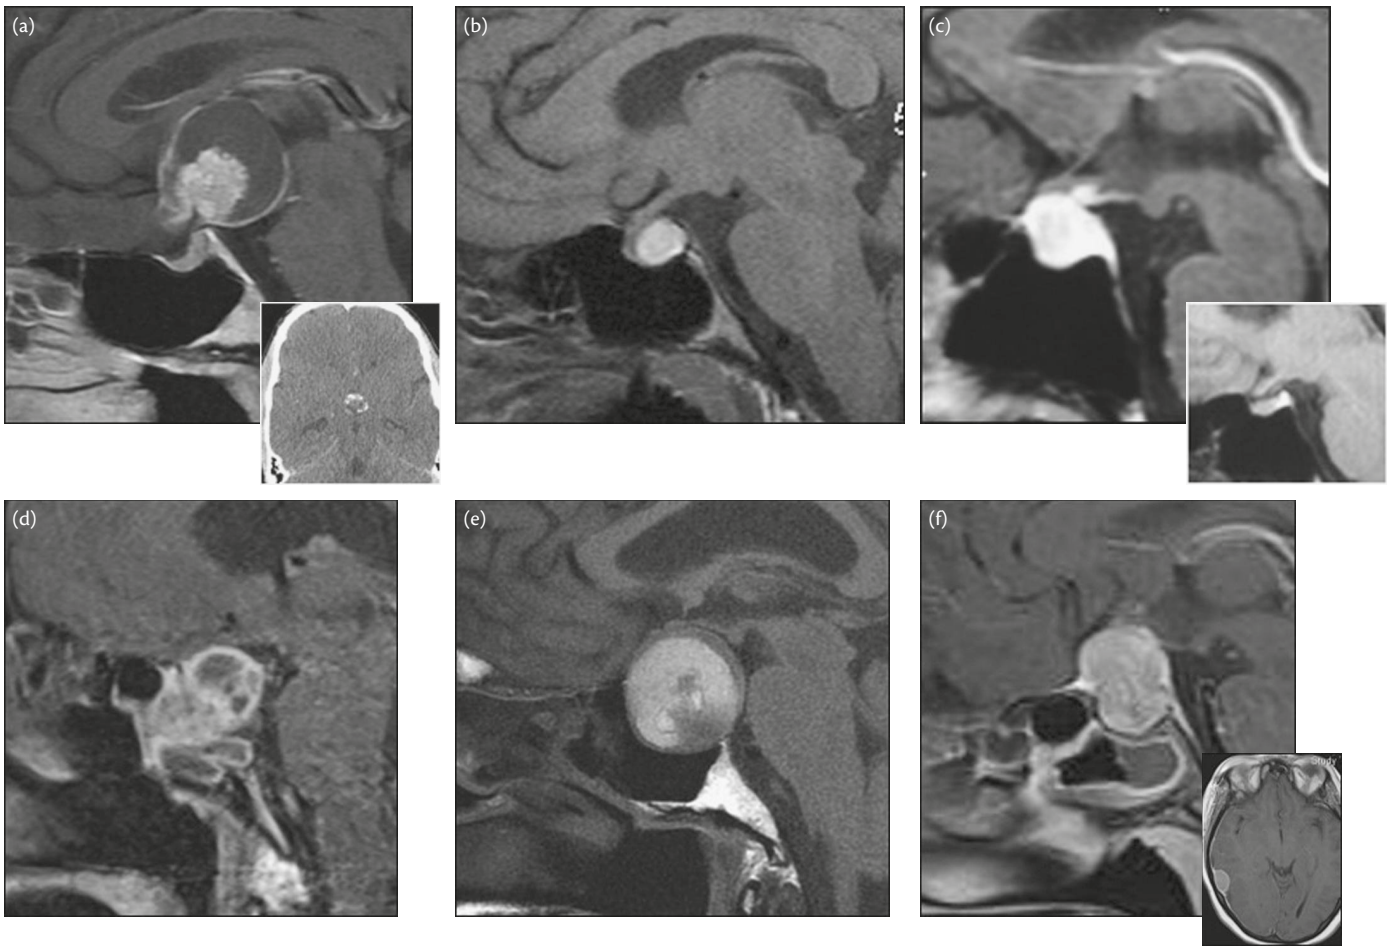

Fig. 25.16 Example of MR images of Craniopharyngioma (A; sagittal T1 with contrast and inset showing calcification on CT), Rathke's cyst (B; sagittal T1 MR), lymphocytic hypophysitis (C; sagittal T1 with contrast and inset showing shrinkage of lesion 8 months later), pituitary abscess (D; sagittal T1 with contrast), pituitary metastasis from adenocarcinoma of bowel (E; sagittal T1 MR) and pituitary carcinoma (F; sagittal T1 with contrast and inset showing right temporal dural metastasis (F).

Neurosarcoidosis: This is a rare presentation of systemic sarcoidosis. It affects the central nervous system in 5–15% of cases with a mortality of 10–20%. Cranial nerves, hypothalamus, meninges, and the pituitary gland are the most frequently affected in the central nervous system. Pituitary sarcoidosis contributes to less than 1% of intrasellar lesions. The most frequently reported hormonal deficit is hypogonadism followed by TSH, ADH deficiency.

Investigations include MRI brain (enhancing sellar and dural lesions), elevated serum ACE levels, and CSF analysis. Surgical biopsy for histological confirmation is usually needed. Medical management consists of hormone replacement, steroids or other immunosuppressants (e.g. prednisolone, methotrexate, cyclophosphamide, and azathioprine) and low-dose radiotherapy. Although MRI abnormalities resolve with steroids, the hormonal deficits persist in the majority of cases (Langrand et al., 2012).

Infections involving the pituitary gland

Infections of the pituitary gland are rare conditions. They can occur on grounds of aseptic necrosis of the gland, haematogenous spread, or direct extension of brain abscesses or tuberculomas (Zhang et al., 2012). Pituitary abscesses constitute approximately 0.5% of pituitary lesions and most common presentations are headaches and visual disturbances. Most frequent organisms are streptococci and staphylococci. Tuberculomas of the pituitary occur in the context of immunosuppressed patients and those with tuberculosis elsewhere.

Imaging findings are classically those of a peripherally enhancing sellar mass with restricted diffusion (Fig. 25.16D). Treatment options include surgical drainage by endonasal transsphenoidal or transcranial routes. Histological and microbiological analysis is paramount to clinch the diagnosis, followed by long-term antibiotics (at least 6 weeks or more) with serial contrast enhanced MRI scans to confirm disease clearance.

Secondary malignancies

The prevalence of metastasis to the pituitary is estimated at between 1% and 3.6% based on autopsy studies (Fassett and Couldwell, 2004). Virtually any tumour can metastasize to the pituitary gland. Spread is usually haematogenous and much less commonly by contiguity from the surrounding bone. The most common primary malignancies are breast and lung (Fig. 25.16E). Pituitary metastasis is only symptomatic in 7% of cases with diabetes insipidus, ophthalmoplegia, headaches, and anterior pituitary deficiency as the most common presentation.

Surgical biopsy/excision is the primary treatment modality combined with postoperative radiotherapy to the tumour bed and systemic oncological treatment depending on the primary malignancy and staging of disease. Most patients have systemic spread of their primary disease by the time the pituitary metastasis is found and therefore prognosis is very poor.

Other parasellar lesions

There are several other lesions such as meningiomas, chordomas, chondrosarcomas, fibrous dysplasia, Langerhans cell histiocytosis, and vascular abnormalities that can occur in the parasellar regions and extend to the sella. Differential diagnosis with pituitary adenomas can at times be challenging but the majority can be identified with reasonable confidence based on the presenting history and imaging (MR/CT) findings. These pathologies are covered elsewhere in this book.

Postoperative endocrine management

Risk of hypopituitarism

The risk of hypopituitarism following surgery varies depending on a number of factors, including the rigorous nature of endocrine tests, degree of compromise of pituitary function preoperatively and the type and size of tumour. Overall the risk of new pituitary hormone deficiency is estimated to be approximately 10–20% after transsphenoidal surgery. However, 50–70% of patients with pituitary adenomas may present with established hypopituitarism, with LH/FSH deficiencies being the commonest (Jahangiri et al., 2014). The risk of transient diabetes insipidus occurs at a rate of 16–25%, although permanent diabetes insipidus is below 5%, again influenced by the type of tumour, with craniopharyngiomas having a relatively high risk.

Steroid replacement protocols

In general patients undergoing pituitary surgery are at risk of hypocortisolaemia, which can be life-threatening. They should receive hydrocortisone on induction of anaesthesia and postoperatively until the endogenous cortisol production is confirmed to be satisfactory.

Peri- and postoperative hydrocortisone replacement protocols vary. A typical example is as follows: 100 mg intravenously in theatre at the time of surgery (and a further dose 8 hrs later), followed by a tapered oral dose of 20 mg (08:00 hrs), 10 mg (12:00 hrs), 10 mg (18:00 hrs) for the next 2 days, and then to a maintenance oral dose of 10 mg (08:00 hrs), 5 mg (12:00 hrs), and 5 mg (18:00 hrs). Two to three weeks later, the patient will need basal (09:00 hrs cortisol levels) and dynamic tests (e.g. insulin or glucagon stress test) to check the need for long-term steroid replacement. Alternatively, with the patient not on steroid supplements, 9am cortisol may be assessed in the days after surgery, with the patient put on steroid replacement when the 9am cortisol levels are low (i.e. <400 nmol/litre). The cortisol axis will also need further tests in the months postoperatively as the pituitary gland function may recover over time. The need for long-term postoperative steroids varies, with the majority of patients not requiring it.

Postoperative hyper- and hyponatraemia

Hypernatraemia: Diabetes insipidus (DI) is the most common cause of postoperative hypernatraemia. Typical biochemical criteria for the diagnosis of DI is polyuria (i.e. urine output >200 ml/hr for 3 or more consecutive hours), associated with hypernatraemia (i.e. serum sodium >145 mmol/litre) and increased serum osmolality together with a decreased urine osmolality. Transient DI immediately after pituitary surgery is frequently seen with prevalence varying between 10 and 30% for transnasal techniques. Permanent DI is much rarer occurring in 0–7% of cases (Schreckinger et al., 2013). DI occurs more often with craniopharyngiomas (especially postoperatively), neurosarcoidosis, and pituitary metastases.

Besides transient and permanent DI, a triphasic pattern can rarely occur (1–3% of postop cases. This consists of an acute phase of DI in the first few days after surgery related to the abrupt discontinuation of ADH release, followed by a surge in ADH from the degenerating hypothalamic nuclei, usually 1–2 weeks postoperatively resulting in low serum sodium (i.e. syndrome of inappropriate ADH release; SIADH). This phase is followed by the relapse to permanent DI phase due to the exhaustion of ADH production.

First line of management in DI is fluid resuscitation (oral or IV as appropriate) with repeat biochemistry at frequent intervals. Depending on the response, DDAVP replacement (IV, oral, or nasal spray formulations available) may be warranted. Gentle correction of serum sodium (i.e. no more than 10 mmol/litre per day) is advisable.

Hyponatraemia Postoperative hyponatraemia is an infrequent complication of pituitary surgery (up to 10–15% of cases) and it can occur in the context of syndrome of inappropriate ADH production (SIADH) or cerebral salt wasting (CSW). Differentiating between these two conditions is essential, as they require different treatments. SIADH is more common that CSW following pituitary surgery. It is characterized by excessive secretion of ADH, which leads to water retention through the distal collective ducts in the kidney. This results in reduced urine output, hyponatraemia, and increased total body water content.

Treatment is with fluid restriction of up to 500–750 ml per day with repeat biochemistry every 24 hours (or more frequently depending on the severity of hyponatraemia) until serum sodium is normal. Gradual correction of sodium is essential (i.e. less than 10 mmol/litre serum sodium per day), to avoid the risk of central pontine myelinolysis. Medical management is occasionally needed with demeclocycline and less commonly hypertonic saline and/or Tolvaptan (a vasopressin receptor 2 antagonist that needs close monitoring).

CSW is less common following pituitary surgery and is more frequently seen after head injury or subarachnoid haemorrhage. It is associated with excessive sodium loss in urine from the kidneys, depleted intravascular volume with raised urine sodium content. Treatment is salt replacement with salt tablets (can be irritant to the stomach), IV saline, and/or fludrocortisone.

Differentiating between SIADH and CSW can be difficult and the most useful differentiating features are assessment of body fluid volume status (eg central venous pressure etc) and response to saline fluid challenge (i.e. hyponatraemia worsens in SIADH and improves in CSW).

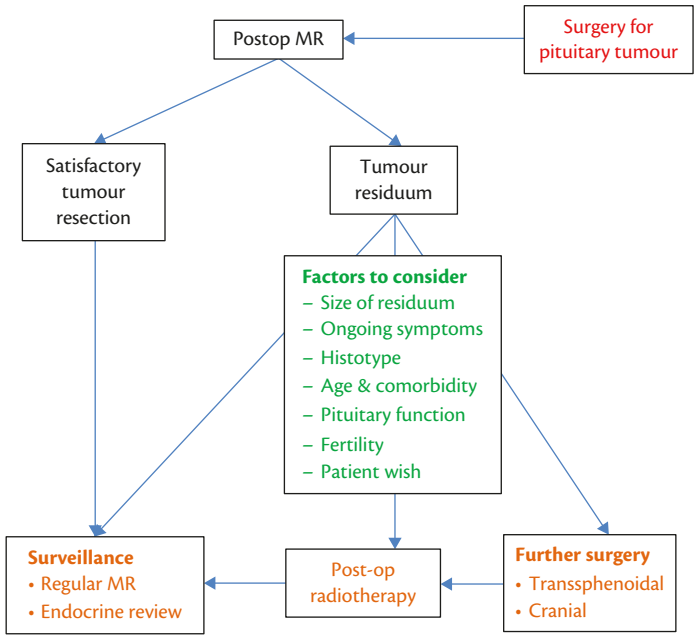

Fig. 25.17 Line diagram depicting clinical decision algorithms for residual tumours.

Topical issues

Management of residual tumour

The management of residual tumours depends on multiple factors and therefore management decisions are best made on a case-by-case basis with involvement of a pituitary multidisciplinary team (MDT; Fig. 25.17).

Most patients have their follow-up MRI scan at 4–6 months after the surgery to allow for blood and other haemostatic materials placed in the tumour bed to be absorbed. The decision on further surgery, radiotherapy, or continued surveillance is influenced by the MR scan findings (e.g. size and invasiveness of tumour residuum) and other factors such as histological features, ongoing tumour-related symptoms (e.g. visual disturbance), age, comorbidity, pituitary function, fertility state (if fertility is desired), and patient wishes.

In general, symptomatic patients with sizeable or progressively enlarging tumours can undergo repeat operation through a transnasal or cranial approach. Radiotherapy and stereotactic radiosurgery are very effective in controlling small residual tumours that are difficult to resect. Early radiotherapy can be favoured in patients with established hypopituitarism and comorbidity. Age is another consideration for radiotherapy as younger patients are more likely to suffer from long term radiation induced complications (e.g. neurocognitive sequelae, development of secondary tumours etc). Suspected small tumour residuum on post-op MR scans without significant associated symptoms can also be observed with regular (mostly annual) MRI scans, with a view to surgically intervening at a later stage. This is especially so in patients with relatively intact pituitary function.

Management of incidentalomas

Pituitary adenomas are being increasingly diagnosed in an incidental fashion due to the greater availability of MR imaging. In adults who underwent cranial imaging for reasons other than pituitary disease, incidentalomas were seen on MRI between 10–38% of patients, although less than 1% are macroadenomas (i.e. >1 cm in maximum diameter).

The general recommendations are that patients presenting with a pituitary incidentaloma undergo an endocrine review, including evaluation for evidence of hypopituitarism and hormone hypersecretion (Freda et al., 2011).

Management of the pituitary incidentaloma will depend on a number of factors, including size of the lesion, endocrine status, visual status, and also taking into account other factors such as patient age, comorbidity, and patient wishes. In general, surgery should be considered in patients with an incidentaloma causing chiasmal compression, visual deficits attributable to the lesion and/or hormone secretion, with the exception of prolactinomas which can invariably be managed medically (Fig. 25.18; Freda et al., 2011).

Patient's with small microadenomas, with no relevant symptoms can be managed conservatively. They usually require annual MR scans for the first 3 years and if the lesion remains radiologically stable then progressively at increasing scanning intervals. Surgery becomes an option if the lesion significantly increases in size during the surveillance period. This is more likely with macroadenomas, which on a recent review increased in 24% of patients, although for all incidentalomas this risk is ~8% per year (Freda et al., 2011). Patients being managed conservatively also need to be warned of the small (~2%) risk of pituitary apoplexy and the potential development of visual symptoms and need for urgent surgical decompression.

Hypopituitarism following traumatic brain injury (TBI) and aneurysmal subarachnoid haemorrhage (SAH)

In recent years there has been increasing recognition of hypopituitarism following TBI or SAH. The incidence of hypopituitarism following TBI is reported to vary between 15% and 68% of cases (an average of 27.5% on a systematic review by Agha et al., 2007; Schneider et al., 2007). Indeed, some of the presenting features of

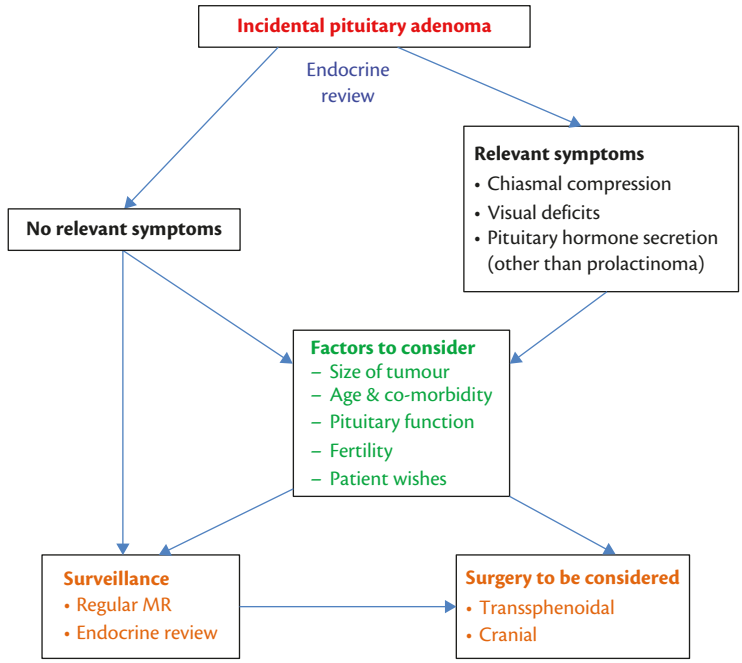

Fig. 25.18 Line diagram depicting clinical decision algorithms for incidental tumours.

hypopituitarism such fatigue, low mood, poor concentration, and other neurocognitive issues are often attributed to the brain injury itself and therefore the impairment of pituitary function remains unrecognized. The reported de novo deficiencies for pituitary hormone production are variable; the most frequently affected hormones are gonadotropins (13%), growth hormone (12%), and ACTH (8%). Spontaneous recovery was seen in 50–70% of cases. Acute phase DI can be present in approximately 20% of cases and in 7% of long-term survivors. Severity of head injury was found to be a possible predictor of hypopituitarism with frequencies of 35%, 11% and 17% for severe, moderate, and mild head injuries respectively (Schneider et al., 2007).

The literature on postop hypopituitarism following SAH is sparse. Acute pituitary dysfunction occurs in about 38–55% of patients (i.e. average of 47% in a systemic review) following aneurysmal subarachnoid haemorrhage but this figure is based on multiple relatively small case series (Schneider et al., 2007). The most frequently affected hormones are gonadotropins (25%) and growth hormone (6%) and ACTH (21%). Moreover, a systemic review of the literature showed a gradual recovery of pituitary function over time with 26% at 6 months post injury and only 7% had pituitary dysfunction after 14 months (Schneider et al., 2007).

Awareness of hypopituitarism in both TBI and SAH is important, because some of the presenting symptoms (fatigue, neuropsychiatric symptoms) can be attributed to the primary pathology rather than a scenario of hormonal deficiency. The benefits of replacing the missing pituitary hormones in managing neurocognitive symptoms are less clear and subject to ongoing studies.

Craniopharyngioma and Rathke's cleft cysts

Rudolf Fahlbusch, V. Gerganov, and H. Metwali

Introduction

Both craniopharyngiomas and Rathke's cysts are rare pituitary lesions of dysembryogenic origin. Their radiological differentiation may be sometimes difficult due to their occasionally similar imaging characteristics. The surgical management of these lesions, especially of craniopharyngiomas, may be very challenging.

Gross total removal of a craniopharyngioma is associated with longer recurrence-free survival but could be associated with higher rate of surgery-related morbidities and pituitary insufficiency. Craniopharyngiomas are considered in most cases to be a 'chronic disease'. A principle difference in the operative management of these two lesions is that in craniopharyngiomas resection of their thicker capsule is mandatory in order to achieve complete removal, whereas it is nearly impossible and not recommended to attempt such cyst wall removal in Rathke's cysts. Emptying of the cyst content is usually sufficient to provide cure in the majority of these patients. Recurrences in Rathke's cyst are only rarely observed in contrast to craniopharyngiomas.

Craniopharyngiomas

Craniopharyngiomas are relatively rare tumours with an overall incidence of 0.13/100 000 neoplasms per year. It has been estimated that approximately 340 new cases should be diagnosed annually in the United States (Bunin et al., 1997). They have a bimodal age distribution, with one peak occurring in the paediatric population between 5 and 14 years of age, and a second peak in adults during the fifth decade of life (Nielsen et al., 2011). In children they account for 5–10% of all primary brain tumours (Hussain et al., 2013). The lesion is so rare that even 'the experts' have between 6 and 10 new patients per year, according to their published surgical series.

Craniopharyngiomas are regarded as histopathologically benign intracranial tumours but may be very adherent to adjacent structures including the pituitary stalk, tuber cinereum, and hypothalamus which makes their complete resection challenging. Nevertheless, resection is possible without major morbidity in most cases, as proven by many recent publications. Alternative treatment strategies include non-radical surgical resection followed by fractionated radiation therapy, cyst aspiration with implantation of an Ommaya reservoir, intracavity radioisotope or chemotherapy instillation, and radiosurgery.

Pathology and pathogenesis of craniopharyngiomas

There are two major subtypes of craniopharyngioma, adamantinomatous and papillary, which differ both clinically and histologically. The papillary subtype (pCR) is more rare and is typical for adults: it comprises 11–14% of all craniopharyngiomas. Papillary CR are thought to arise from metaplastic transformation of anterior pituitary or pituitary stalk epithelial cells (**Fig. 26.1**). Adamantinomatous craniopharyngiomas (aCR) are found predominantly in children but can present at any age. They arise from neoplastic transformation of ectopic embryonic rests during the development and involution of the Rathke pouch. aCR resemble some odontogenic tumours, which indicates a common embryonic origin. Macroscopically adamantinomatous craniopharyngiomas are usually lobular with a sharp irregular interface, frequently adherent to surrounding structures and invasive. Histologically they consist of mature squamous epithelium and pseudopapillae (**Fig. 26.1**). These CR can have solid or cystic components. The cystic contents are usually viscous, from yellow to dark brown or black in colour ('motor-oil' appearance), which reflects the variable cholesterol crystal content. In contrast, pCR are encapsulated, often solid, and do not adhere to surrounding structures. If they have a cystic component, the fluid content is clear (Crotty et al., 1995; Shin et al., 1999; Larkin and Ansorge, 2013).

In addition to the clinical and histopathologically differences, the two subtypes are thought to have distinct genetic origins. The development of CR is driven by mutations in a single well-established oncogene, catenin beta-1 (CTNNB1) in the adamantinomatous form and *BRAF* in the papillary form, independent of age. The CTNNB1 mutation in aCR and *BRAF* mutation in pCR are clonal. No other recurrent mutations or genomic aberrations have been detected in either subtype (Brastianos et al., 2014).

In recent years, the molecular pathogenesis of craniopharyngioma initiation, growth, and recurrence have been extensively studied. Due to advances in molecular biology, such as comparative genomic hybridization, genetic sequencing, targeted genotyping, and development of appropriate genetically engineered animal models, some of the pathogenetical mechanisms of CR development have been elucidated.

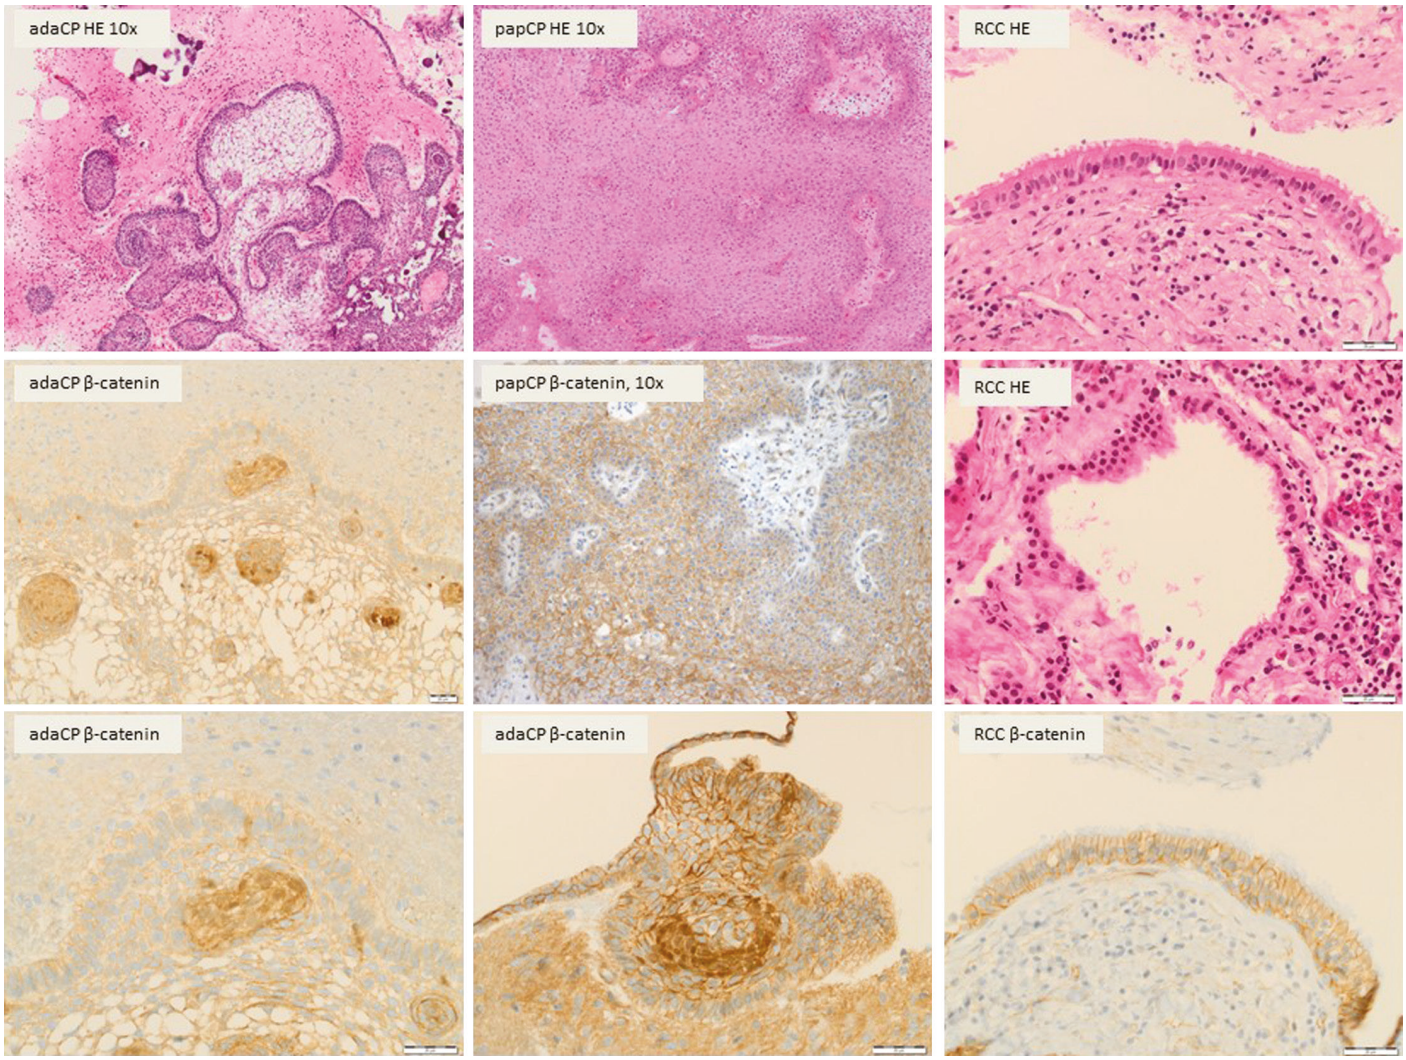

Fig. 26.1 The left column shows the histological features of an adamantinomatous craniopharyngioma, the upper slide was stained with H&E and the middle and lower by β-catenin. In the middle column, the upper two images demonstrate the histological features of a papillomatous craniopharyngioma where the upper slice was stained with H&E, and the middle slices by β-catenin. The lower image of the middle column shows an adamantinomatous craniopharyngioma stained for ß-catenin together with brain tissue. The right column shows the histological features of Rathke's cleft cyst. The upper and the middle slices show the columnar partially pseudostratified lining. The lower slice shows that Rathke's cysts are not stained by β-catenin which is useful in differentiating them from craniopharyngiomas.
Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

The main abnormality at molecular level or driver in the oncogenesis of the adamantinomatous subtype is related to the Wnt/β-catenin pathway. This signalling pathway is crucial during embryogenesis in forming the dorsoventral axis of the developing neural tube in vertebrates. Adamantinomatous, but not papillary craniopharyngiomas harbour β-catenin mutations (Crotty et al., 1995; Prabhu and Brown, 2005; Holsken et al., 2009; Larkin and Ansorge, 2013).

The CTNNB1 mutations in the β-catenin gene on chromosome 3 and aberrations in β-catenin expression have been implicated in the development of other cancers including colorectal, hepatocellular carcinomas and medulloblastomas (Hussain et al., 2013).

Mutations in CTNNB1 have been found in approximately 70% of adamantinomatous craniopharyngiomas. Recent studies, however, have identified mutations in CTNNB1 in nearly all aCR, 92% when whole exome sequencing is used and 96% with targeted genotyping is used (Brastianos et al., 2014).

Such mutations stabilize b–catenin thus leading to constitutive activation of the Wnt signalling pathway (Holsken et al., 2009; Holsken et al., 2010; Larkin and Ansorge, 2013). It is known that most CTNNB1 mutations occur in exon 3 (Sekine et al., 2002). Experiments with genetically engineered animal models have proven a role for Wnt/β-catenin pathway dysregulation in the pathogenesis of craniopharyngiomas. The tumourigenic anomaly in the remaining aCR tumours, that do not have the CTNNB1 mutations, has not been identified. However, the anomaly is likely to be related to Wnt pathway activation.

Along with the pathogenesis of CR, many studies recently focus on the molecular mechanisms underlying tumour behaviour and relation to surrounding structures. These issues are very relevant from a practical neurosurgical point of view because invasion of adjacent structures is a limiting factor in successful surgical removal of aCR. Interestingly, β-catenin mutations are present in all cells but nuclear location of the β-catenin mutation is found only in small clusters of

cells near the infiltrating edge of the aCR. It has been hypothesized therefore, that Wnt signalling via β-catenin is implicated in the migratory behaviour of aCR. Furthermore, in aCR the concentration of fascin (FSCN1), which is a key cytoskeletal protein related to cell mobility, is increased. The Wnt/β-catenin/TCF pathway is linked to the expression of FSCN1. Down regulation of CTNBB1 reduces levels of fascin and subsequently tumour cell migration (Holsken et al., 2010). EGFR is overexpressed in aCR but in a heterogeneous pattern with the highest levels at the infiltration zone between tumour cells and normal brain tissue. The involvement of b–catenin, fascin and EGFR in the migratory behaviour of aCR cells suggests that the cell clusters with nuclear β-catenin may promote the infiltration of tumour into the surrounding tissues (Holsken et al., 2010; Larkin and Ansorge, 2013).

The molecular mechanisms underlying the development or recurrence of aCR may be related to different gene expression patterns. In recurrent tumours there is an increased expression of growth factors and related receptors which normally regulate cellular proliferation such as the platelet-derived growth factor receptor–a (PDGFR-a) and fibroblast growth factor-2 (FGF-2) (Sun et al., 2010).

We observed very unusual cases of invasive craniopharyngiomas with a high tendency to recur. One of them was a young 12 years old female patient who was operated on for a craniopharyngioma several times within one year with frequent recurrences. The tumour invaded all the suprasellar and the parasellar areas as well as the basal ganglia with a high proliferation rate (MiB 20%). The patient died at the age of 13, 6 months after the last surgery and subsequent radiotherapy.

The mechanism of pCR development at molecular level has been only recently elucidated (Brastianos et al., 2014). Using whole exome sequencing recurrent mutations in *BRAF* (V600E) have been detected in all papillary craniopharyngiomas, while with targeted genotyping this mutation is detected in 95% of tumours.

Better understanding of the molecular pathogenesis of CR has important implications for the diagnosis and may provide targets for future molecular guided medical therapies.

Clinical presentation

In the senior author's series, including 291 patients (83% adults and 17% children) operated in the period 1983–2005, 47% presented with visual compromise, 31% with endocrine deficits, 17% with hydrocephalus and headache, and 5% with neurological deficits. Objective findings at examinations were a chiasmal syndrome in 75% and endocrinological deficits in 77%. Diabetes insipidus was present in 30%.

Adults

Visual disturbance

Craniopharyngiomas can cause different patterns of visual field defects depending on the tumour location and extension. The classical bitemporal hemianopia can develop due to compression of the optic chiasm from below by intrasellar and suprasellar tumours. Other patterns are also possible especially in cases of retrosellar and parasellar tumour development. Subjective visual symptoms at the time of presentation are encountered in approximately 47% of the patients but ophthalmological findings at the time of presentation occur in 75%. Optic pathway dysfunction at the time of presentation is observed in 40–70% of patients. Visual field abnormalities are followed with decreased visual acuity and in later stages with optic atrophy.

Endocrine manifestations

Only 31% of the patients presented with symptomatic endocrine deficiency due to compression of the pituitary stalk or gland. Endocrinological analysis of the diagnosed cases revealed anterior lobe deficiency in 77% and diabetes insipidus (DI) in 30%. Nearly 80% of adults complained of decreased sexual drive, and almost 90% of the male patients complained of impotence. Most women reported amenorrhea. At presentation, 40% of the patients had symptoms related to hypothyroidism. Almost 25% had signs and symptoms of adrenal failure, and 20% had DI. Growth hormone deficiency is a laboratory finding in almost all cases of craniopharyngioma, if adequately tested.

Hypothalamic vegetative manifestations

Change in the sleep-wake rhythm, obesity, abnormal electrolytes, and caloric regulation also occur in patients with craniopharyngiomas. Unfortunately, objective criteria to document vegetative dysfunction are missing. Exclusive pituitary dysfunction of the hypothalamus can also manifest with endocrine disturbance (tertiary pituitary insufficiency).

Neurological manifestations

Headache can be the first presenting symptom of a craniopharyngioma. It is typically in the forehead area and is accentuated in the morning. Headache can be the only indication for surgery, especially in small craniopharyngiomas. The cause of headache may also be developing hydrocephalus due to large tumours that compress the foramina of Monroe or the Sylvian aqueduct.

Oculomotor palsy is seen in cases of parasellar extension of the tumour and compression of the oculomotor nerve. Diminished hearing and trigeminal nerve symptoms can occur in cases with cerebellopontine angle extension. Epilepsy occurs in parasellar craniopharyngiomas that compress the mesial temporal lobe. Short term memory deficits may also be observed and are due to compression of the fornix.

Special findings in children

Visual disturbance

Visual disturbances are recognized late in children. They are frequently unaware of having even significant vision loss but this symptom occurs at presentation in 20–60% of the paediatric patients with craniopharyngioma. The pattern of visual loss depends on the extension of the tumour in relation to the optic pathway. Fundus examination shows papilledema in 20% of cases (Poretti et al., 2004; Yosef et al., 2015).

Endocrine manifestations

Short stature due to growth hormone deficiency and delayed puberty due to gonadotropin deficiency are common clinical presentation in children with craniopharyngioma. They may present with adrenocorticotropin deficiency or hypothyroidism (Poretti et al., 2004; Halac and Zimmerman, 2005). Adiposogonadal syndrome (Fröhlich's syndrome) is a combination of hypogonadism and obesity and is due to hypothalamic pituitary failure.

The presenting symptom in children can be DI, which may be accompanied with absence of thirst (adipsia). This condition is very dangerous due to the excess fluid loss without adequate compensation.

Vegetative symptoms

These include manifestations of hypothalamic failure including obesity, alteration of the sleep rhythm, electrolytes disturbance, and endocrinal deficiencies.

Radiological assessment

The main diagnostic imaging used is magnetic resonance imaging with and without gadolinium enhancement. The imaging allows assessment of the extent of the tumour, as well as its relation to the neurovascular structures. The anatomy of the optic nerve and optic chiasm, the length of the internal carotid artery, the location of the anterior communicating artery, the floor of the third ventricle and the presence of a true intraventricular component should be noted.

Computer tomographic scans can be useful in detecting calcification, which is a typical radiological sign of craniopharyngiomas. A CT scan is also important to define the anatomy of the bone of the skull base, especially if a skull base approach is planned. It also has value as an emergency diagnostic measure where there has been an acute deterioration in the level of consciousness from hydrocephalus.

Classification

There are several classification systems (Yasargil et al., 1990), the following are commonly used.

Depending on the tumour location, craniopharyngioma can be classified into intrasellar and suprasellar. Considering the relation of the tumour to the diaphragma sellae, craniopharyngioma can be classified into supradiaphragmatic and infradiaphragmatic. The tumour can be located anterior to the optic chiasm or posterior to the optic chiasm. The tumour can elevate the floor of the third ventricle but in some cases it will even grow through the floor of the ventricle and have an intraventricular component. The tumour can extend all directions mainly laterally in the parasellar area and posteriorly in the retrosellar space. We have observed ectopic locations of craniopharyngiomas (e.g. in the cerebellopontine angle, sphenoid sinus, or in the pharynx).

Morphologically, the craniopharyngiomas are usually partially solid and partially cystic. Few cases are purely solid or purely cystic. Intensely calcified tumours are also well described.

Preoperative evaluation

Extensive preoperative endocrinological evaluation of the anterior lobe of the pituitary gland is mandatory. This evaluation should include T3, T4, TSH, LH, FSH, testosterone or oestrogen, ACTH, cortisol, prolactin, GH, and IGF-1. Dynamic tests should be performed whenever needed to complete the evaluation. The visual status evaluation should include visual acuity, visual fields, and

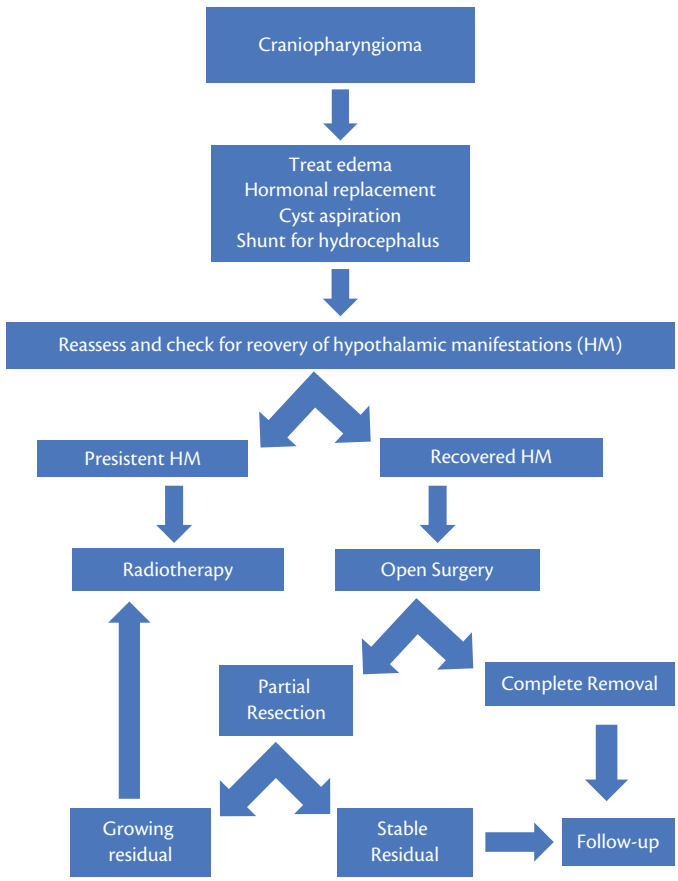

Fig. 26.2 Management algorithm for craniopharyngioma.

fundoscopy. This is important when planning the management and as a baseline for follow-up.

Treatment

The decision on how and when to operate on a patient with a craniopharyngioma depends on many factors, both tumour-related (size, extension, adhesion, or involvement of vital adjacent structures) and patient-related (age, endocrine status) (Fig. 26.2). In some cases prompt surgery is required, while in others the best option might be initial conservative treatment or radiotherapy.

Symptomatic treatment

Insertion of a ventriculoperitoneal shunt may be required in patients with hydrocephalus. Direct treatment of the tumour can be with insertion of cystoventricular shunt or more rarely cystoperitoneal shunt. Tumour debulking may be appropriate in patients with profound vegetative symptoms in whom radical surgery is contraindicated or in those with a progressive chiasm syndrome. Radiotherapy may be indicated.

Indications for surgical intervention

Surgery is indicated to achieve decompression of the pituitary gland and preserve endocrine function, to achieve decompression of the optic chiasm or optic nerves or to decompress the oculomotor nerve. Surgery is absolutely indicated to manage hydrocephalus.

Contraindications to radical resection

Preoperative contraindications include significant peritumoural oedema or bilateral infiltration of the hypothalamus. Patients with irreversible hypothalamic dysfunction manifest clinically with extreme obesity or a change in the sleep/wake rhythm and radiologically with massive hypothalamic compression or the presence of peritumoural oedema. In these cases we recommend treatment with dexamethasone to verify the reversibility of the hypothalamic disturbance. If they are reversible, surgical resection can be performed. However, if they prove to be irreversible, only symptomatic treatment is indicated (see next).

Intraoperative limitations to radical resection include heavily calcified tumours, tumours with an attachment to the hypothalamus or to the small perforator vessels and those demonstrating repeated intraoperative bradycardias.

Surgical treatment

The treatment concept of the senior author has evolved since 1982 but has always aimed to achieve safe and radical resection. In the first period, between 1982 and 1996, 168 patients had surgery, and gross total tumour removal was achieved in 45.7% of the transcranial cases and in 85.7% of the transsphenoidal ones. The main reasons for incomplete removal were attachment to, or infiltration of, the hypothalamus, major calcifications, and attachment to vascular structures (Fahlbusch et al., 1999). Between 1996 and 2005 the author's technique advanced further and the rate of safe radical resection increased, gross total resection was achieved in 88.5% of the transsphenoidal cases and in 79.5% of the transcranially operated ones (Fahlbusch and Hofmann, 2008).

Since 2005, the author has adopted the concept of personalized treatment. Patient selection and planning of therapy depend mostly on the patient's clinical condition with special attention to the endocrine and vegetative statuses.

Clinical examples

A male patient presented with large cystic craniopharyngioma. He complained about a short-term memory deficit without endocrine or visual deficits. A cystoventricular shunt was performed and then the patient was followed. His memory deficits improved and radical surgery was not required.

A female patient presented with a cystic craniopharyngioma. She wished to have a child so a cystoventricular shunt was inserted as a first step. After her successful pregnancy and birth, radical tumour removal was performed.

An 18-year-old male was initially misdiagnosed as having a cannabis psychosis. Neuroimaging, however, revealed severe hydrocephalus caused by a large cystic craniopharyngioma. Considering his pronounced cognitive disturbances, a decision was taken to use a ventriculoperitoneal shunt. Later, a cystoperitoneal shunt had to be inserted. Only when his cognitive function improved did we proceed to radical tumour resection.

Surgical considerations

Hoffmann et al. (1992) and Yasargil et al. (1990) were the first to report the possibility of radical resection of a craniopharyngioma. Following which, total resection of craniopharyngiomas was carried out using various approaches. Especially challenging were the large and giant tumours. Various modifications and combinations of approaches have been used for resection of such craniopharyngiomas with the presumption that sufficient exposure of all parts of the tumour is essential for their safe and complete removal.

The first precondition to resect a craniopharyngioma through a small frontolateral craniotomy is that the slowly growing tumour causes a continuous stable displacement of the neurovascular structures and thus provides a potentially large preformed resection corridor. Importantly, these corridors remain more or less stable during and after tumour resection, which is performed via the subchiasmatic, the opticocarotid, the carotido-occulomotor, and the translamina terminalis pathways. This gives the surgical advantage that the tumour bed does not collapse after the early steps of tumour resection and remains opened, providing access to the deeper parts of the tumour. The first series used a frontal craniotomy confined to one side, but later the size of the craniotomy was reduced to the current frontolateral approach. The main goal is to protect the frontal lobe, which in giant tumours is especially vulnerable. Moreover, the larger opening of the skull did not enhance our ability to remove deep-seated lesions. Once sufficient internal decompression has been achieved, the more peripheral tumour portions can be mobilized and brought into view by slight traction.

A second requirement for any operative approach is that there should not be a high risk of approach related morbidity. The frontolateral approach meets this criteria and is the one favoured by us even in cases of giant craniopharyngiomas (Fig. 26.3), which tend to develop in the suprasellar region and rarely have intrasellar extensions. A subset of craniopharyngiomas, even of large size, can be successfully removed via a transnasal transsphenoidal microscopic, endoscopic, or combined approach.

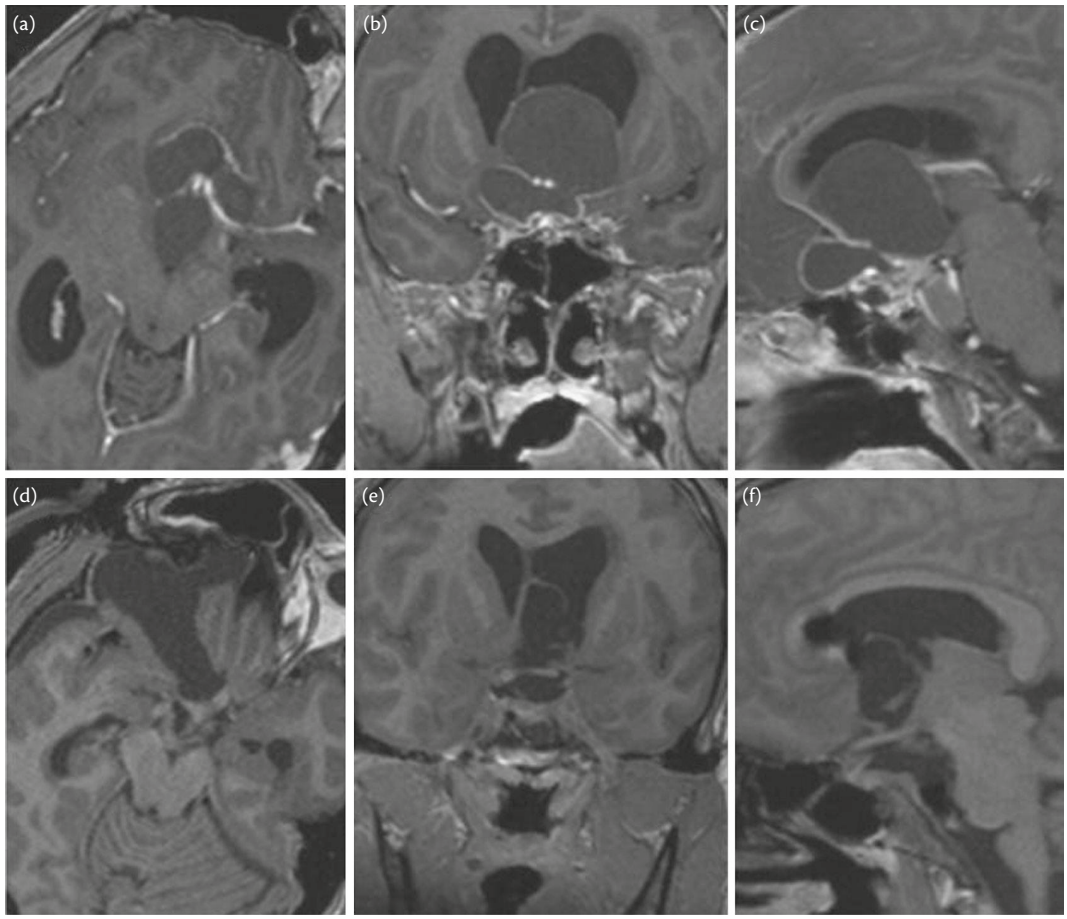

Fig. 26.3 Preoperative (A, B, and C) and postoperative (D, E, and F) MRI showing resection of a large craniopharyngioma via a right frontolateral craniotomy. The patient was operated on using an iMRI.

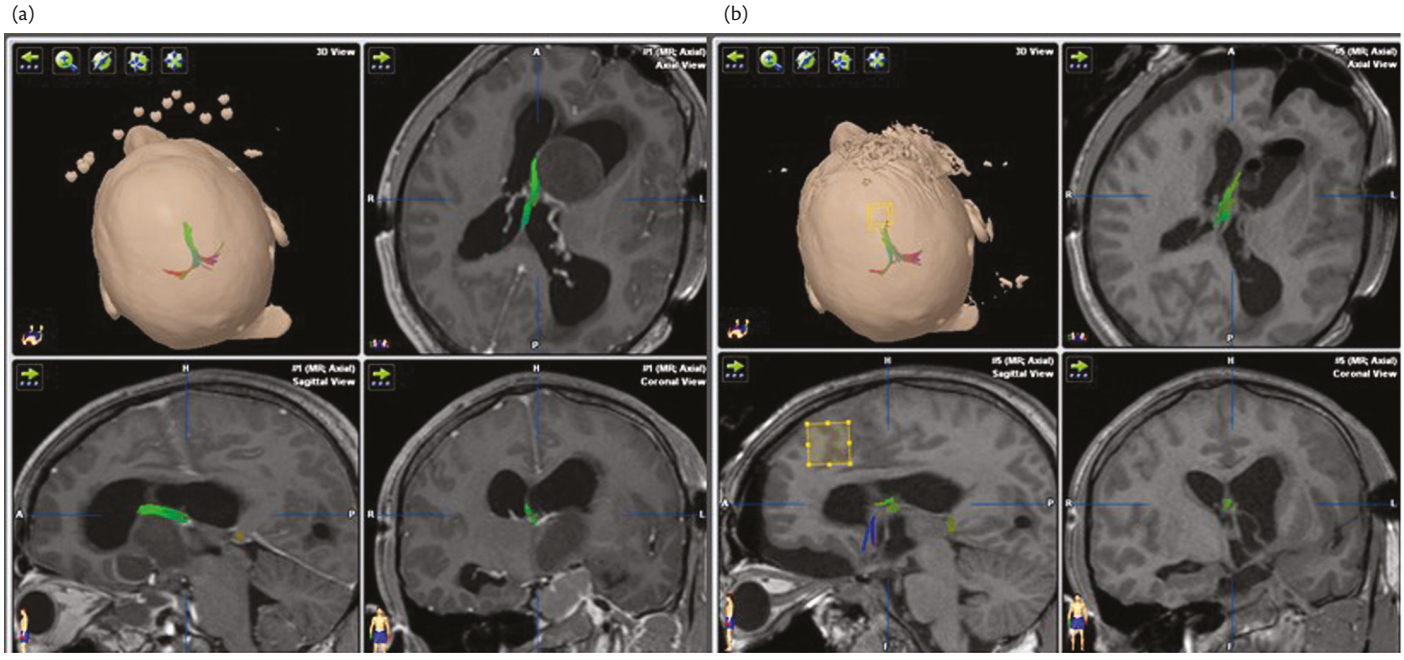

Fig. 26.4 Fibre tracking for localization and navigation of the fornix especially in tumours with a large extension into the third ventricle. (A) shows the fornix preoperatively, while (B) shows the preserved fornix after resection of the craniopharyngioma via a frontolateral approach.
Source data from Gerganov, et al. *J Neurosurg.* 2014 Feb;120(2):559–70.

The intraventricular craniopharyngioma can be approached either through the interhemispheric translamina terminalis approach or the transcallosal approach. The transcallosal approach is restricted to the ventricle and the midline and cannot access craniopharyngiomas with parasellar extension. The interhemispheric translamina terminalis approach can expose both the intraventricular part and, to some extent, the parasellar part.

The size of the parasellar extension can influence the side of the surgical approach. The parasellar component, which is insinuated lateral to the supraclinoidal internal carotid artery and the posterior communicating artery and its perforators, is approached through the carotido-occulomotor space on the same side. Therefore, in cases of parasellar extension the craniotomy should be placed on the ipsilateral side.

In cases where there is a prefixed chiasm or in tumours with large retroclival extensions some authors have described the petrosal approach, accessing the tumour from inferior to superior and from posterior to anterior.

Special attention is given to the course and location of the fornix, especially in tumours with extension into the third ventricle (Fig. 26.4).

Details of the commonly used surgical approaches

Transsphenoidal approach

The classical transsphenoidal approach is indicated in all subdiaphragmatic intra- and suprasellar craniopharyngiomas (Fig. 26.5). In supradiaphragmatically located tumours the extended transsphenoidal approach via the removed tuberculum sellae ('transtubercular') can be used (initially published by Weiss et al). However, limitations for safe total removal are tumour growth outside the arachnoid space and an intimate relation to surrounding brain structures. In cases with small supradiaphragmatic extensions of a mainly intra- but even suprasellar craniopharyngioma, the diaphragma sellae can be split to allow total tumour removal (senior author's experience).

The nasal approach to the sphenoid sinus is usually performed directly pernasal, microscopically, endoscopically, or combining these techniques. The sublabial incision is preferred in small children with tiny nasal openings, rarely in combination with a transmaxillary approach when the tumour is more lateral. Additional help in cases where the sphenoid sinus is not yet or not sufficiently pneumatized or the configuration of the sella turcica is invisible (children <3–4 years) is provided by neuronavigation or the c-arm. Although some authors regard this situation as a contraindication to a transsphenoidal approach experienced pituitary surgeons are able to safely drill and open the sellar floor. In sufficiently pneumatized sinuses the protuberance of the carotid artery serves to provide midline orientation. Special attention should be given when bony septi within the sphenoid sinus insert into the area of the protuberance, as this bony layer over the carotid artery serves as its protector.

After drilling the sellar floor to achieve its maximal wide opening, the normal sella size is 10 × 6 × 8 mm, the dura is opened from the midline laterally, reaching the medial wall of the cavernous sinus. Posteriorly it reaches the posterior intercavernous sinus and anteriorly the connection to the diaphragm sellae. In half of these cases the pituitary gland is located anteriorly (which is in contrast to pituitary adenomas). In such cases the diaphragma has to be split for one or more millimetres before the usually thick wall of the craniopharyngioma capsule is reached.

The tumour content, whether cystic, solid, or calcified is removed first from all parts of the sella. The surgeon should start in the midline or laterally, then move in the suprasellar direction, expecting the descent of the elevated diaphragma sellae.

Removal of the mainly thick tumour capsule, although time-consuming and challenging, is mandatory (in contrast to the thin wall of Rathke's cysts) in order to prevent recurrences. The senior author recommends starting with resection of the easy to identify tumour wall then dissect the posterior part, moving laterally and from anterior to posterior below the diaphragma sellae. The pituitary stalk can normally be preserved. Occasionally firm tumour parts have to be resected sharply at their origin on the pituitary stalk. Where the last piece of tumour is not completely resectable, careful bipolar coagulation is an option.

In some cases, cerebrospinal fluid (CSF) leaks are unavoidable in the attempt to achieve total removal. The leak originates most

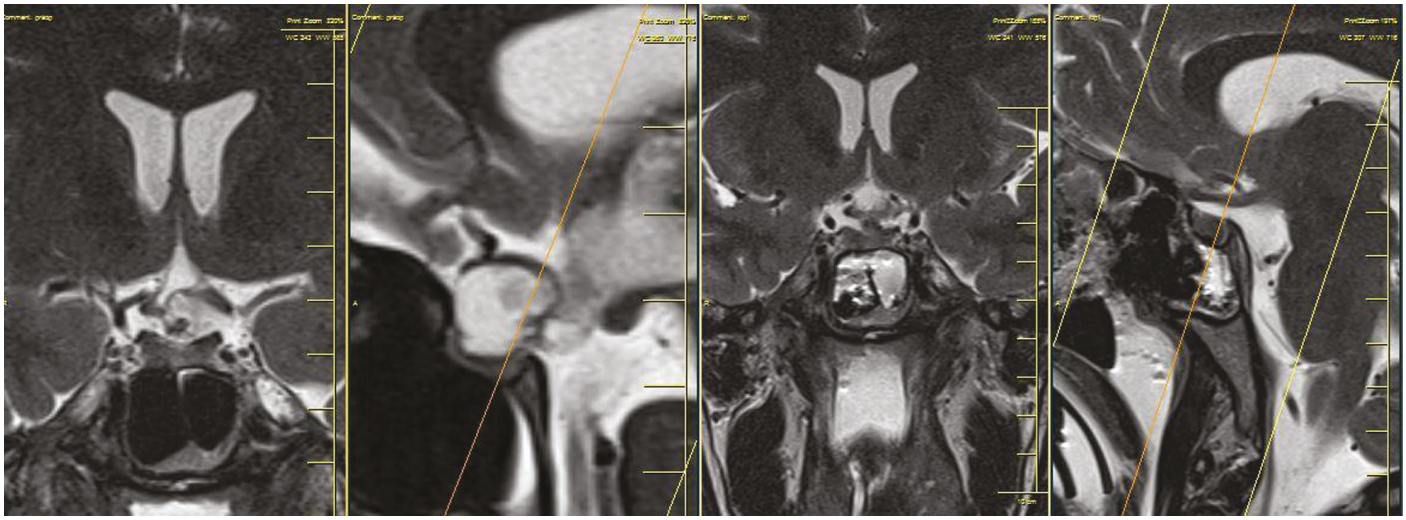

Fig. 26.5 Pre and postoperative MRI after transsphenoidal resection of a craniopharyngioma. The first two images showed the tumour preoperatively. The last MRI shows tumour resection through splitting of the pituitary gland.

frequently from the thinner anterior diaphragma sellae. The leak is repaired using tiny pieces of fat, taken from the upper limb or abdomen that are then sealed with fibrin glue. Some authors prefer more complex reconstructive procedures of the sella floor. In extended transtubercular approaches all patients have a CSF leak, which is a major disadvantage and burden of this kind of approach. Reoperations are reported in up to half of these cases although experienced endoscopic surgeons have reported recent significant improvements in this regard, using a mucosal flap as a covering.

The frontolateral approach

Tumour resection in cases of long optic nerves and a postfixed chiasm

In these cases, the optic chiasm is usually displaced posteriorly and superiorly creating a wide working space to the subchiasmatic and prechiasmatic areas. The surgeon performs gradual internal tumour decompression. The contralateral optic nerve is dissected from the tumour initially from its medial side taking care to preserve the small vessels on the surface of the nerve. Subsequently the central part of the suprasellar portion is removed bringing the contralateral suboptic part into view. The contralateral suboptic part is gradually decompressed and dissected from the inferior surface of the optic nerve, the inferior cerebellar artery (ICA), and the posterior communicating artery. After removal of the suboptic part, the contralateral oculomotor nerve can be seen entering the oculomotor trigone. Moving the microscope to a more central trajectory, the retrosellar compartment can be seen. Due to the commonly preserved membrane of Liliequist in this area, the tumour can be dissected relatively easily from the basilar artery and its branches. Liliequist's membrane is stretched by the tumour and separates the descending part of the tumour in the prepontine and CPA cisterns from the nearby structures although in previously operated cases it is less obvious.

The ipsilateral suboptic part is usually not in the direct line of vision. This portion can be removed by opening the carotid cistern with an incision in the medial carotid membrane and removing the tumour through the created space between the ipsilateral optic nerve and the ICA (the opticocarotid triangle).

Tumour resection in cases of short optic nerves and a prefixed chiasm

The prechiasmatic and the subchiasmatic spaces in these cases are usually very narrow and do not allow access to the tumour in the suprasellar region. In this situation, further arachnoid dissection is required in the lamina terminalis cistern. The A1s and A2s on both sides are exposed. The A1s are dissected from the optic nerves on both sides and from the optic chiasm keeping them attached to the frontal lobe to minimize injury of the perforators. The anterior cerebral artery complex is elevated with the frontal lobe exposing the lamina terminalis. In order to remove the intraventricular part of the tumour, the lamina terminalis is opened in the midline remembering the tumour's relationship to the optic chiasm, the branches of the anterior cerebral and anterior communicating arteries that run to the hypothalamus.

Surgery around the pituitary stalk

Only in cases in which the stalk is extensively involved by the tumour is it justified to resect it for the sake of radicality. In cases in which it is involved to a lesser extent, however, an attempt may be made to preserve its continuity as well as its blood supply by performing partial stalk sectioning (one-third to one-half of its diameter). Medial optic nerve mobilization by opening the roof of the optic canal and resection of the lateral part of the tuberculum sellae can help to better visualize the pituitary stalk.

Resection of the parasellar part

The part of the tumour that extends lateral to the ICA and the posterior communicating artery can be tackled by incising the intracarotid membrane and dissecting between the uncus and the ICA. During resection of this part of the tumour, the course of the anterior choroidal artery should be taken into consideration.

Cyst aspiration

Aspiration of the cyst content is an option that can provide temporary relief of symptoms that are related to mechanical compression of surrounding structures. As the cysts tend to re-accumulate, a viable option is to place an Ommaya or Rickham reservoir in the cyst, which will then allow repeated cyst aspirations. In order to position the catheter optimally, some kind of navigatory control is very helpful. Cyst aspiration is usually indicated in patients presenting in a poor condition as a temporary solution or in recurrent cystic CR that are not suitable for surgical removal.

Craniopharyngiomas in children

The quality of life is frequently impaired in long-term survivors mostly due to endocrine, metabolic, and visual abnormalities. In a series published by an endocrinologist, it was documented that radical resection obtained by differently experienced surgeons reduced the quality of life in almost 50% of long-term survivors (Muller, 2013). Particularly problematic are the disturbances of pubescent development, the overall growth, and morbid hypothalamic obesity. Some authors stress that because of the surgically induced hypothalamic deficits and the high rate of recurrence even after apparently complete resection, planned radical resection in children should not be attempted.

In children above the toddler age an attempt at complete resection with preservation of all functions should be made in order to minimize the risk of recurrence. Children presenting earlier benefit form prolongation of the interval until treatment. In children presenting with a large cystic CR and clinically in poor condition or of a very young age, catheter drainage via an intracystic catheter or implantation of an Ommaya reservoir may be a valuable treatment option. This approach provides pressure relief and symptomatic improvement while the patient matures. The two-staged approach is an alternative strategy in patients with large cysts causing mass effect, cyst drainage to relieve pressure followed soon afterwards by resection (Fahlbusch et al., 1999).

In toddlers, as well as in cases of unfavourable CR extension, for example when the hypothalamus is involved, a planned partial resection might be the optimal temporary treatment option. The tumour, if growing, could be approached later on, when the child matures. Although radiotherapy following incomplete tumour resection is favoured both in adults and children, it should be applied with extreme caution at younger ages. The outcome of irradiation after incomplete resection is under investigation in randomized multinational trials (Muller, 2013).

Postoperative outcome and care

Hormonal

Postoperative hormonal evaluation is mandatory. Patients with preoperative cortisol insufficiency receive high-dose hydrocortisone during and early after surgery. It is then reduced to the normal daily maintenance dose. Assessment of the basal hormonal status is performed usually after 6–10 days. Hormonal deficiencies, if present, should be replaced. Special attention should be given to children and adolescents to support normal growth and puberty (Honegger et al., 1999).

In the first series from the senior author with safe resection operated via the transsphenoidal approach, 10% of cases showed secondary hypothyroidism and 10% adrenocorticotropic deficiency. In patients operated via the transsphenoidal approach using the same concept, 20% suffered from secondary hypothyroidism and 40% from adrenocorticotropic deficiency. The percentages of new endocrine deficiencies were worse in the series with aggressive resection. Around 20% showed secondary hypogonadism, 30% secondary hypothyroidism, and 60% secondary hypocorticism. Endocrine deficiencies are less frequent in cases treated via the transsphenoidal approach.

Electrolytes

The patients after surgical resection of craniopharyngioma are liable to electrolyte disturbance from diabetes insipidus. The rate of DI increases from 16% preoperatively to 59.4% postoperatively (up to 70% in cases of aggressive resection). DI manifests early after surgery or delayed, after 5–7 days. DI is characterized by polyuria, polydipsia, and hypernatraemia. Conscious patients can compensate for the polyuria by drinking and thus the sodium level may stay within the normal range. The management of patients that are not fully conscious or are unable to drink sufficiently is challenging. DI is typically managed with Desmopressin. We start Desmopressin usually on demand depending on the urinary output, the urine-specific gravity, and sodium level. The dose of Desmopressin is then slowly adjusted to the final fixed dose, as required. Some patients develop only transient DI that resolves within 1–2 weeks. We prefer to give the main Desmopressin dose in the evening and in the day, only if needed, which allows the patient a chance of uninterrupted sleep.

Rarely, some patients develop hyponatraemia after surgery. If the cortisol level is normal or well replaced, the patients are managed with fluid restriction. Some patients may require temporary sodium infusions. If hyponatraemia persists, the patient can be given fludrocortisone or even tolvaptan (ADH antagonist) (Ichimura et al., 2015). Correction of sodium should be slow, and the sodium level should not fluctuate. A fluctuating sodium level can cause brain oedema and pontine myelinolysis.

Vision

The visual acuity and the field of vision are tested after surgery. In the published series of the senior author, the chiasm syndrome completely regressed in approximately one-third of the patients after transcranial surgery, and in an additional one-third of the patients in whom vision recovered partially. Visual deterioration was found in 14.7% of patients after transcranial surgery. After transsphenoidal surgery, the chiasm syndrome normalized completely in 46.7% of the patients and partially in another 40%. None of the patients developed visual deterioration after surgery (Fahlbusch et al., 1999).

Cognitive outcome

Cognitive dysfunction can present preoperatively and postoperatively due to compression of the fornix. Some patients show improvement after surgery (5/8). There is also improvement in the reduction of drive (2/4), loss of concentration (2/2), abolished diurnal rhythm (2/2), and loss of attention span (1/1). There was no worsening of cognitive function in our operated series but cognitive development and school performance in children after resection of craniopharyngioma can decline after surgery (Honegger et al., 1998).

Degree of resection

In the first report of the senior author about the first 168 cases (Fahlbusch et al 1999), total tumour removal was achieved in 45.7% of transcranial and 85.7% of transsphenoidal procedures. The rate of recurrence-free survival after GTR was 86.9% at 5 years and 81.3% at 10 years. On the other hand, the 5-year recurrence-free survival rate was 48.8% after subtotal removal, and 41.5% after partial removal. Following primary surgery, the overall survival rate was 92.7% at 10 years, with the best results after GTR. Furthermore, 117 (79%) of 148 patients who underwent primary surgery were independent and without impairment.

Subsequently, the senior author has reported experience with a further 73 cases (Hofmann et al., 2012). GTR was accomplished in 88.5% of cases in whom a transsphenoidal approach was applied and 79.5% of those in whom a transcranial approach was applied. In the total series, GTR was achieved in 83.1% of cases (vs. 49.3% in the authors' former series). The complication rate was 13.8% without any mortality. New endocrine deficits were observed more frequently in patients treated with transcranial approaches (16.3–66.7% vs. 2.6–50.0%) but were less frequent after transsphenoidal approaches (5.2–19.2% vs. 2.9–45.7%).

Surgical complications

After transsphenoidal surgery, CSF leak was observed in 2% of cases. CSF leak should be promptly managed to avoid subsequent meningitis. A lumbar drainage can be inserted as a prophylactic measure immediately after surgery, if there is CSF leak during surgery with evidence of large opening of the arachnoid membrane. Delayed CSF rhinorrhoea can be managed as a first trial with lumbar drainage but in other cases with direct surgical repair.

After transcranial surgery, hypothalamic dysregulation was observed in two cases (from 176 transcranial procedures). Other nonspecific complications like wound infection, epidural hematomas, and seizures have also been reported.

Controversies

Gross total resection versus partial resection

In the recent literature, GTR has been achieved on average in 53% of the cases (Yang et al). It ranges from 13% (Lo et al., 2014) to 83% (Hofmann et al., 2012) in the recently reported large series (**Table 26.1**). GTR can be achieved in 87.5% of giant craniopharyngiomas (Gerganov et al., 2014). Partial resection is indicated when only symptomatic decompression treatment is appropriate and in order to avoid damage to vital structures. Contraindications to GTR

include irreversible hypothalamic dysfunction but the rate of GTR also depends on institutional and personal experience.

While GTR is associated with better overall survival and a lower recurrence rate, it is contraindicated in cases of irreversible hypothalamic dysfunction or peritumoural oedema. Preservation of function is one of the main purposes of surgery, if the tumour is adherent to the hypothalamus or small vessels or heavily calcified then GTR should not be attempted. Such patients should be followed until the remnant grows when redo surgery is the favoured management option. Radiotherapy should be recommended if the remnant is considered inoperable due to unacceptably high associated morbidity (**Table 26.2**, **Figs. 26.6**, **26.7**, and **26.8**).

Surgical approaches

We operate on subdiaphragmatic craniopharyngiomas (either intrasellar or intra- and suprasellar) using an endoscopically assisted transsphenoidal approach. Transcranial approaches are reserved for supradiaphragmatic craniopharyngiomas. In such cases the senior author has previously used interhemispheric and pterional approaches. Recently, however, we have favoured the frontolateral approach.

The pure endoscopic extended transsphenoidal approach has been described for resection of supradiaphragmatic craniopharyngiomas. It is associated with high incidence of CSF leak and low rate of GTR. Kassam's group reported a series of 16 patients in 2008 where total resection could be achieved in 50% but with a high incidence of postoperative CSF leak that required reoperation (58%) (Gardner et al., 2008). The reported CSF leak rate in the recent reports by the same group is between 15% and 23%, DI occurred in 48–67% of the patients and hypopituitarism 25–58%. The GTR rate varies between 37% and 69% (Koutourousiou et al., 2013; Cavallo et al., 2014).

Radiotherapy for craniopharyngioma

Fractionated radiotherapy is used in the management of patients with residual or recurrent CR and in cases where complete surgical removal is considered inappropriate due to an unacceptably high associated morbidity. Its use in cases of deliberate incomplete tumour removal is controversial. The rationale for this strategy is the reported high morbidity and mortality of radical surgery if attempted.

Another controversial concept is the use of radiotherapy immediately following CR removal or later on without considering the option of repeat surgery. The rationale once again is the greater surgical difficulty in repeat operations. Some studies have shown that the 10-year CR control rates (75–90%) are superior to the results obtained from incomplete excision alone (30–50%). However, there are no prospective randomized studies comparing the various management options.

The main drawbacks of radiotherapy are the side effects of irradiation in a region, which is composed of highly radiosensitive and vulnerable structures leading to late pituitary insufficiency and epilepsy. In children below 6 years, it can cause cognitive impairment. Even with recent advances in fractionated radiotherapy, which allow for greater precision and a reduction in radiation exposure to the normal brain, the risk of radiation-induced morbidity remains high. Early cystic enlargement, occurring within some months of completion of radiotherapy, while not disease progression, may still cause compression of the optic apparatus and hydrocephalus. The rate of such cystic enlargement in CR is reported to be between 10 and 20%.

The major side effects of irradiation are late and include cerebrovascular disturbance, radiation necrosis, neurocognitive dysfunction, and radiation neuropathy. It has been shown that radiation optic neuropathy occurs in 1–2% patients receiving doses up to 50 Gy. The most frequent late complication is pituitary dysfunction with new hormone deficiencies requiring replacement after a 5–10-year period occurring in 30–50% of the patients (Brada and Thomas, 1993). The clinical results of radiosurgery in CR are less favourable than those after fractionated radiotherapy with worse tumour control and the toxicity is not lower (Aggarwal et al., 2013).

Modern CR microsurgery allows achieving complete tumour removal without high surgical morbidity and almost no mortality (Gerganov et al., 2014). As mentioned elsewhere in the text, the best long-term results in regards to tumour control are observed in patients without residual tumour. Some authors recommend radiation therapy even after complete tumour removal. Surgery after previous radiotherapy is more challenging with higher morbidity. Therefore, in our opinion, radiotherapy should be reserved only for those patients that are not surgical candidates.

In patients, in whom part of the tumour cannot be removed safely and has to be left, we recommend initial follow-up. Modern MRI imaging allows detection of even slight growth in the remnant. If a tumour remnant is seen to progress, the main management option again is surgery. Only in cases where such surgery is impossible due to the particular location or other characteristics of the remnant would radiotherapy be considered.

Intracavitary therapy

Intracavitary delivery of radiation therapy or intracavitary irradiation is a method used to instil a radioisotope into the tumour cyst

Table 26.2 List of selected recent publications of large surgical series of craniopharyngiomas focusing on the percentage of total resection, morbidity, mortality, and rates of recurrence

	Year	No	GTR	Morbidity	Mortality	Recurrence
Van Effenterre & Boch, 2002	2002	122	Total in 59%, subtotal in 29%, and partial in 12%	Excellent in 85%, good in 9%, fair in 5%	2.5%	29/122
Mortini et al., 2011	2011	112	71.6%	Some 8.8% patients were partially or completely dependent on others for daily living activities before surgery	2.7%	24.5%
Karavitaki et al., 2005	2005	121	16/121			38% recurrence-free survival in patients with partial resection vs. 100% in GTR
Zuccaro, 2005	2005	153	69%	After surgery, endocrine status worsened in almost all patients, but visual status improved markedly	N/A	0% in GTR
Caldarelli et al., 2005	2005	52	40/52	At long-term follow-up, all survivors showed good clinical condition, even though approximately 60% relied on hormone replacement, and some patients presented obesity. DI has subsided in about 80% of the cases; visual deficits improved or remained stable, whereas postoperative neurological deficits subsided in all but one patient	2/52 early 1 late	Nine recurrences occurred 1–8 years after surgery (three true recurrences, and six re-growths of incompletely resected tumours) that required reoperation. Twelve patients underwent radiotherapy, six after an initially incomplete tumour resection and six following relapse
Duff et al., 2000	2000	121	69/121	The overall 'good outcome' rate was 60.3%		29 (24%) recurrences
Maira et al., 2004	2004	92	63%	All patients had good clinical results. Postoperative cerebrospinal fluid leakage occurred in ten cases, but only one case required a surgical repair of the sella	2/92	8/92
Puget et al., 2007	2007	66	20%	There have been no new cases of postoperative hyperphagia, morbid obesity, or behavioural dysfunction in this prospective cohort	NA	NA
Shi et al., 2006	2006	284	83.5%	The pituitary stalk was preserved in 176 (62.0%) patients, severed in 52 (18.3%), and unidentified in 56 (19.7%). Normal activities of daily living were regained in 63 (80%) patients, independence in 29 (14.2%), and daily life with assistance in 9 (4.4%)	12 within one month 4 later on	During the follow-up, 23 (14.1%) patients experienced tumour recurrence 1.0–3.5 years (mean, 1.8 +/–1.6) after total tumour removal, and 24 (64.9%) had recurrent tumour 0.25–1.5 years (mean, 0.5 +/– 0.4) after subtotal or partial resection
Yang et al., 2010	2010 (metanalysis)	442	58%		The 5- and 10-year overall survival (OS) rates for the GTR group versus the STR+XRT group were 98 versus 99%, and 98 versus 95%, respectively	The 2- and 5-year PFS rates for the GTR group versus the STR+XRT group were 88 versus 91%, and 67 versus 69%, respectively
Lo et al., 2014	2014	123	15%	Kaplan–Meier rates for visual deterioration, anterior pituitary hormone deficiency, DI, seizure disorder, and cerebrovascular events (CVE) due to treatment, not tumour progression, were 27%, 76%, 45%, 16%, and 11%, respectively	DSS was 88%, and OS was 80%. Primary treatment modality did not affect DSS or OS, while older age was a negative prognostic factor for OS but not DSS	Patients treated with STR+RT or CD+RT had the highest PFS (82% and 83%, respectively). There were no significant differences between PFS after adjuvant versus salvage RT (84% vs. 74%, respectively; $P = 0.6$)
Hofmann et al., 2012	2012	73	83.1%	13.8% New endocrine deficits were observed more frequently in patients treated with transcranial approaches over the years (16.3–66.7% vs. 2.6–50.0%) but were less frequent after transsphenoidal approaches (5.2–19.2% vs. 2.9–45.7%)	0%	NA

cavity and has been used over the last six decades. Radioisotopes emitting short-range beta radiation with a short half-life are used, most frequently 90 yttrium, 32 phosphorus, or 186 rhenium. They are instilled stereotactically following aspiration of the cyst content. The delivery of a very high radiation dose of approximately 150 Gy to the cyst's secretory epithelial lining provides good tumour control (70–96%) (Derrey et al., 2008). On the other hand, it may affect visual function, the endocrine system, or the major surrounding vessels due to the radiation effect over the next 3–3.5 mm beyond the cyst wall. The published morbidity data vary widely in the literature. Therefore, the technique has not been widely accepted.

Another method, favoured in the past is the stereotactic instillation of bleomycin into the cyst cavity (Hukin et al., 2007). The reported response rates vary widely—from 57% to 100% and the risk of injury to surrounding structures due to the effect of bleomycin or its spillage may be high.

Future developments

Future developments for improved therapy for craniopharyngiomas are based on new knowledge of the morphological structure of the hypothalamus, including the nuclei with specific endocrine and vegetative functions. Advanced 7 Tesla MRI techniques may lead to more objective criteria for deciding on surgical treatment.

Conventional treatments could be enhanced by molecular based therapies including antihormonal treatments.

Hypothalamic obesity currently controlled mainly temporally by Baretić therapy remains challenging to treat (Rottembourg et al., 2009). Leptin-oriented approaches are not encouraging (Trivin et al., 2009; Roemmler-Zehrer et al., 2014). Recent trials with diazoxide and metformin should be regarded as preliminary (Aubert et al., 2011; Hamilton et al., 2011; Malin and Kashyap, 2014).

Rathke's cleft cyst

Rathke's cysts are non-neoplastic cystic formations from the glandular rests of the Rathke's cleft in the region of the intermediate lobe of the pituitary gland (Saeger et al., 2007). They are found in the pars distalis or pars intermedia in up to 22% of routine autopsy series (Teramoto et al., 1994). From the 4335 operations in the sellar region performed by the senior author between December 1982 and September 2005, 7% were craniopharyngiomas and only 2% were non-adenomatous cysts, mostly Rathke's cysts. It is a common incidental finding in neuroradiology and most frequently is asymptomatic. The main differential diagnosis is a craniopharyngioma. Surgical intervention is indicated in symptomatic lesions, which present with a typical headache, and in lesions showing growth, particularly when a craniopharyngioma cannot be ruled out. We recommend fenestration of the cyst with evacuation of the cyst contents and discourage aggressive attempts to remove the cyst wall. Attempts at total resection are associated with a high incidence of postoperative endocrine disturbance and are not related to a lower risk of recurrence.

Rathke's cysts are thought to originate during the development of the pituitary gland. It is thought that a rostral outpouching of the stomodeum in the third or fourth week of gestation meets a downward projection from the diencephalon, the infundibulum, forming the two lobes of the pituitary gland. The anterior wall of the pouch then proliferates to form the anterior lobe of the pituitary gland and pars tuberalis. The posterior wall becomes the pars intermedia. In a large percentage of human pituitaries the lumen is obliterated by epithelial infoldings. But after the formation of the adenohypophysis and neurohypophysis, a cleft may remain in the area of the pars intermedia. This cleft has been called the Rathke's cleft. A symptomatic Rathke's cleft cyst develops when this cleft fails to regress and starts to increase in size due to retention of secretions. Other theories of development of these cysts have included an endodermal origin or reverse metaplasia of pituitary cells (Ikeda and Yoshimoto, 2002).

The histopathological diagnosis of a Rathke's cyst has been confused, in some cases, with craniopharyngiomas. Nowadays, maturation of the β-catenin pathway, which is present in craniopharyngiomas, not in Rathke's cysts, facilitates differentiation between the two pathologies (**Fig. 26.1**). Sometimes, especially after drainage of a Rathke's cyst, it may be difficult to obtain a surgical specimen of the cyst wall, which does not permit conclusive histological diagnosis. The cyst has typically simple columnar or cuboidal epithelium, often with ciliated or mucinous goblet cells. Pseudostratified columnar cells are also frequently observed. Squamous metaplasia has been noted in 9–39% of the patients and is associated with higher rates of cyst recurrence. Rarely, the cyst is lined with stratified squamous epithelium and is thought to pose a higher risk of cyst recurrence. Rathke's cleft cysts with squamous metaplasia and transitional features (such as squamous epithelial cells) may resemble cystic craniopharyngiomas on histopathological examination and imaging studies. Some authors have pointed out the possible continuum between Rathke's cysts and craniopharyngiomas. Ikeda et al reviewed 42 patients with Rathke's cysts and found that three cases had squamous epithelium in the cyst wall similar to that observed in craniopharyngiomas (Ikeda and Yoshimoto, 2002).

Rathke's cysts developed usually intrasellarly in the pars intermedia. The cyst may be large and may extend also into the suprasellar cistern. Isolated suprasellar Rathke's cysts are rare. Ectopic Rathke's cysts are even more rare in the nasopharynx, sphenoidal sinus, the clivus, and cerebellopontine angle.

Clinical features

According to the largest published series on Rathke's cysts from the Weiss's group (Aho et al., 2005), approximately 70% of the incidentally discovered Rathke's cysts remain asymptomatic. Around 30% develop symptoms due to local mass effect and compression of the visual pathways and the pituitary gland, causing pituitary insufficiency. The most common symptom is headache. In a small group of patients, patients with Rathke's cysts show clinical evidence of panhypopituitarism, progressive visual loss, and symptoms mimicking meningitis or hypophysitis.

Asymptomatic lesions

Aho et al. (2005) reported on 160 cases of Rathke's cyst. In 42 of them the cyst was incidentally discovered during MRI examination for other reasons, they did not grow or cause endocrine or visual signs and symptoms (Aho et al., 2005). In another series from Teramto's group (Sanno et al., 2003), as few as 5.4% increased in size during the follow-up period (Sanno et al., 2003).

Symptomatic lesions

Symptomatic lesions present most frequently during the fourth or fifth decade of life, with a slight female preponderance. The typical symptoms associated with Rathke's cysts include headache, pituitary insufficiency, and visual disturbance. Headache is present in all symptomatic lesions and could be the only indication for surgery. It is usually felt around the bregma in cases of intrasellar lesions. In lesion with compression of the cavernous sinus, the patient may have periorbital pain.

As examples, a 17-year-old school boy with a Rathke's cyst presented only with severe headache that interfered with his school performance. After surgery, the headache was completely resolved with resumption of successful school activities. A 57-year-old lady presented with intermittent headache, then several weeks of persistent therapy resistant pain and she decided to have surgery. After surgery her headache completely and permanently resolved.

Visual disturbance preoperatively has been reported in 35–50% of patients undergoing surgical intervention. This includes visual field defects as well as declining visual acuity. Jahangiri et al. reported that preoperative hypopituitarism occurred in 41% of adults and 45% of paediatric patients. The most common endocrine findings are hyperprolactinemia and growth hormone deficiency, followed by hypocorticism and hypogonadism. DI has been described as a presenting condition in approximately 7–20% of the patients, less frequent than in craniopharyngioma. Other rare presentations include

chemical meningitis, or intracystic haemorrhage (Harrison et al., 1994; Jahangiri et al., 2011; Neidert et al., 2013). Some cases have presented with a sudden onset of symptoms together with imaging evidence of intracystic bleeding. This condition has been described as Rathke's cleft cyst apoplexy (Neidert et al., 2013).

Radiological features

Magnetic resonance imaging is the main imaging modality for preoperative assessment of Rathke's cysts and for differentiating Rathke's cysts from other cystic sellar lesions like craniopharyngiomas (Zada et al., 2010). The signal intensity of the cyst varies, and could be hypo-, hyper-, or isointense, depending of the composition of its content. Although most of the cysts display homogeneous signal intensity, up to 40% contain an intracystic nodule composed of protein and cellular debris that typically does not enhance following contrast administration (Brassier et al., 1999; Byun et al., 2000; Binning et al., 2005). A thin rim of enhancement can be attributed to inflammation or squamous metaplasia of the cyst wall, or to a circumferential displacement of the pituitary gland (Brassier et al., 1999; Byun et al., 2000; Kim et al., 2004; Zada, 2011). Even if the thin cystic capsule were to enhance, this would be below the resolution capacity of MRI. The pattern and the intensity of contrast enhancement are not constant findings in all cases. This is probably due to an inflammatory reaction in the surrounding tissues, namely the pituitary gland and sometimes the sellar dura, due to occasional leaks of the cyst contents. The pituitary gland is usually displaced by the cyst and in some cases the cyst remains encased inside the gland. The cysts are commonly intrasellar or intra-, para-, or suprasellar. Pure suprasellar cysts are rare.

Computer tomography can be used to detect calcification which appears more in cases of craniopharyngiomas. Nevertheless, Rathke's cysts are reported to exhibit calcifications but rarely and for a lesser extent. Further entities in the differential diagnosis are sellar abscess and lymphocytic hypophysitis.

Management

Asymptomatic Rathke's cysts (usually <1 cm) are followed up with serial MRI imaging, endocrine, and ophthalmic examinations.

A symptomatic Rathke's cyst is an indication for surgical intervention. Headache can be the only symptom. The aim of surgery is local decompression and, if possible, gaining tissue for histological diagnosis. Evacuation of the cyst contents is the most frequently used strategy. In the best operative situation, when the cyst has a superficial location and is directly related to the dura of the sellar floor, it can be fenestrated without incision of the pituitary gland and part of the wall can be taken for histology. The sellar and the intra or suprasellar cysts can be drained, the cyst wall will collapse, and the functions of the pituitary gland are preserved (Fig. 26.9). In some cases the cyst is inside the pituitary gland and the surgeon needs to split the pituitary gland. In this situation, the surgeon can only evacuate the cyst but should not risk taking a biopsy from the cyst wall. An attempt to completely or aggressively remove the cyst wall is associated with a higher incidence of endocrine deficiencies including DI. According to some reports, however, the cyst wall remnant is associated with higher

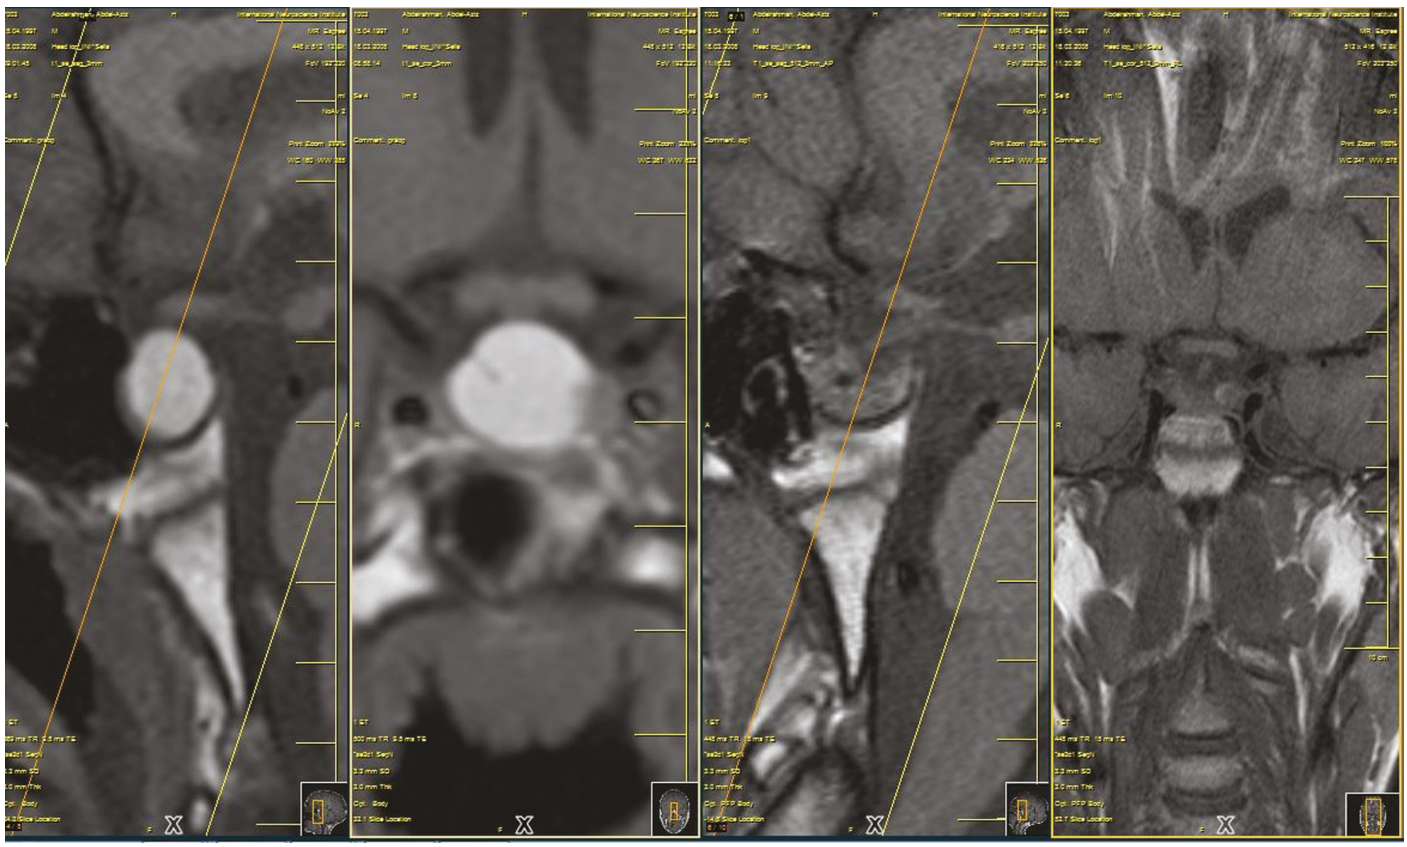

Fig. 26.9 Preoperative and postoperative MRI showing complete drainage of Rathke's cyst via a transsphenoidal approach.

recurrence rates. The experience of the senior author has shown that the potential risk of recurrence does not justify the morbidity risk, associated with aggressive cyst removal.

In pure suprasellar cysts the transcranial approach should be used, especially if a craniopharyngioma cannot be ruled out.

Outcome and follow-up

The rate of resolution of Rathke's cyst on postoperative MRI imaging after drainage is more than 90%. The headache improves immediately after surgery in all cases and visual functions improve in more than 80% after surgical drainage. Weiss's group (Aho et al.) presented a large surgical series of Rathke's cyst in adults, with an initial gross total resection rate of 97% and a recurrence rate of 18% after 5 years follow-up (Aho et al., 2005). Headache, visual symptoms, and hyperprolactinemia usually improve after surgical treatment, but panhypopituitarism and DI are less likely to improve because of the chronic compression of the pituitary gland. DI is more likely to occur after aggressive removal of the cyst wall. We have experienced, in some patients, postoperative temporary hyponatraemia that has been managed with fluid restriction.

Overall long-term recurrence rates after fenestration or resection of Rathke's cysts vary from 3% to 33%. The recurrence risk may correlate with the preoperative enhancement pattern of the cyst wall on imaging studies, the presence of squamous metaplasia, chronic inflammation, or stratified epithelium, the aggressiveness of cyst wall resection, and the insertion of an abdominal fat graft.

After surgical treatment of a Rathke's cyst, MR imaging is recommended after 3 months and then on a yearly basis for 5 years. After that every 2–3 years, if clinically stable, for a further 10 years.

Symptomatic recurrences of the Rathke's cysts are rare and are reported to range between 5 and 18%. Recurrence is usually manifested on the follow-up MRI, with or without reappearance of symptoms. Radiological evidence of recurrence on its own, is not an indication for reoperation. Symptomatic recurrence is an indication for operation to achieve adequate drainage. If the recurrence is asymptomatic, it should be followed with serial MRIs and with serial ophthalmic and endocrine examinations.

Controversies

One of the main points of discussion in the management of Rathke's cyst is how to measure the degree of resection. It is either described as the surgeon's impression or according to the postoperative MRI findings. The surgeon's impression is subjective and it is difficult in many cases to visualize and resect the thin wall of the cyst from the normal tissue of the pituitary gland safely. The cyst wall is normally not visible on the MRI and only the cyst contents give the radiological characteristics of the Rathke's cyst. Postoperative MRI cannot confirm removal of the cyst wall but can show complete evacuation of the cyst content. Accordingly, the term gross total resection of Rathke's cyst is very controversial.

We recommend fenestration and evacuation of the cyst via the transsphenoidal approach. The arachnoid should be kept intact. If there is intraoperative evidence of a CSF leak, we seal it with a small fat graft, taken from the subcutaneous tissue of the thigh or the abdomen. Transcranial approaches can be used in cases of isolated suprasellar symptomatic Rathke's cyst especially if large or when a craniopharyngioma cannot be excluded.

Acknowledgement

The authors would like to thank Professor Dr Rolf Buslei, Neuropathology institute, University of Erlangen, Germany for providing the histological sections.

Surgical management of sellar and suprasellar tumours

Jayson A. Neil and William T. Couldwell

Introduction

Despite their shared location, sellar and suprasellar tumours are an extremely diverse group of lesions with multiple sources of origin. These tumours may be congenital lesions, such as lipomas, Rathke's cleft (pars intermedia) cysts, arachnoid cysts, and hamartomas, or they may develop from any of the surrounding structures, resulting in pituitary adenomas, meningiomas, craniopharyngiomas, chordomas, optic nerve gliomas, among others. Non-neoplastic lesions, such as cavernous malformations, fibrous dysplasia, and inflammatory lesions such as sarcoidosis also present here, and tumours from remote sites are found in the form of metastasis in both the pituitary gland and the cavernous sinus. This extraordinary variety can make management of cases with these tumours more complicated because of the myriad of pathologies encountered.

To add to the complexity of treatment for sellar and suprasellar tumours, there are numerous critical structures in this region, including the pituitary gland, critical vessels, and multiple cranial nerves. Avoiding injury to these important structures is a key component of treatment planning.

In this chapter, we will discuss the anatomy of the sellar and suprasellar region with these factors in mind. We will discuss the workup, management, operative strategy, postoperative care, and complication management of these tumours, then elaborate on controversies related to these issues.

Surgical anatomy

A thorough understanding of the sellar and suprasellar anatomy is critical to an understanding of the pathology and its development and to the planning of any operative approach to this region. To simplify the discussion, we will divide the anatomy into the nasal cavity and sphenoid sinus and the sellar, parasellar, and suprasellar compartments, although much of the pathology in this area will encompass multiple compartments.

Nasal cavity and sphenoid sinus

The nasal cavity is a paired structure that opens anteriorly to the nares and posteriorly to the nasopharynx through the choana. It is bordered medially by the nasal septum. The bony nasal septum is formed by the vomer inferiorly and the perpendicular plate of the ethmoid superiorly with attachments to the rostrum or anterior wall of the sphenoid sinus providing a reliable midline landmark. On the lateral wall are the inferior, middle, and superior conchae and openings for the ethmoidal, frontal, and maxillary sinuses, as well as the nasolacrimal duct. The superior border is the cribriform plate, and the posterior border is the sphenoid bone. In the superior and posterior aspects, the nasal cavity communicates with the sphenoid sinus through the sphenoid ostia just medial and superior to the superior turbinates. The inferior turbinate is a separate bone and is the largest turbinate.

The sphenoid sinus is a single midline structure that communicates anteroinferiorly through the paired sphenoid ostia into the paired nasal cavities. It is encompassed by sphenoid bone and may be divided by multiple and eccentric septi. The blood supply to the sphenoid sinus arises from the sphenopalatine and posterior ethmoid arteries. The posterior septal branch of the sphenopalatine artery provides the pedicle for the nasoseptal flap and courses below the inferior border of the sphenoid ostium and passes anteriorly to supply the septal mucosa. The carotid arteries and optic nerves are closely apposed to the superolateral wall of the sphenoid sinus, and the sinus itself is often contoured around these structures, which may be dehiscent within the sinus. The horizontal petrous carotid continues to the cavernous segment, which in the endoscopic literature is termed the 'paraclival' carotid, and is vertically orientated in the posterolateral sphenoid sinus. This continues as an intracavernous segment which, more distally, loops posterolaterally and is not visible in the sphenoid sinus. It re-emerges on either side of the sella as the 'parasellar' carotid. It is important to recognize that the bone over the parasellar carotid can be thin and dehiscent.

The junctures between the parasellar carotid and the impression of the optic nerve are termed the optico-carotid recesses (OCR). The lateral OCR marks the location of the optic strut and anterior clinoid process and can be aerated and appear as a hollow from an endoscopic view. The medial OCR is in the vicinity of the middle clinoid process and medial cavernous sinus. The sella turcica hangs within the superior and posterior aspect of the sphenoid sinus (**Figs. 27.1** and **27.2**).

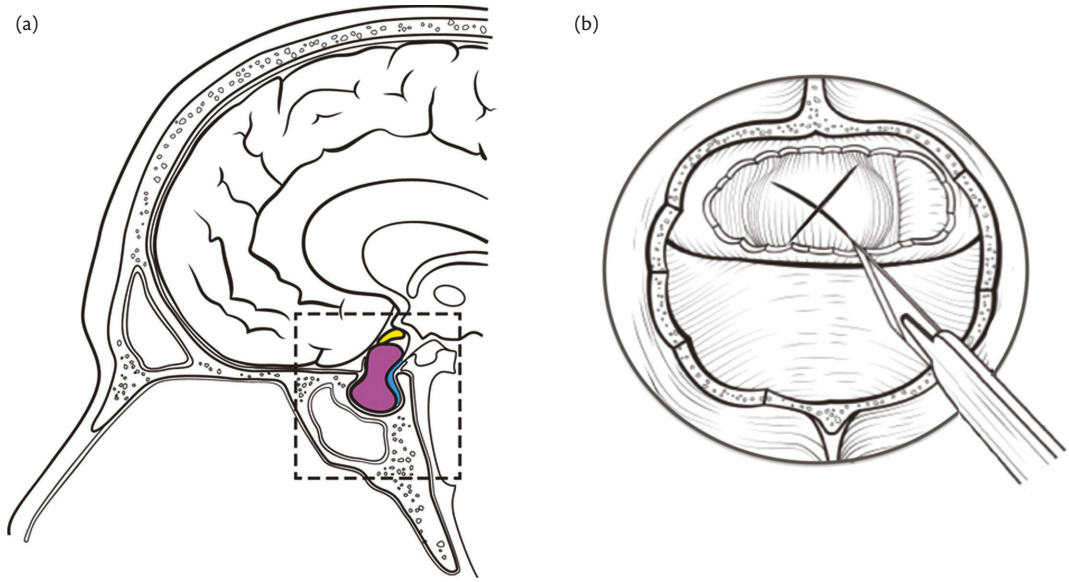

Fig. 27.1 (A) Sagittal view with pituitary adenoma shown in purple filling the sella and projecting into the suprasellar space. The optic chiasm, in yellow, is displaced upward and the normal pituitary gland, in blue, is displaced posteriorly or superiorly. (B) Anterior skull base as viewed from below through a microscope showing the incisions in the dura overlying the sella, which hangs in the posterior and superior aspect of the sphenoid sinus.

Sellar compartment

The sella turcica is a saddle-shaped depression in the body of the sphenoid bone. The hypophyseal fossa sits in the centre of the depression and is bordered anterosuperiorly by the tuberculum sellae, posteriorly by the dorsum sellae, laterally by the cavernous sinuses, anteroinferiorly and inferiorly by the sphenoid sinus, and superiorly by the suprasellar diaphragm sellae and suprasellar cistern. The pituitary gland sits in the hypophyseal fossa and is composed of an anterior lobe (adenohypophysis) and posterior lobe (neurohypophysis). The adenohypophysis originates from Rathke's pouch in the stomodeum and ascends along the craniopharyngeal duct into the sella. The neurohypophysis is an invagination of the floor of the third ventricle, which descends into the sella.

Parasellar compartment

The parasellar compartment is composed of the cavernous sinuses bilaterally, which are composed of dilated venous channels through which the cavernous portion of the carotid arteries and cranial nerves III, IV, V1, V2, and VI run. The cavernous sinus is bordered by a single layer of periosteal dura medially; the dura from the floor of the sella turcica, middle fossa floor, and clivus join the periosteal dura, creating a double layer of dura around the rest of the cavernous sinus (Fig. 27.2).

Suprasellar compartment

The suprasellar compartment is composed predominantly of the suprasellar cistern. The suprasellar cistern is a cerebrospinal fluid (CSF) filled space directly above the sella turcica and below the third ventricle. It contains the infundibular stalk, optic chiasm, and circle of Willis (Figs. 27.1 and 27.2). It appears pentagonal in shape on axial imaging.

Preoperative workup

Clinical evaluation

The clinical signs and symptoms with which a patient presents depend on the pathology, size, location, and chronicity of the lesion. A detailed clinical history should be combined with a physical examination including detailed head, neck, and cranial nerve examination, with a special focus on cranial nerves I–VI. Common symptoms include headache, double or blurry vision, loss of vision, and symptoms related to endocrinopathy (galactorrhoea, amenorrhea, acromegaly, Cushing syndrome, hypopituitarism), vascular compromise (e.g. transient ischaemic attack, stroke), and hydrocephalus

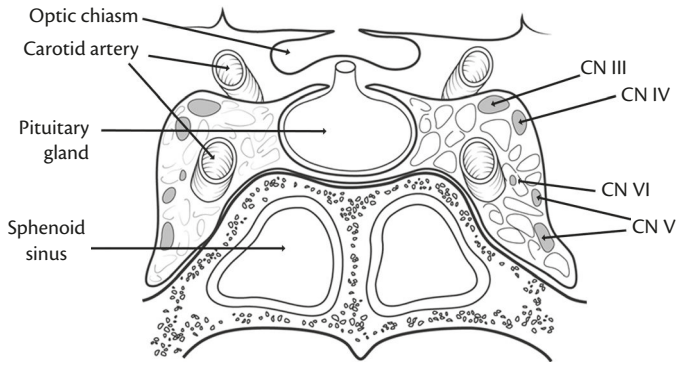

Fig. 27.2 Coronal cross-sectional drawing of the sellar region depicting the sella, bilateral cavernous sinuses (with contents), suprasellar cistern.

in very large tumours. If the tumour invades the paranasal sinuses, the patient may present with symptoms related to sinus occlusion (nasal obstruction, sinusitis).

The formal neuro-ophthalmological evaluation should include visual acuity testing, and visual field evaluation, as well as funduscopic examination to evaluate for papilloedema, venous congestion, or other findings indicative of raised intracranial pressure. The funduscopic examination may also provide evidence of optic nerve injury and atrophy. Formal visual fields are necessary to evaluate further nerve injury, which may be indicative of optic nerve compression from suprasellar components of a tumour. Typical bitemporal hemianopsia from chiasmal compromise as well as other forms of compression including within the optic canal can be identified. Optical coherence tomography (OCT) can also be utilized to obtain high-resolution images of the retina to better assess optic nerve atrophy and axonal integrity. If the retinal nerve fibre layer (RNFL) thickness is maintained this is a positive predictor of visual improvement following adequate surgical decompression of the optic nerve pathway.

Laboratory evaluation

Standard laboratory evaluations, including a complete blood count, a basic metabolic panel, and coagulation evaluations, should be completed. Furthermore, if the patient has a history of cancer, lymphoma, infection, or granulomatosis diseases, specific workup pertaining to those entities should be ordered; a lumbar puncture for CSF analysis can be part of this evaluation. A complete endocrinologic workup should also be performed; this is covered in detail in Chapter 25.

Radiographic evaluation

Magnetic resonance imaging (MRI) remains the best study with which to evaluate sellar and suprasellar lesions. In particular, thin-cut T1-weighted MRI with and without contrast enhancement should always be performed (usually done as part of a pituitary protocol). In addition, fat-suppressed imaging and thin-cut T2-imaging with sagittal and coronal reconstructions can be helpful in elucidating the extent of the lesion and its relationship to the cavernous sinus, optic and other cranial nerves, and carotid arteries. Computed tomography (CT) allows visualization of the sella and skull base osseous structures, can assist in evaluating for calcium within the tumour (such as in craniopharyngioma, chordoma, or chondrosarcoma, among others), and may also provide information regarding haemorrhage (e.g. pituitary apoplexy). In addition, it is superior to MRI in determining whether there is bone involvement from the lesion, such as hyperostosis or pneumosinus dilatans with meningioma, or bone erosion with other lesions. If a vascular lesion such as a large aneurysm is included in the differential diagnosis or if there is vascular encasement or compromise, a CT angiogram, or formal angiogram should be performed prior to any intervention.

Surgical planning

Multiple approaches exist for accessing sellar and suprasellar lesions. These include, but are not limited to, the transnasal–transsphenoidal, pterional, and subfrontal approaches and their variations. All of these approaches can be performed with the operative microscope, endoscope, or both, and multiple approaches may be combined to resect particularly large or difficult lesions. The expected pathology, location, and attachment of the lesion should be considered in choosing an approach. Likewise, the direction of displacement of the pituitary gland, stalk, optic nerves, and other cranial nerves are noted to assist in determining the side and nature of the approach. To avoid postoperative complications such as a CSF leak, there should be a clear plan for the surgical resection and closure. The necessary equipment and experience should be available before the procedure is started.

Intraoperative

Transcranial approaches

Pterional

The pterional approach has several advantages, including its familiarity to most neurosurgeons and the early visualization of the optic nerves, chiasm, pituitary stalk, carotid artery, and anterior cerebral artery vasculature. This approach also offers the shortest distance to access the suprasellar cistern and provides the ability to look behind the optic nerves early in the dissection to allow control of the carotid artery and its branches. In addition, there is early access to CSF for brain relaxation and less frequent transgression of the frontal sinus, which reduces the risk of CSF leak or infection. If there is significant anterior skull base involvement or if substantial skull base reconstruction is anticipated, this approach affords less access than a bilateral subfrontal approach.

For the pterional approach, the patient is positioned supine with an ipsilateral shoulder roll, and the operating table is slightly reflexed to position the head above the right atrium of the heart. The head is fixed in a Mayfield 3-pin head holder, rotated 30–40°, and slightly extended. The head may be variably extended to afford a more inferior-to-superior trajectory to access lesions that extend superiorly. Further extension facilitates the superior view and aids in frontal lobe retraction by gravity. The skin incision follows a gentle curve behind the hairline from just anterior to the tragus at the level of the zygoma to the midline at the anterior most aspect of the normal hairline. The temporalis fascia and muscle are incised linearly, and in most instances a combined musculocutaneous flap is elevated and retracted anteroinferiorly (Fig. 27.3). Burr holes are placed at the keyhole, along the posterior superior temporal line, and at the lower temporal fossa. The dura is separated from the calvaria, and a high-speed drill with footplate is used for the craniotomy, which should be customized to the patient and access needed.

The lateral aspect of the lesser wing of the sphenoid bone is removed down to the meningo-orbital artery using bone rongeurs and a high-speed drill. The dura is incised in a C-shaped fashion and retracted anteriorly. Early dissection of the Sylvian fissure allows for brain relaxation by CSF egress and exposes the olfactory, optic, and oculomotor nerves, as well as the carotid and anterior cerebral arteries. At this point, the suprasellar cistern is visualized, and most suprasellar tumours will be visible (Fig. 27.4). Tumour debulking

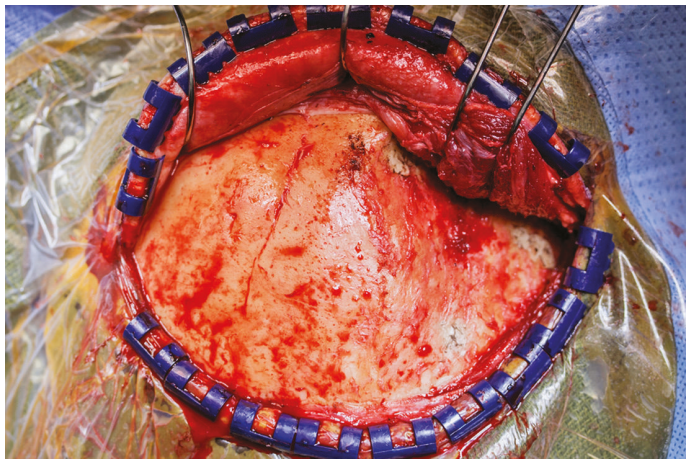

Fig. 27.3 Operative photograph of skin incision, elevation of musculocutaneous flap, and right pterional craniotomy.

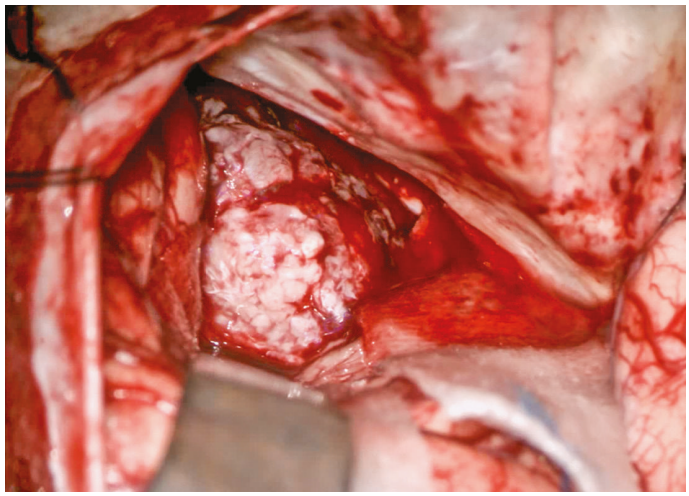

Fig. 27.4 Operative photograph of the occipital grey matter (just superior to the metal retractor) as viewed through a right pterional approach.

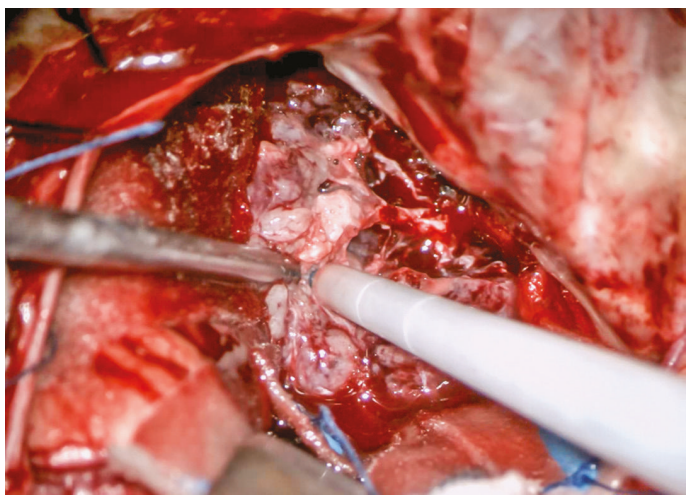

Fig. 27.5 Operative photograph of debulking of occipital grey matter using and ultrasonic aspirator as viewed through a right pterional approach.

will assist in dissection from the surrounding neurovascular structures (Fig. 27.5). The dura is closed primarily in a watertight fashion, and the bone flap is replaced using titanium plates and screws. A cranioplasty over the craniectomized sphenoid wing is performed using Medpor polyethylene implants to offset temporalis wasting. The temporalis muscle and fascia and the overlying soft tissues are closed in a standard fashion. See Box 27.1.

Variations on the frontotemporal approach: Fronto-orbital and orbitozygomatic

The primary indication for extending the standard frontotemporal approach to a fronto-orbital (removal of the orbital rim) or orbitozygomatic approach (removal of the orbital rim and zygoma) is to provide additional inferior-to-superior viewing trajectory while minimizing frontal and temporal lobe retraction. Which of these variants to use depends on the particular tumour. In most instances, the fronto-orbital variant is used, and a segment of the anterior and lateral orbital rim is included in the flap (extending from just lateral to the supraorbital notch to the lateral aspect of the orbital rim). Careful cuts are made to avoid disruption of the periorbita. The orbitozygomatic variant is used when a more extensive superior trajectory is needed. It is performed by eliminating the temporalis muscle by reflecting the muscle down and posteriorly and can be carried out in a one- or two-piece fashion, the technical details of which are covered in other chapters.

Subfrontal

Frontal or subfrontal craniotomies can be performed either unilaterally or bilaterally as needed for access to the lesion, a subcranial extension can be utilized if necessary (Fig. 27.6). For a unilateral subfrontal craniotomy, the patient is positioned similarly to the pterional approach, but with the head turned less, approximately 10–20° from the midline. The bicoronal skin incision generally ends just across the midline or at the contralateral superior temporal line. The scalp flap and periosteum are reflected anteriorly to expose the supraorbital vessels and nerves and to identify the orbital rim. Burr holes are placed, usually at the keyhole (the temporalis muscle is reflected in its anterior region to accommodate this hole). A decision will need to be made whether the sagittal sinus will be exposed, and the holes in the midline will be placed accordingly. The bone flap is brought low, just above the orbital rim. The frontal sinus is invariably entered with this flap. We usually choose to cranialize the sinus (remove the posterior table) and drill out the mucosa. The nasofrontal duct will then be plugged with muscle or fascia. The dura is usually incised in a C-shaped fashion with the base directed inferiorly.

For bilateral subfrontal craniotomy, the patient is positioned strictly supine with the bed reflexed to place the head above the right atrium of the heart. The head is fixed in a Mayfield 3-pin head holder and slightly extended to place the bilateral maxillary process at the highest point to facilitate brain retraction (Fig. 27.7). The skin incision is carried from zygoma to zygoma just anterior to the tragus bilaterally. Dissection is carried anteriorly with care taken to preserve the pericranium for use in reconstruction of the skull base. Minimal temporalis dissection is necessary and primarily only along the superior aspect near the keyhole bilaterally. Burr holes are made at the keyhole, posterior along the superior temporal line, and posteromedially lateral to the superior sagittal sinus (Fig. 27.6). Care must be taken to dissect the superior sagittal sinus from the calvaria, and if the sinus dura is very adherent, a trough can be created by using a drill with a diamond bit or the ridge of bone between the burr holes over the sinus can be removed using a Kerrison's

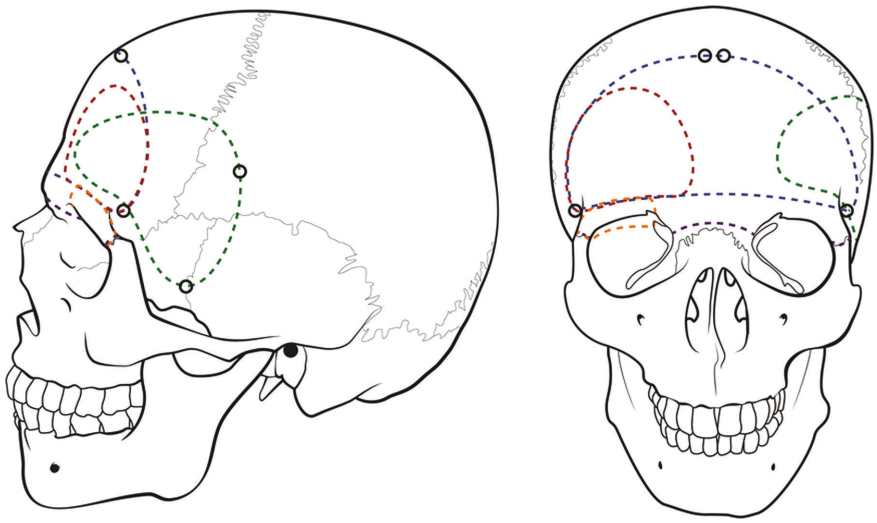

Fig. 27.6 Diagram of craniotomy paths based on operative approach. Displayed are the unilateral frontal (red), pterional (green), and bifrontal (blue) approaches. Additional orbital (orange) and subcranial (purple) cuts may be performed.

Fig. 27.7 Operative photographs of patient positioning and marked skin incision.

punch. No burr holes are placed over the forehead. The dura is dissected from the calvaria, and the craniotomy is performed using a high-speed drill with a footplate. The frontal sinus is exenterated and cranialized by removing the posterior wall with a high-speed drill and rongeurs. The mucosa of the frontal sinus is completely removed, and the frontonasal ducts are plugged using fascia and temporalis muscle. The dura is incised lateral to the superior sagittal sinus as far in the anterior direction as is afforded by the pathology (generally well within the anterior third of the sinus). The sinus is ligated using two double loops of 2-0 silk suture through the falx and incised between the sutures.

For both the unilateral and bilateral subfrontal approaches, the brain is gently elevated and the olfactory nerves can be followed back to their crossing with the optic nerves. If possible, the arachnoid over the olfactory bulb and nerves should be released to avoid injury to these nerves. The tumour should be visualized along the anterior skull base or in the suprasellar cistern. Tumour resection is carried out in an anterior-to-posterior fashion. As in any approach, if the tumour base is anchored to the dura (as in meningiomas), early detachment from the base will devascularize the tumour and aid in resection. Internal debulking will assist in tumour dissection from the surrounding neurovascular structures, which is critical in this approach because most of these structures will be located posterolateral to the lesion. The dura is closed primarily in a watertight fashion, and a dural graft may be necessary. If skull base reconstruction is necessary, then the anterior skull base can be packed with autologous fat and fascial grafts. The vascularized pericranial graft harvested at the beginning of the surgery can be used for further reconstruction. The bone is replaced with titanium plates and screws, with care taken to avoid positioning any hardware over the forehead and to allow adequate blood flow to the pericranium to avoid strangulation. The soft tissue is closed in the usual fashion. CSF diversion may be considered to assist in preventing CSF leakage through the wound.

Endoscopic approaches

Endoscopic approaches generally refer to transnasal approaches to the anterior skull base, sphenoid sinus, suprasellar cistern, and parasellar regions, and this section will focus on that approach. Nevertheless, the endoscope may be selected for use with any approach. Both cranial and transnasal approaches can be performed with the microscope, endoscope, or both. Even if the majority of the procedure is performed with the microscope, it can be extremely helpful to inspect the resection cavity with an endoscope using an angled lens to look around structures for residual tumour. Likewise, there is no reason for a surgeon to be restricted to an endoscope for a transnasal surgery, as the tools are complementary and should be utilized as such.

In general, the transnasal approach is ideal for lesions contained within the ethmoid and sphenoid sinuses and sella. For lesions outside the sella, further bone removal along the anterior skull base including opening the dura has been described by Weiss in 1987 (Weiss, 1987). In these cases, the relative merits and drawbacks of this approach (expanded endonasal) compared with a transcranial approach should be considered. The expanded endonasal approach is best utilized for small to medium-sized tumours and tumours that involve the ethmoid and sphenoid sinuses or the sella. The approach is advantageous because there is no evident skin incision, no ligation of the superior sagittal sinus, essentially no brain retraction, and early access to the tumour, and, in anterior skull base meningiomas, their vascular supply. The disadvantages are late visualization of neurovascular structures in suprasellar lesions, higher rates of CSF leak, and potentially lower rates of gross total resection if the tumour extends laterally over the orbits, superiorly and anteriorly against the frontal sinus, or above medialized carotid arteries posteriorly. In particular, meningiomas with a dural tail extending beyond the anterior skull base opening are challenging. Maintaining olfaction when using this approach for anterior skull base meningiomas can also be problematic if the region of the cribriform plate is involved with the tumour or opening.

Immediately prior to surgery, the patient is given decongestant nasal spray and positioned supine with the endotracheal tube taped to the left side. The bed is reflexed to position the head above the right atrium of the heart. The head is fixed in a Mayfield 3-pin head holder slightly extended to the left and rotated right; this allows the surgeon to stand to the patient's right to have a neutral view of

the head. The nasal cavities are packed with decongestant-soaked pledgets, and neuronavigation is registered with monitors for the navigation and endoscope at the head of the bed. The right lower quadrant of the abdomen or the lateral thigh is prepped for fat and fascia graft harvesting.

The packing pledgets are removed, and the nostrils are explored with a zero-degree endoscope to reveal the anatomy of the inferior, middle, and superior turbinates. The septum, choanae, and sphenoid ostia are also visualized. The nasal mucosa may be infiltrated with anaesthetic and epinephrine for haemostasis if needed. Although a deviated septum is more likely than not, a significant angulation ('septal spur') will need to be flattened to allow unobstructed access. It is important to appreciate that while the middle turbinate is attached to the ethmoid bone laterally via a basal horizontal lamella, more anteriorly there is an additional vertical attachment to the cribriform plate. The middle turbinate attachment is vertical anteriorly, before becoming progressively more horizontal and attaching to the palatine bone at its posterior extent. Frequently this turbinate needs to be mobilized (lateralization) if not removed altogether on the side of the surgeon, to expand the access and allow placement of the endoscope. During mobilization of the middle turbinate a crack of the vertical attachment can result in a fracture into the cribriform plate and difficult to treat CSF fistula. In some cases, the middle turbinate harbours air cells ('concha bulosa'), which may be seen on preoperative thin-slice CT, and this can make the middle turbinate bulky and necessitate excision.

Depending on the location of the lesion, a sphenoidectomy and posterior or superior septectomy is performed (especially if binasal access is required). For anterior skull base meningiomas the anterior and posterior ethmoidal arteries can be coagulated to assist in haemostasis and to devascularize the tumour. An important step in endoscopic surgery is the identification of the sphenoid ostia in the sphenoethmoidal recess medial to the superior turbinate. However, on occasions, this is not readily visible as it is covered with mucosa. If a Freer's dissector is passed into the sphenoethmoidal recess ~15 mm posterior to the superoposterior choana, it will enter the sphenoid ostium. Enlargement of the ostia is followed by excising or drilling the anterior wall and opening of the sphenoid sinus. In well-aerated sphenoid sinuses, the sella floor is surrounded with the air cell completely and is termed a 'sellar' type sinus. If it is only partially aerated, anteriorly it is termed 'presellar' and if non-aerated, as in young children (aeration begins from age 3) may persist as the 'conchal' type, which even with image guidance may limit transnasal approaches to the sella. The septations within the sphenoid sinus can be multiple and are rarely midline. The attachment of these septae posteriorly may abut the carotid, and they should therefore be drilled down as a fracture may lacerate the vessel. During the operation, the endoscope is generally in the superior aspect of the field and the suction in the dependent aspect, with microinstruments navigating between the two. If lateral exposure is necessary, the lamina papyracea can be removed but the periorbita is respected. Any bony removal is performed using a high-speed drill with a diamond drill bit. If a dural opening is required, the dura is first coagulated and then incised. Tumour removal is then performed using a standard microsurgical technique including internal debulking and dissection away from neurovascular structures. As the capsule is dissected, care should be taken to avoid traction on the neurovascular structures as these are generally poorly visualized until the end of the procedure.

Many transnasal cases present a significant risk of CSF leak and require a multilayer closure. The dead space created by tumour removal is occasionally packed with Gelfoam or fat graft. An autologous fascia graft or layer of allogenic acellular dermal allograft (AlloDerm) is tucked under the edges of the dura and, rarely, in large defects, reinforced with autologous vomer or septal bone, or Medpor. Lastly, a vascularized nasoseptal flap is rotated over the opening and can be reinforced with fat graft or sealant. The nasoseptal flap is pedicled on the posterior septal branch of the sphenopalatine artery inferior to the sphenoid ostium and is usually raised with monopolar diathermy from the floor of the nose, as far anterior as the nare and superiorly along a line from the superior portion of the sphenoid ostium sparing the olfactory mucosa (which extends 1–1.5 cm over the superior septal mucosa). Injudicious use of diathermy superiorly can also damage this mucosa and impair olfaction. CSF diversion is used in cases with large openings, to aid in graft healing, usually for 2–3 days postoperatively.

Endoscopic endonasal trans-sphenoidal hypophysectomy (EETSH)

Pituitary adenomas are the most common lesions removed by the endoscopic endonasal route. The bone over the sellar floor is drilled to expose the sphenoid sinus. The extent of bony removal depends on the location of the tumour and, although not always necessary, exposure superoinferiorly of the intercavernous sinuses may be required. Similarly, exposure of the cavernous sinuses is not required for large midline tumours but can be achieved by identifying the bluish colour medial to the carotids. An x shaped dural incision of the sellar floor avoiding extension into the venous sinuses and coagulation of the edges of the dural leaves allows good access into the sella.

The vast majority of macroadenomas are soft in consistency and, after obtaining adequate pathological specimens are easily removed by curettes and suction. It is advisable to clear the inferior aspect of the sella first as premature descent of the diaphragm may obscure residual tumour more posteriorly. In some cases the consistency of the adenoma may allow 'extracapsular' resection by circumferentially passing a dissector between the outer edge of the tumour and the dural walls of the sella, starting at the open dural edges. In these cases, care should be exerted at the superior pole to avoid breaching of the arachnoid layer of the diaphragm resulting in CSF leak and disruption of the compressed normal pituitary gland. After clearing of the superior aspect, the diaphragm is expected to descend fully, indicating adequate decompression. The normal pituitary can usually be spared as it is of a firmer consistency than the tumour and its location may be predicted from the direction of deviation of the stalk on the preoperative MRI.

fter debulking, inspection of the cavity using a 30° scope may identify further tumour remnants 'around the corners'. Operating using the 0° endoscope allows visualization in a 'cone' fashion and hence the portion of sellar lesions extending anteriorly on the anterior fossa lies in a blind spot; for full exposure the lip of bone at the tuberculum sellae may need to be drilled. If a wider dural

opening is required, the superior intercavernous sinus is coagulated and the view is supplemented by using the angled lens on an endoscope.

Microadenoma resection requires the identification of the lesion within the surrounding 'normal' pituitary gland. Lateralization of microadenomas is predicted on preoperative scans (both MRI and PET, e.g. C11-methionine) and biochemistry (such as inferior petrosal sinus sampling) but at surgery may be deep within the sella. They are identified by their different colour and softer consistency. Because the commonest indication for microadenoma resection is hypersecreting endocrinopathy complete resection for cure is required, and extension of the resection beyond the soft margins ensures removal of infiltrating tumour cells beyond the 'pseudocapsule'. Some authors recommend 'hemihypophysectomy' to ensure adequate removal.

Intraoperative breaches of the diaphragma sellae resulting in CSF leak can vary from a pinpoint hole to larger defects to the suprasellar cisterns and are repaired accordingly by simple fat or synthetic grafts or using a nasoseptal flap.

Extended endoscopic endonasal transplanum surgery (EEETS)

The favourable factors on MRI for selection of a lesion for an endonasal endoscopic extended transplanum approach for suprasellar lesions include the absence of encasement of blood vessels indicated by a cuff of cortical tissue between tumour and vessel, absence of lateral tumour extension beyond the carotids or beyond the midpupillary line in the coronal plane, and a bright T2-weighted signal indicating a soft consistency. An important consideration is extension of the tumour into the optic canal. From this approach the inferior and medial perimeter of the optic canal can be drilled, opened, and decompressed while the superolateral corner is not readily accessible.

The planum sphenoidale is related to the gyrus rectus on each side, so a transplanum trajectory to the suprasellar cisterns must be directly obliquely from anteroinferior to posterosuperior. Therefore, for lesions such as craniopharyngioma, drilling of the planum does not have to extend too far anteriorly but rather, drilling of the thick bone at the tuberculum sellae and even dividing the superior intercavernous sinus is advantageous.

The OCRs and optic canals are identified, and V-shaped drilling of the planum in between the diverging optic canals is completed. Caution is needed while elevating this bone fragment to avoid tilting of its edges onto the optic nerve by mobilizing it from an anterior to a posterior direction. The superior intracavernous sinus is controlled and may be divided to widen the access.

During intracranial dissection of lesions compressing the chiasma, the supplying branches from the superior hypophyseal arteries, which arise on its inferior aspect and onto the pituitary stalk, should be preserved to avoid ischaemia. Similarly, the ophthalmic artery should be protected during drilling of the optic canal. The endonasal endoscopic approach provides good visualization and a direct corridor to extensions into the third ventricle through its floor. Craniopharyngiomas in a retroinfundibular location are more challenging than those in a preinfundibular position particularly if stalk integrity is to be preserved.

Extended endonasal endoscopic approaches to parasellar lesions

If a transpterygoid endoscopic approach to a parasellar lesions is to be considered, then the first step is entrance into the maxillary antrum via the middle meatus behind the uncinate process after removal of the middle turbinate. The structures in the middle meatus such as the bulla ethmoidalis and hiatus semilunaris are identified, and coagulation of the sphenopalatine artery at its foramen, which overlaps the position of the Vidian nerve may be necessary. If a nasoseptal flap is planned, then this should be based on the other side. Important anatomic landmarks are the location of the Vidian canal in the plane of the floor of the sphenoid sinus laterally and the V2 branch of the trigeminal nerve emerging from the foramen rotundum orientated 45° superolateral to the Vidian canal. The pterygopalatine fossa communicates with the infratemporal fossa through the pterygomaxillary fissure and harbours the terminal maxillary artery. The pterygopalatine ganglion is suspended from V2 and it provides several branches including the greater and lesser palatine nerves, while V2 continues as the infraorbital nerve. Both parasympathetic and sympathetic fibres pass through the Vidian nerve into the pterygopalatine ganglion although only the parasympathetic fibres synapse. The trigeminal ganglion straddles the petrous carotid artery superolaterally in the depths. The ganglion is accessed through the posterior wall of the maxillary sinus. Drilling guided by the Vidian canal leads to the horizontal petrous-vertical cavernous junction of the carotid artery. This route to the petrous apex can be expanded naturally by trigeminal schwannomas eroding the bony corridor. This route is also used for cholesterol granulomas at the petrous apex.

Postoperative

outcomes

Postoperative outcomes vary considerably depending on the pathology and tumour location. For non-functioning pituitary adenomas, a large meta-analysis demonstrated overall mortality, morbidity, and risk of recurrence of less than 1%, 5% or less, and 18%, respectively (Murad et al., 2010). In craniopharyngiomas, a meta-analysis demonstrated new endocrinopathies in 37% of patients after surgical resection, with 2.5 times the rate of new endocrinopathies after gross total resection as compared with subtotal resection with or without radiotherapy (Sughrue et al., 2011). Another recent review noted that subtotal resection followed by radiotherapy demonstrated the best progression-free survival with rates at 5 and 10 years of 93% and 82%, respectively (Lo et al., 2014). For anterior skull base meningiomas, a recent review demonstrated gross total resection was more frequently achieved in open craniotomy (92.8%) than with endoscopic surgery (63.2%), with a higher rate of CSF leak in the endoscopic (31.6%) than the open craniotomy (6%) groups (Komotar et al., 2012).

Complication management

Complications related to transcranial procedures typically relate to encephalomalacia and postoperative seizures, infection,

postoperative hematoma, and cranial nerve or vascular injury. The risk of postoperative encephalomalacia and seizure can be reduced by minimizing brain retraction with adequate bone removal and a meticulous intradural technique. Infection risk is reduced by pre- and intraoperative antibiotic dosing and strict sterile technique. Postoperative hematomas may be prevented through preoperative cessation of medications such as anticoagulants and antiplatelets and good haemostasis; aggressive evacuation of clinically significant postsurgical hematomas is recommended. Lastly, cranial nerve and vascular injury can be avoided by thorough review of the patient's individual anatomy and imaging prior to surgery including vascular imaging if applicable. Internal debulking of the tumour, including the use of an ultrasonic aspirator, can improve visualization and increase the safety of dissection. If major arteries are encased in tumour, leaving a small residual may be preferable to complicated revascularization procedures or vascular injury. Lastly, if vascular injury is suspected, an intra- or postoperative angiogram should be considered.

Complications related to transnasal procedures typically relate to inadequate tumour removal or CSF leak; neurovascular injury

Box 27.1 Case illustration

A 21-year-old man presented with a one-month history of worsening double vision and an inability to abduct his left eye. A detailed neurological examination demonstrated an isolated left VI cranial nerve palsy. An MRI performed with contrast enhancement demonstrated a large sphenoid sinus, sellar, suprasellar, skull base, and left cavernous sinus lesion. Non-contrast CT demonstrated large calcifications within the lesion (**Fig. 27.8**). A left pterional craniotomy was used for an extradural approach to access the cavernous sinus through Parkinson's triangle. The tumour within the cavernous sinus was resected using ultrasonic aspiration, suction, and transsphenoidal ring curettes. Throughout this portion of the procedure, both the microscope and endoscope were used for visualization. In the same operative sitting, a transnasal approach was used to access the tumour within the sphenoid sinus, sella, and skull base. This tumour was resected using suction and transsphenoidal ring curettes, and the skull base was drilled using a diamond bit. Again, both the operative microscope and endoscope were used during this portion of the operation. Autologous fat graft was used to pack the cavernous sinus and sphenoid sinus, fibrin glue was used to seal the sphenoid sinus graft, and an external ventricular drain was placed then clamped and removed after six days. Postoperative MRI demonstrated minimal residual tumour at the posterior superior aspect. There were no complications, and no new deficits. The pathological analysis indicated the tissue was consistent with a chondrosarcoma, and the patient will undergo radiotherapy.

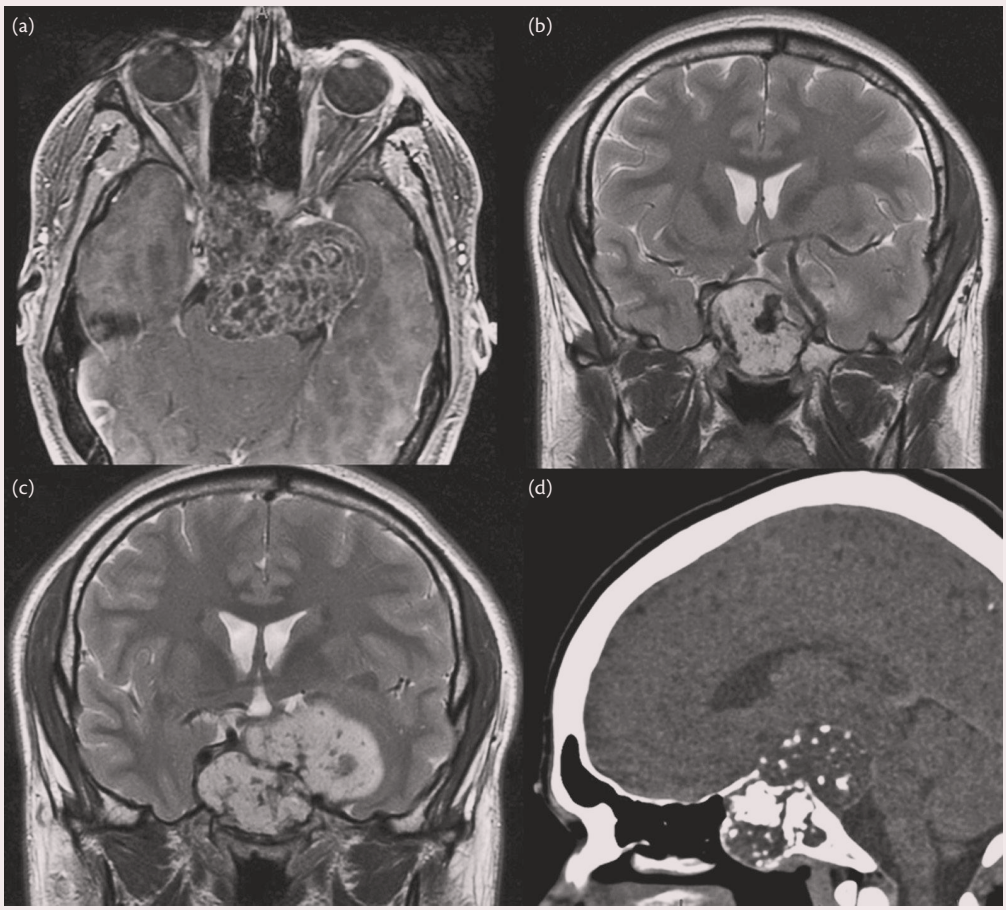

Fig. 27.8 Axial T1-weighted MRI with contrast (A) demonstrating tumour involving the sphenoid sinus, left cavernous sinus, and prepontine cistern. Coronal T2-weighted MRI demonstrating anterior and superior displacement of the left internal carotid artery (A), elevation of the optic chiasm and invasion of the left cavernous sinus (C). A sagittal non-contrast CT demonstrates large calcifications within the lesion filling the sphenoid sinus, sella, and suprasellar regions (D).

is noted occasionally. The risk of inadequate tumour removal can be reduced through careful evaluation of preoperative imaging, and by looking for the extent of the tumour and its attachments. Inadequate tumour removal often stems from inadequate bony removal. The bony opening should be adequate to encompass at least the attachment of the tumour and should not limit the exposure. If this is not possible, then the chosen approach may be inadequate for the lesion. The risk of CSF leak can be reduced using meticulous closure. Multiple techniques have been advocated, but generally a multilayer closure with an inlay of fascia or other dural substitute, fat, nasoseptal flap, and nasal packing is advised. Multilayer closure with inlay combined with 3–7 days of CSF diversion dramatically reduces postoperative CSF leak. Lastly, the risk to neurovascular structures can be reduced by proper preoperative planning and with understanding of the patient's anatomy based on imaging. The surgeon's experience will also play a role with the technique because of the long and narrow working distances. Furthermore, especially with angled endoscope lenses, visualization may be excellent, but access may be limited by working angles or poor microsurgical access. See Box 27.1.

Controversies

Transcranial vs. extended endoscopic approaches for meningiomas

Surgeons should familiarize themselves with both transcranial and extended endoscopic techniques for resection of tumours such as anterior skull base meningiomas, as both techniques are not only useful but required for some tumours such as large esthesioneuroblastomas. Nevertheless, deciding on which approach to use can and should be a very personalized decision based on a number of factors, not least of which is the operating surgeon's comfort and experience.

Transnasal extended or expanded endoscopic transcribriform approaches can confer specific advantages for certain tumours based on location and size. First, the hyperostotic bony attachment on the anterior skull base is directly accessed and resected, and any tumour growth into the paranasal sinuses is much more suited for resection through this approach. Likewise, the tumour is devascularized very early in the procedure and even the anterior and posterior ethmoidal arteries can be coagulated and cut prior to tumour resection. Furthermore, brain retraction and manipulation of neurovascular structures is reduced.

The disadvantages of the aforementioned endoscopic approaches are related to the inherent limitations of the midline exposure and risk of postoperative CSF leak. Tumour or dural tail extension laterally over the medial orbital wall or orbital roof, lateral to the optic canal, or into the sphenoid wing are very difficult to completely resect through the midline exposure and are more readily accessible via a transcranial approach. Neurovascular structures are often visualized later in the endoscopic approach when compared with the transcranial approach and are prone to injury if manipulated. Therefore, tumours that significantly encase the cranial nerves or the carotid, anterior communicating, or anterior cerebral arteries are often best approached through a transcranial approach where they can be visualized (and controlled if necessary) proximally and distally to the lesion. CSF leaks requiring repair can be more common in endoscopic approaches than transcranial approaches because of the increased difficulty in closure from the transnasal route when compared with the transcranial route and because of the increased size of the dependent osteodural defect created using the endoscopic approach. Nevertheless, modern surgical techniques including multilayer closures with the use of substances such as allogenic acellular dermal allograft (AlloDerm) and nasoseptal vascularized flaps combined with CSF diversion may drastically reduce the rate of CSF leak from these procedures.

Conclusion

The sellar and suprasellar tumours remain among the most challenging neurosurgical cases because of the complexity of the surrounding anatomy with a high concentration of important neurovascular structures. Furthermore, the multitude of pathologies results in significant clinical differences in outcome and treatment based on the pathology being addressed; however, continued advancements of surgical technique, including the use of the endoscope and endoscopic techniques in both open craniotomy and transnasal approaches, are consistently providing improved outcomes.

Medulloblastoma

James Rutka

Introduction

With their seminal work in 1925, Bailey and Cushing described a 'common type of midcerebellar glioma of childhood' which they named *medulloblastoma* (Bailey and Cushing, 1925). They postulated that this tumour originates from embryonic undifferentiated cells in the ependymal lining of the fourth ventricle and described the prominent histological features of increased cellularity and frequent mitoses. It was later noticed that several other supratentorial tumours share these features and a similar grim outcome. The heterogeneous group of '*small, round, blue cells*' tumours was named CNS–primitive neuroectodermal tumours (PNET). According to the 2007 WHO classification (Louis et al., 2007), these are composed of undifferentiated or poorly differentiated neuroepithelial cells. With respect to their most prominent cell line they were described as neuroblastomas, ependymoblastomas, medulloepitheliomas, ganglioneuroblastomas, and pineoblastomas. Medulloblastomas were grouped as the infratentorial PNETs. However, emerging evidence from molecular studies showed that medulloblastoma is a biologically distinct malignancy. In addition, similar analyses showed that a classification of CNS-PNETs based on their biological features is more elegant and realistic, compared to their histopathological classification (Picard et al., 2012).

The recent report from the Central Brain Tumor Registry of the United States (CBTRUS) (Ostrom et al., 2013) utilized the WHO classification for embryonal tumours (medulloblastoma plus CNS–PNET) and showed that the most common brain and CNS histologies at the age group of 0 to 14 years were pilocytic astrocytomas (17.5%) and embryonal tumours (15.7%). The percentage of embryonal tumours at the ages 15–19 years fell to 4.3%. The age-adjusted, pick incidence for medulloblastomas was 0.66/100 000 at the age group 5–9 years. A modest male predominance was again noticed (1.4/1).

Aetiology, pathogenesis, and current classification

Different polyomaviruses have been used to induce tumours with phenotype similar to human medulloblastoma (MB) in rats and hamsters. However, no definite causative factor has been found so far, regarding human embryonal tumours. Some theories describe the external granular layer (EGL) of the developing cerebellum as the cell group from where medulloblastomas originate, while others focus on the ventricular and dorsal brainstem neuronal progenitor zone. Proliferation of precursor neurons in the EGL is controlled by the Sonic Hedgehog (SHH) pathway (Wechsler-Reya and Scott, 1999). Similar insights in the genomics and molecular biology of medulloblastomas have increased our knowledge and understanding of their pathogenesis and behaviour. Currently, it has been shown that at least four distinct variants exist which are genetically and clinically distinct (Taylor et al., 2012). Medulloblastomas are now classified according to these subgroups which show significant prognostic value and prediction of survival.

1. The WNT (Wingless) subgroup shows activation of the WNT pathway from mutations of the *CTNNB1* gene. This results in intranuclear accumulation of β-catenin. Another common finding is monosomy 6. This group represents about 10% of medulloblastoma cases and is frequent in older children and adolescents with a 1:1 sex ratio. Most patients have classical histology and the prognosis is very good.
2. The SHH (Sonic Hedgehog) subgroup shows activation of the SHH pathway and frequently encountered mutations include the *PCTH1, SMO*, and *SUFU* genes, while *GLI2* and *MYCN* amplifications are also observed. Common chromosomal aberrations are 9q and 10q deletions. It represents 30% of all the cases and shows bimodal age distribution, in infants and adults, with a 1:1 sex ratio. Common histological type in this group is the desmoplastic one and infants harbouring this type in the SHH group, have favourable prognosis. Other SHH activated medulloblastomas show intermediate prognosis.
3. Group 3 has not yet revealed a dominant pathway activation. The *MYC* amplification is the hallmark of this group and an important cytogenetic aberration is isochromosome 17q. About 25% of medulloblastomas are group 3 and is frequently found in children and infants, with a slight male predominance. The large cell anaplastic (LCA) histological type is commonly represented and the survival in these patients is dismal.
4. Group 4 is the least understood. Common amplification is the *MYCN* and structural alteration is the *SNCAIP* duplication (subgroup 4α). As in group 3, the majority of patients have isochromosome 17q. It is the commonest subgroup (35%) and patients are typically children with male predominance (3:1). The histology is mainly classical with several LCA cases and the prognosis, as with the SHH group, is heterogeneous.

Table 28.1 Familial syndromes associated with medulloblastomas

Syndrome	Penetrance	Gene	Locus	Other manifestations
Gorlin	AD	*PTCH*	9q31	BCCs, palmar-plantar pits, jaw cysts, dural calcifications, bifid ribs, ovarian fibromas, macrocephaly
Turcot	AD	*APC*	5q21	Multiple colorectal neoplasms, other brain tumours (astrocytomas, ependymomas)
Li-Fraumeni	AD	*TP53*	17p13	Sarcomas, premenopausal breast cancers, acute leukaemias, other brain tumours (astrocytomas, choroid plexus tumours)
Bloom	AR	*BLM1*	15q26.1	Dwarfism, sun sensitivity, facial rash
Fanconi anaemia	AR	several genes		bone marrow failure, leukaemia, solid tumours

AD, autosomal dominant; AR, autosomal recessive; BCC, basal cell carcinoma.

Medulloblastomas are associated with familial cancer syndromes, as shown on Table 28.1. In Gorlin syndrome (Nevoid Cell Carcinoma syndrome) the common MB histology is of desmoplastic type and belongs to the SHH group. In Turcot syndrome, such tumours would present in patients younger than 10 years old, while in Li-Fraumeni syndrome, medulloblastomas can be found in 5% of the cases.

The PNET pathogenesis concept assumed that MBs and supratentorial PNETs derive from subependymal matrix cells which give rise to neuronal and glial cells. It was presumed that a common precursor cell was involved. However, emerging evidence showed different genetic alterations between medulloblastomas (aka infratentorial PNETs) and supratentorial PNETs. Two additional entities described under the umbrella of embryonal tumours are the atypical teratoid rhabdoid tumour (ATRT) and the embryonal tumour with abundant neuropil and true rosettes (ETANTR). The ATRTs are common in young children and distinguishable from medulloblastomas based on *INI1/hSNF5* negative staining. ETANTRs are the previously named 'ependymoblastomas' and have a particularly poor survival rate. An attempt to classify CNS-PNETs based on transcriptional signatures has currently defined three molecular subgroups (Picard et al., 2012):

1. Group 1: Amplification of *C19MC* at 19q13.41-42 and positivity for LIN28. This group enriches for neural stem cell genes and clinically, includes younger patients with midline tumours (cerebellum, brain stem, spinal cord) and dismal prognosis.
2. Group 2: Has more oligoneural markers (positivity for OLIG2—a marker for motor neuron and oligodendrocyte differentiation).
3. Group 3: No definite marker has been proposed so far and is described as LIN28/OLIG2 negative. Genes in this group have mesenchymal differentiation. Patients are more likely to present with metastatic disease, compared to both the other groups, although the overall prognosis is actually better (Adamski et al., 2014).

Histopathology

A typical medulloblastoma arises from the vermis and fills the fourth ventricle as a pink, grey, or purple mass. Small foci of necrosis can be evident. Similar macroscopic appearances present the supratentorial PNETs. The parenchymal tumours may have massive growths with more frequent cysts, haemorrhages, and necroses (Louis et al., 2007). Three main types are described:

1. The classic type (Fig. 28.1A) is the commonest (70%) and is composed of densely packed cells with round to ovoid or more elongated hyperchromatic nuclei, surrounded by scanty cytoplasm. A type of neuroblastic pseudorosette (Homer-Wright) is observed in less than 40%. Neuronal differentiation is common

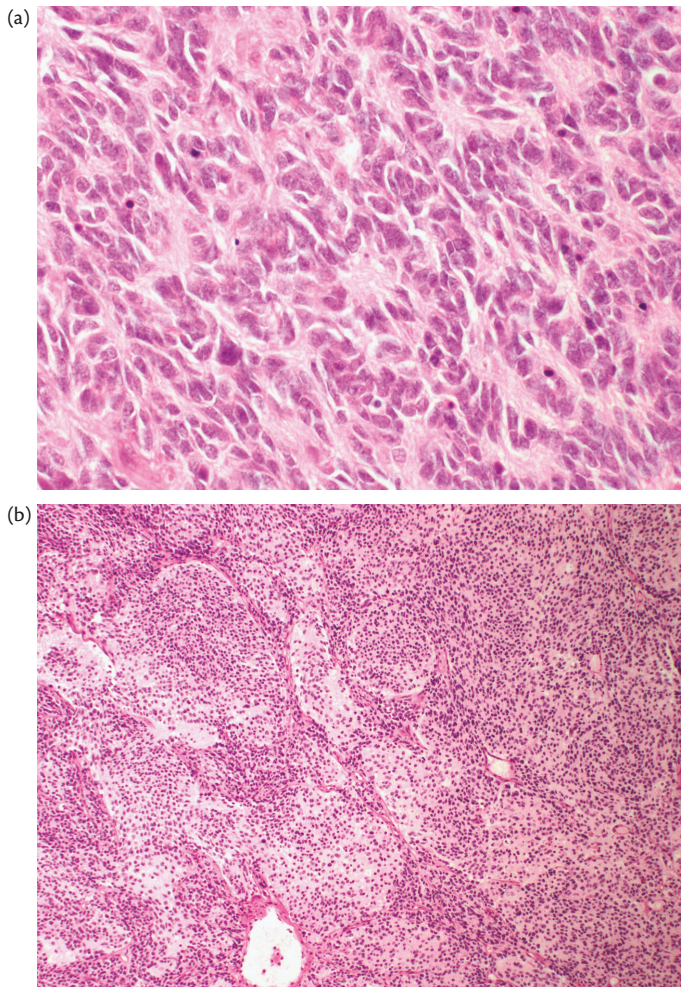

Fig. 28.1 (A) Classical medulloblastoma demonstrating neuroblastic (Homer-Wright) rosettes are an uncommon but highly characteristic feature of this grade IV neoplasm. (B) Desmoplastic/nodular medulloblastoma showing pale nodules of better differentiated tissue is a prognostically favourable feature in medulloblastoma. This histological pattern predominates in the desmoplastic/nodular variant.
Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

and reveals as immunopositivity for the neuronal marker synaptophysin.

2. The desmoplastic type (Fig. 28.1B) is more common in infants and adults and typically associated with the SHH molecular subgroup. Presents a biphasic pattern with nodular, reticulin-free zones ('pale islands') surrounded by highly proliferative tumour cells with pleomorphic nuclei and a dense intercellular reticulin fibre network. Within the nodules there is synaptophysin positivity, while the outside cells show higher Ki-67 proliferation index and GFAP positivity. A variant of this type is the medulloblastoma with extensive nodularity (MBEN), previously known as cerebellar neuroblastoma. The desmoplastic type has shown favourable prognosis in infants (Rutkowski et al., 2005).
3. The large cell and anaplastic types are currently described in a unified group due to the significant overlapping between them. This variant presents in 4% of medulloblastomas, is more common in molecular group 3 and has the poorest prognosis. The cells lack cohesiveness and show abundant mitotic and apoptotic figures.

Though previously regarded as separate variants, medullomyoblastomas and melanotic medulloblastomas are now described as cases of medulloblastoma with myogenic and melanotic differentiation, respectively.

CNS-PNETs have the same 'small, round, blue cells' microscopic appearance found in embryonal tumours. More precisely, these cells are poorly differentiated with high nucleus/cytoplasm ratios. Neuronal features can be found to better differentiated types. Frequency of Homer-Wright rosettes varies. Calcifications are common and vascular endothelial proliferation may also be seen. The Ki-67 proliferation index varies among groups but generally is high.

Clinical presentation

Presenting signs and symptoms depend on the patient's age. Typically, a posterior fossa midline tumour causes obstructive hydrocephalus and increased intracranial pressure. In infants and toddlers with open sutures, this would result in macrocephaly and bulging fontanel. Poor feeding, irritability, regression of milestones, and vomiting usually follows. Not infrequently, these babies are investigated for milk allergies and gastrointestinal issues. In severe cases, patients present at the emergency department with lethargy, apnoeas, bradycardias, and seizure-like episodes ('hydrocephalic crises' with tonic posturing). Young children with huge PNETs can rapidly deteriorate after intratumoral bleeding and present with herniation phenomena.

Older children typically suffer from morning headaches and vomiting episodes which relieve the headache. Possibly, the accumulation of CO_2 during sleep causes vasodilation and further increase of the intracranial pressure (ICP). The duration of these symptoms varies from few weeks to 2 months. Alarming signs in later stages are strabismus and/or diplopia due to VI nerve paresis. Symptoms from direct mass effect depend on tumour location. Midline lesions cause truncal ataxia and long tract signs, while more lateral locations—as seen in older children and adolescents—present with cranial nerve paresis, vertigo, and appendicular ataxia. Sudden onset of torticollis in a child should prompt further investigations.

About 30–40% of medulloblastomas have metastases on diagnosis but these are mainly found on diagnostic imaging. Groups 3 and 4 are characterized by early disseminated disease. Spinal metastases may present with paraparesis, bladder dysfunction, or radiculopathies.

Imaging features

Head ultrasound can be used as an initial imaging modality for the diagnosis of hydrocephalus caused by posterior fossa tumour in children with open fontanel. *Computed tomography (CT)* would show a midline cerebellar lesion with surrounding vasogenic oedema and obstructive hydrocephalus (Fig. 28.2). Medulloblastomas are hypercellular tumours and they present as hyperdense lesions on CT. Calcifications can be seen in 22% of the cases and cystic formation in 59% (Poretti et al., 2012). All patients

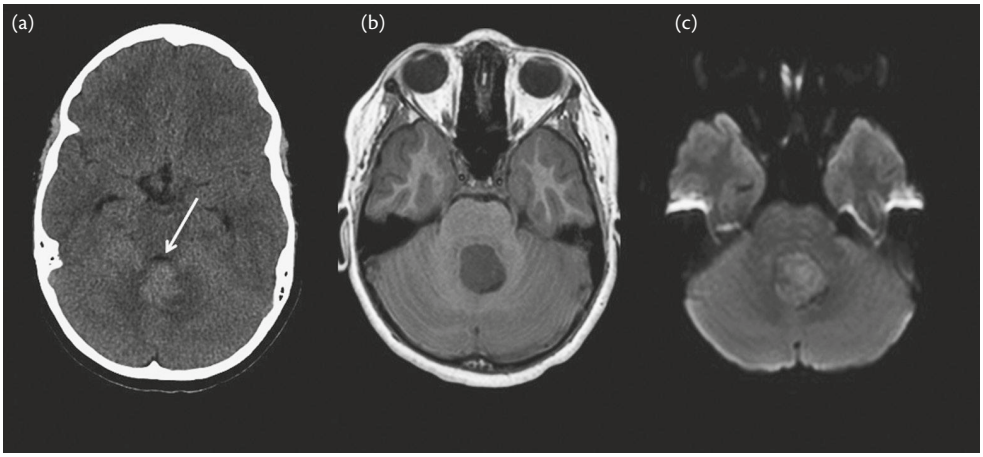

Fig. 28.2 A 12-year-old boy with typical medulloblastoma. (A) Non-contrast CT shows the hyperdense lesion filling the fourth ventricle (arrow) from posteriorly and causing triventricular hydrocephalus. (B) On axial T1-weighted MRI, the tumour has low signal and (C) the DWI imaging shows high signal (restriction). Hyperdensity on CT and restriction on DWI are indicators of hypercellularity and increased malignancy.
Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

with a posterior fossa tumour should undergo detailed examination of head and spine with magnetic resonance imaging (MRI). Young children would require general anaesthesia for such scanning. If the patient deteriorates rapidly due to increased intracranial pressure, then MRI should not delay adequate neurosurgical management. On T1-weighted images the tumour appears hypo- to isointense compared to the normal brain. On T2-weighted MRI the signal intensity is variable. Hypercellular lesions usually show low signal on T2W. This hypercellularity of high-grade tumours such as medulloblastomas, with high nucleus/cytoplasm ratio, results in reduced free water and gives the high signal (restriction) on diffusion-weighted imaging (DWI) (Jaremko et al., 2010). This can differentiate a medulloblastoma from the other common posterior fossa tumours, the pilocytic astrocytoma (PA) and the ependymoma. In addition, the medulloblastoma typically originates from the roof of the fourth ventricle, while ependymoma from the floor. The later shows a 'plastic' behaviour and can be found extending through the outlet foramina of the fourth ventricle. Such an extension is seen in 14% of medulloblastomas. Disseminated disease with 'drop' metastases into the ventricles or the craniospinal subarachnoid spaces are found in 40% of newly diagnosed medulloblastomas (Fig. 28.3). Ideally the whole neuraxis should be scanned preoperatively with and without gadolinium administration to detect such metastases. Postoperative imaging of the neuraxis for grading purposes should be delayed for 2 weeks, to minimize the false positive findings due to debris and blood degradation products (Meyers et al., 2000).

CNS-PNETs may have similar imaging features. MRI of supratentorial PNETs shows a large complex mass with minimal peritumoral oedema (Fig. 28.4). Enhancement is heterogeneous and commonly they restrict on DWI with low according apparent diffusion coefficient (ADC) values (hypercellularity). Calcifications and intratumoral bleeding are frequent. Both they present as susceptibility areas on gradient imaging (GE). Imaging of the entire neuraxis is mandatory due to the common leptomeningeal spreading of these lesions.

Management

Children with medulloblastomas and CNS-PNETs should be managed by a multidisciplinary approach in experienced paediatric centres. These patients would present with signs and symptoms of increased intracranial pressure from obstructive hydrocephalus. Detailed preoperative evaluation is paramount but only if the clinical status allows such investigations. Usually the symptomatology will improve with intravenous administration of dexamethasone which decreases the vasogenic oedema. Whole neuraxis MRI is done with the appropriate sequences as per each centre ('tumour protocols'). If there is time, evaluation of hearing and renal function is performed for baseline assessment, as the adjuvant chemo- and radiotherapies have known toxicities. The family is consented for the proposed treatment, research enrolments, and blood products transfusions.

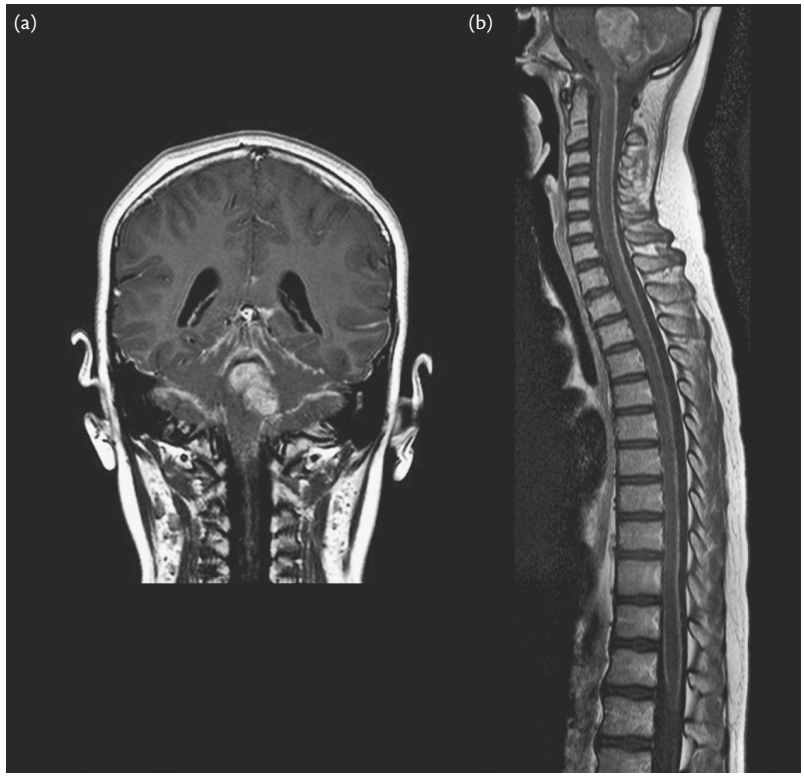

Fig. 28.3 A 10-year-old boy with disseminated medulloblastoma. (A) Coronal T1-weighted MRI postgadolinium administration with homogeneously enhancing fourth ventricular primary tumour and diffuse leptomeningeal enhancement of the cerebellum. (B) Midsagittal T1-weighted MRI postgadolinium of the whole spine shows leptomeningeal enhancement of the entire cord surface laminar, 'sugar-coating' pattern.

Management of hydrocephalus is controversial. If the patient presents in extreme condition, a life-saving insertion of external ventricular drain (EVD) is justified, with extreme care to avoid upward herniation through the tentorial incisura. Routine insertion of ventriculoperitoneal shunts (VPS) should be avoided because only 10–40% of children will eventually require permanent CSF diversion postoperatively and these patients will be exposed to the significant risk for VPS complications throughout their lives (Lee et al., 1994). Risk factors for postoperative need for permanent shunting are young age, severe preoperative hydrocephalus, larger tumour size, and disseminated disease. A study from Paris found that preoperative endoscopic third ventriculostomy (ETV) in such cases, significantly reduced the risk of persistent postoperative hydrocephalus (Sainte-Rose et al., 2001). The authors acknowledged the risk of exposing several patients to an unnecessary procedure, especially in routinely performed ETVs. In any case where CSF is obtained preoperatively, a specimen should be sent for cytology.

Surgical management

Most surgeons prefer the prone position to perform a midline suboccipital craniotomy. Intraoperative neuromonitoring is important. Persistent bleeding usually indicates residual tumour. The endoscope is a useful tool to inspect for remnants 'around the corners'. The target is gross total resection (GTR) under maximum safety. Residual more than 1.5 cm^3, as measured in postoperative MRI, was associated with worst outcome (Zeltzer et al., 1999). If the tumour invades the floor of the fourth ventricle or is firmly attached to the lower cranial nerves, the surgeon should avoid aggressive resection and resulting palsies which significantly decrease the quality of life. Some centres utilize intraoperative MRI scans to achieve GTRs with encouraging results (Avula et al., 2013). Postoperative MRI should be performed within 72 hours or after 2 weeks, to avoid false positive findings due to blood products. Lumbar CSF is obtained for cytology and staging purposes, in conjunction with the whole neuraxis MRI, for increased sensitivity (Fouladi et al., 1999). Lumbar CSF sampling is more reliable compared to EVD or intraoperative CSF sampling (Gajjar et al., 1999).

Non-surgical management

The child's age grossly determines further treatment options after the initial medulloblastoma resection. In children less than 3 years of age, radiation therapy is avoided due to devastating neuro-cognitive sequelae.

Age less than 3 years

Even in cases of disseminated disease, current protocols follow radiation-free approaches (Rutkowski et al., 2005). Commonly, they start with systemic, platinum-based regimens, followed by myeloablative chemotherapy with autologous stem cell support. Systemic chemotherapy is also combined with intraventricular methotrexate. This is administered through a subcutaneous reservoir (Ommaya) or via an already placed VP shunt, with special care to avoid intraperitoneal spreading of methotrexate (e.g. through transient flow occlusion valves). Focal radiation is reserved for relapses and the results, compared to chemotherapy alone, are controversial (Grill et al., 2005; Ashley et al., 2012). Prognosis is poor in this age group with 5-year survival of 50–70%. The desmoplastic histological variant is an exception with almost 90% survival.

Age more than 3 years

Administration in of adjuvant therapies in this age group is stratified into average and high-risk patients, according to clinical criteria (Fig. 28.5). Poor prognosticators are metastatic disease (Chang et al., 1969), tumour residual more than 1.5 cm^3, positive CSF cytology and, for some authors, large cell/anaplastic histology. Children in the high-risk group receive 3600 cGy of craniospinal irradiation with a boost at the tumour bed and to focal metastases. Adjuvant systemic chemotherapy follows. Five-year survival rates are 40–82% (Adamski et al., 2014). Average-risk patients receive reduced craniospinal irradiation (2340 cGy) with a boost to the tumour bed of 5400–5580 cGy. Concomitant chemotherapy with vincristine is typically given. Systemic chemotherapy (cisplatin based) follows and the 5-year survival rates are 85% (Gajjar et al., 2006). Proton radiotherapy delivers the same radiation amount to the target area but is superior to the photon radiotherapy due to the significantly less penetration into the surrounding healthy tissues. Higher costs and

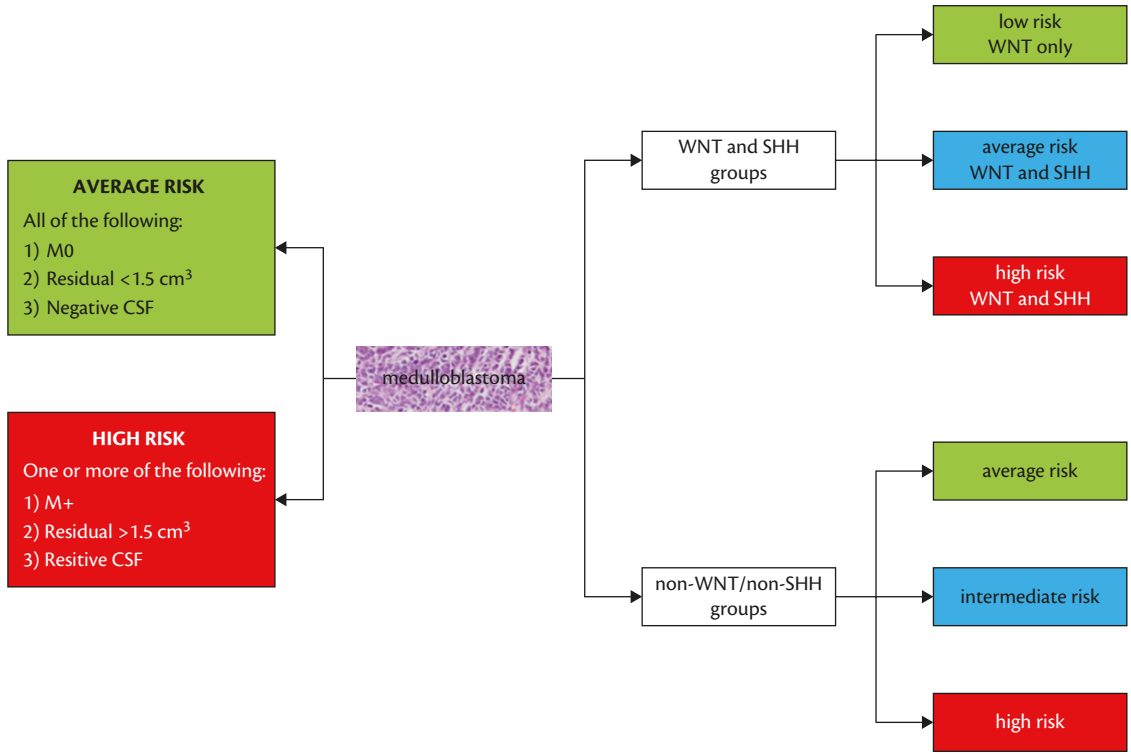

Fig. 28.5 Diagram showing on the left, the current clinical stratification on average and high-risk medulloblastoma for patients aged more than 3 years. On the right, a stratification currently under investigation, based mainly on molecular features—adapted from (Gottardo et al., 2014). Criteria for increased risk are metastatic disease (M+), *MYC* amplification, non-gross/near total resection and large cell/anaplastic histology.

poor availability are currently important drawbacks. Radiotherapy strategies designed to improve outcomes are hyperfractionation and the use of radio-sensitizers. Significant risks of radiotherapy, besides poor cognitive outcome in young children, are ototoxicity, endocrine issues (thyroid dysfunction and growth failure), radiation necrosis, and secondary malignancies. Recurrent disease has very poor outcome with a salvage rate less than 10%. Better chances have localized recurrences amenable to surgical resection, with relative chemosensitivity and if re-irradiation is possible (Pizer et al., 2011).

Current management of CNS-PNETs in infants is based on similar to medulloblastoma protocols. Dose-intensive chemotherapy, including high-dose modalities with autologous stem cell rescue is used in attempts to avoid or delay radiation. Overall survival is dismal, ranging from 0 to 49%. In older children, CNS-PNETs are rare and strong evidence-based management strategies are absent. They are treated as high-risk patients. It is not clear if residual tumour or metastatic disease are strong prognostic factors of poor outcome. Overall survival rates between 15 and 73%, and PNETs localized in the pineal region, tend to have better outcome than other sites (Chintagumpala et al., 2009).

Future management of embryonal tumours is an area of intense investigations. Subgrouping of patients, based on cytogenetic biomarker-driven stratification may predict survival and add information for improved treatment strategies (Shih et al., 2014). The excellent survival rates in the WNT group may suggest overtreatment approaches at these patients (Adamski et al., 2014). In the SHH group, new molecular targeted therapies with the smoothened inhibitors LDE225 and GDC-449 are under investigation with promising results (Kool et al., 2014). Management of metastatic disease may dramatically change after the discovery that metastases are extremely similar to each other but significantly divergent from the matched primary tumour (Wu et al., 2012). Regarding the significance of biology based prognostic factors, currently it has been shown that for medulloblastomas poor outcome is linked to non-WNT/SHH group, *FSTL5* overexpression, *MYC*/*MYCN* amplification and gain of 17q chromosome. For the CNS-PNETs, poor prognosticators are *C19MC* amplification and LIN28 positivity.

Case presentation—controversies

Figure 28.6 presents a case of a 2.5-year-old girl. She was admitted with a 2 week history of worsening weakness of her lower extremities and bladder dysfunction (Fig. 28.6A). Sagittal T1-weighted postgadolinium MRI showed a heterogeneously enhancing fourth ventricular tumour, with triventricular hydrocephalus (Fig. 28.6B). Imaging of her spine revealed multiple nodular metastases causing cord compression at T_2 and T_9 levels and a large mass in her lumbar spine with mass effect on her cauda equina. Note the enlarged bladder. Her treatment required prioritization of three issues: dealing with her neurological deficits, oncological management, and treatment of hydrocephalus. Which one should be dealt with first is a matter of controversy. The multidisciplinary neuro-oncological decision was to operate first on the primary posterior fossa tumour and irradiate the spinal lesions as soon as possible. It was not clear as to which one of the spinal metastases was causing her symptoms so the option to operate on the spine first was rejected. The primary lesion (medulloblastoma) was gross totally

removed within 24 hours (Fig. 28.6C) and the first postoperative day the spinal irradiation commenced. In 5 days, she received 2000 cGy locally on the lower thoracic and lumbar region. Her hydrocephalus persisted postoperatively. The management controversy was between ETV and VP shunt insertion. The decision was for VPS based on the urgent necessity for adjuvant treatment and the need to minimize the postoperative complication rate after shunt diversion procedures (Kulkarni et al., 2010). Her weakness improved and she was further managed on a high-risk medulloblastoma protocol.

Ependymoma

Christopher Chandler

Epidemiology

Ependymomas which include both subependymoma and myxopapillary ependymoma variants are slow growing tumours of glial origin, believed to arise from radial glial stem cells within the ependymal surface within the central nervous system (CNS) and spinal cord. Consequently, they are most commonly found in association with a ventricular surface, primarily within the fourth ventricle. The majority of these tumours occur in children, representing approximately 10% of all paediatric CNS tumours, following astrocytomas and PNET in frequency, and there does not appear to be a gender bias. The majority of paediatric ependymomas are intracranial and about half occur in children less than 5 years old (Foreman et al., 1996). Interestingly in children while the majority (more than two-thirds) of ependymomas are found within the posterior fossa, adults present with an almost equal incidence of intracranial and spinal cord tumours, and in those adults with intracranial ependymomas, an almost equal incidence of supra and infratentorial locations. In adults, ependymomas are much less common; with many arising within the spinal axis, either as intramedullary tumours or as extramedullary tumours in the region of the conus medullaris.

Two rare subtypes of ependymoma are recognized: subependymoma and myxopapillary ependymoma. Subependymomas are benign slow growing indolent tumours and their true incidence is not well characterized as many never cause symptoms and may be discovered incidentally as a post-mortem finding. Those that are symptomatic are found to occur most frequently in middle aged and elderly patients. Like other types of ependymoma, they are found in association with a ventricular surface, predominantly the fourth ventricle followed less commonly by the lateral ventricles. If found incidentally many may not progress nor require removal. Surgical removal is usually curative unless a subtotal resection is performed.

In contrast myxopapillary ependymomas, which are also slow growing, tend to affect young adults, and occur almost exclusively within the spinal canal (extramedullary) in the region of the conus medullaris, though they have been reported within other CNS sites. They may rarely metastasize and surgical resection is, as for subependymoma, usually curative unless a subtotal resection is performed.

Pathology

The older World Health Organization (WHO) grading of ependymomas identified four subtypes of tumour: subependymoma (WHO 1), myxopapillary (WHO 1), classic (WHO 2) and anaplastic (WHO 3). Several morphological variants are also recognized within the classic subtype: cellular, papillary, clear cell, and tanycytic though these variants have no prognostic significance.

Leaving aside the rare subtypes (subependymoma and myxopapillary ependymoma), the vast number of paediatric ependymomas fall into either the Classic or Anaplastic category. In the remainder of this chapter these are the two subtypes of tumour whose features and management will be discussed.

Classic ependymomas (**Fig. 29.1**) are moderately cellular tumours with rare or absent mitoses. The cells are uniform in size with minimal pleomorphism and a high nuclear/cytoplasmic ratio. The typical structural features are perivascular pseudorosettes or much less commonly the appearance of ependymal rosettes. Perivascular pseudorosettes are formed by radial disposition of tumour cells around blood vessels, while true ependymal rosettes are formed by tumour cells arranged in a columnar fashion creating a central lumen defined by the tumour cells themselves. Most ependymomas stain positive for GFAP especially in the fibrillary processes immediately adjacent to the region of the perivascular pseudorosettes. Occasional areas of necrosis may be seen but do not necessarily indicate the presence of the anaplastic subtype of tumour. Though the histological criteria necessary to classify a tumour as an ependymoma are clearly set out, the identification of histological features to definitively classify its subtype, so important in predicting prognosis, has been challenging. Combinations of intratumoural heterogeneity, interobserver variability, variations in definitions, the use of different histological criteria, the uneven application of criteria for anaplasia by review pathologists, and idiosyncratic small patient cohorts have led to significant disagreements in pathological grading. This has presented difficulties in classifying ependymomas, particularly with reference to anaplastic tumours, well documented in excellent works dealing with this subject (Tihan et al., 2008; Ellison et al., 2011).

Anaplastic ependymomas (**Fig. 29.2**) are malignant tumours with a poor overall prognosis. They are highly cellular, show accelerated growth, high mitotic activity, and a tendency towards dissemination.

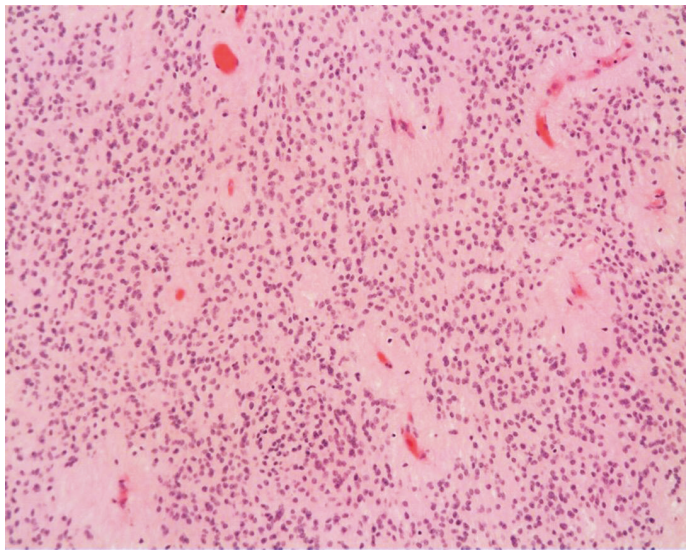

Fig. 29.1 Ependymoma, WHO grade II. Moderate cellularity, vascular pseudorosettes, and infrequent mitosis. Intradural/extramedular lesion in L1, 61-year-old-man. Epithelial membrane antigen (EMA) expressed in paranuclear dot pattern, GFAP positive, Ki67 2%, and RELA negative.

Histologically they show pseudopalisading necrosis, microvascular proliferation, and perivascular pseudorosettes. Unfortunately, at present there is not a reliable widely accepted neuropathological consensus of criteria for anaplastic ependymoma, though most neuropathologists would accept the importance/significance of mitotic index, Ki67, cellularity, and degree of differentiation. Ki67 proliferation index appears to correlate well with survival with lower survival seen in patients whose tumours have a Ki67 greater than 5%.

This lack of consensus can present serious challenges to clinicians (Robertson et al., 1998) whose treatment paradigms are markedly different between classic and anaplastic ependymoma. It may also result in widely different outcomes and create difficult decisions for clinicians making treatment decisions.

Tumour molecular genetics

A range of cytogenetic anomalies is found in ependymomas though there is not yet enough consistency in these changes to influence grading or treatment decisions (Table 29.1). Up to 30% of ependymomas have been found to contain anomalies of chromosome 22, which may include monosomy, deletions, or translocations (Hamilton and Pollock, 1997).

Interestingly and perhaps not surprising is the finding that intramedullary spinal ependymomas are found more frequently in NF-2 patients leading to the belief that the NF-2 gene is somehow involved in ependymoma tumourigenesis (Slavc et al., 1995). Other genetic anomalies include losses in 6q, 9q, 3p, 10q, and 11q. In the clear cell variant, which histologically may resemble oligodendrogliomas there is no 1p 19q codeletion. In the future these cytogenetic changes may very well play a significant role in diagnosis and tailored, biologically driven treatment paradigms.

Biological markers are also the subject of intense scrutiny though to date there has been no significant validation of any current biomarkers (Andreiuolo et al., 2013). The tremendous advance in molecular profiling, which may in future lead to changes in treatment, has led to a newer WHO classification of ependymoma (Box 29.1).

Treatment

Surgery

The role of radiotherapy

Ependymomas are truly surgical tumours. The prognosis in all age groups and all CNS locations has long been recognized to be utterly dependent on the extent of surgical resection (Healey et al., 1991; Perilongo et al., 1997). The terrible dilemma for the neurosurgeon is that due to this tumour's propensity to adhere to the brainstem and cranial nerves in the posterior fossa, to spinal cord tissue/nerve roots (intramedullary and myxopapillary ependymoma), total resection may result in serious and significant neurological morbidity. This aggressive surgical strategy must be carefully weighed up against the poor overall prognosis if a subtotal resection is achieved even with advanced multimodality neuro-oncological treatment (Merchant, 2002; Merchant et al., 2009).

The initial workup of these patients involves full cranio-spinal axis MRI to accurately determine the location of the tumour, its relationship to adjacent structures (brainstem, cranial nerves) and presence or absence of metastases. MRI appearances are not unique to ependymoma but they are most often iso/hypointense on T1 sequences, high signal on T2 sequences, and enhance avidly after contrast (Figs. 29.3 and 29.4). FIESTA (fast imaging employing steady state acquisition) sequences may allow more accurate resolution of cranial nerves and vascular structures, and both diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) mapping are now routinely used to identify high grade tumours. MRS may also be a useful with ependymomas showing a low NAA/Choline ratio somewhere between a PNET and a glioma. Calcification, cyst

Table 29.1 Summary of molecular pathology and genetics of ependymoma subtypes

Anatomic location	Group	Genetics	Histology	Age group
Supratentorial	ST-EPN-RELA	*RELA* fusion gene	Classic/Anaplastic	Infant -> adult
Supratentorial	ST-EPN-YAP1 ST	*YAP1* fusion gene	Classic/Anaplastic	Infant/child
Supratentorial	ST-SE	Balanced genome	Subependymoma	Adult
Posterior fossa	PF-EPN-A	Balanced genome	Classic/Anaplastic	Infant
Posterior fossa	PF-EPN-B	Genome-wide polyploidy	Classic/Anaplastic	Child -> Adult
Posterior fossa	PF-SE	Balanced genome	Subependymoma	Adult
Spinal	SP-EPN	*NF2* mutation	Classic/Anaplastic	Child -> Adult
Spinal	SP-MPE	Genome-wide polyploidy	Myxopapillary	Adult
Spinal	SP-SE	6q deletion	Subependymoma	Adults

formation, and haemorrhages may also be seen. A particular imaging feature, which is strongly suggestive of ependymoma is when the tumour fills the lateral recesses of the fourth ventricle or may even extend out through the Foramina of Luschka and Magendie into the cerebellopontine angle (CPA) and spinal canal, respectively. High dose steroids are highly beneficial in the pre and peri-operative management to reduce brain swelling particularly when hydrocephalus is present. Patients with infratentorial tumours often present with symptomatic hydrocephalus and the initial decision for the surgeon is how to manage this. At present there does not appear to be any significant consensus/advantage over which method is used to treat the hydrocephalus. Endoscopic third ventriculostomy, external ventricular drainage, and shunting all have their proponents, as do surgeons who advocate tumour resection without a preresection cerebrospinal fluid (CSF) drainage procedure. Given only a small percentage of cases will develop postoperative hydrocephalus a preop shunt is the least practised option.

The optimal surgical approach utilized is dependent on the tumour location. Infratentorial tumours may be accessed via a standard midline suboccipital craniotomy/craniectomy and for more lateral tumours a retromastoid craniotomy/craniectomy may be used. If a preresection CSF drainage procedure has not been undertaken the surgeon might initially create a posterior burr hole and insert an external ventricular drain (EVD) immediately before undertaking the craniotomy. Many neurosurgeons use a telo-velar approach to access 4th ventricular tumours to avoid/minimize damage to the vermis, to try and reduce the risk of posterior fossa mutism/syndrome.

The aim is always to achieve gross total resection given its massive importance in prognosis and outcome. Ependymomas are frequently adherent to the brainstem and cranial nerves in the CPA and avoiding damage to these structures can challenge even experienced surgeons. It is therefore no surprise that the use of intraoperative neurophysiology and ultrasound are increasing, in hopes that a more complete resection is achieved and neurological morbidity is minimized. Following the operation it is essential to obtain an MRI scan within 24 hours to accurately document the extent of the resection, as this influences both the treatment paradigm and the outcome. The use of intraoperative MRI helps to immediately identify if residual tumour is present. If resectable tumour is identified on the post-op scans the surgeon should be prepared to re-operate and attempt total resection. The increasingly aggressive surgical strategies employed to achieve total resection of the tumour do come at a price and there are often significant neurological deficits, which may result in the need for tracheostomy and gastrostomy. Despite this aggressive approach less than 50% of all paediatric ependymomas are able to be completely resected.

Consistent treatment paradigms in the management of ependymomas have proven difficult to establish due to several factors: its uncommon occurrence; inconsistencies in pathological tumour grading; and the resultant difficulties of comparing outcomes between different groups of patients. Most studies have been retrospective. This introduces an element of bias, particularly when it involves small numbers of patients accrued over long periods of time, during which treatment modalities and classification criteria may alter. The significant positive elements, which have most influenced ependymoma management, are the importance of the extent of surgical resection, improved surgical treatment, and widespread access to MRI imaging.

The overall management of intracranial ependymoma is controversial but includes surgery combined with radiation and chemotherapy. Poor 5-year survival results leads to a lack of uniformity in treatment protocols. Local relapse is the primary cause of treatment failure. The decision to treat the patient with radiation and or

Box 29.1 Key points

- Ependymomas are primarily tumours of childhood
- The majority occur in the posterior fossa
- Complete surgical resection is the single most important factor in prognosis
- Significant difficulties exist in histological differentiation between classic and anaplastic subtypes
- Conformal adjuvant radiation therapy increases survival after surgery
- Chemotherapy is used primarily in children under 3 to control disease and delay need for radiation therapy
- Most tumours relapse locally
- Overall 5-year survival is 36–64% in children

chemotherapy is based on several factors; age of the patient, tumour grade, extent of resection, and the presence of metastatic disease. There is a consensus that those patients who are treated with radiation therapy have better event free survival than those treated with chemotherapy and therefore radiation therapy is considered to be mandatory adjuvant therapy except in those children less than three years of age (Shuman et al., 1975; Mork and Loken, 1997).

Cranio-spinal radiation (CSI) was, for a considerable period of time, the standard adjuvant therapy as for medulloblastoma until it became apparent that with ependymomas the presence of disseminated disease at presentation and at relapse was much less frequent than originally appreciated. CSI has now been replaced by conformal radiotherapy, which uses 3D imaging and software to optimize dose delivery (Merchant et al., 2004; Merchant et al., 2009) unless metastatic disease is present.

A range of different radiotherapy paradigms is now available which include: hyperfractionated accelerated radiotherapy, IMRT (intensity modulated radiotherapy), LINAC, SRS (stereotactic radiosurgery), and proton beam radiotherapy. Continuing active debate persists as to the optimal format and dose. Newer methods of radiation therapy, particularly proton beam, by reducing the dose to surrounding structures, aims to reduce side effects, which is critical in children while continuing to deliver a lethal dose to the tumour/tumour bed. At the heart of all radiation strategies is minimizing the collateral damage while delivering a lethal dose to the tumour bed to reduce recurrence of the tumour. In children less than 3 years old or those with metastatic disease, a number of different strategies are available, primarily chemotherapy based, to try and control the disease and delay radiation therapy until the child has reached an age where radiation can be considered (Zacharoulis and Moreno, 2009). However, studies looking at radiation therapy in children under 3 years old have shown reasonable progression free survival with good functional outcome and this treatment may be one which becomes more prevalent in the future (Merchant et al., 2004). Radiosurgery is currently only utilized in the context of relapsed disease but may in the future be used together with conventional radiotherapy paradigms.

The role of chemotherapy is much less clear and there are a multitude of different regimens and drugs used (Bouffet and Foreman, 1999). It has not been shown to greatly affect the clinical course of ependymoma either singly or in combination. Its main role is in delaying radiotherapy in small children and it also has a smaller role in facilitating the resection of residual tumour.

Prognosis

The overall prognosis for ependymoma depends on a number of factors the most critical of which is the extent of surgical resection (Healey et al., 1991). Most studies have shown that the prognosis of patients with totally resected tumours is substantially higher in all age groups compared with those patients whose tumours are subtotally resected (Bouffet et al., 1998; Merchant, 2002).

In children, aged below 3, incomplete tumour resection, presence of metastases at presentation and anaplastic histology are all considered to be poor prognostic indicators. In older patients important prognostic factors include age, presence of metastases, location (posterior fossa vs. spinal) and histological subtype (myxopapillary vs. anaplastic). Once relapse occurs there is no hope of a cure and the focus of management is on disease control (Pollack et al., 1995; Robertson et al., 1998).

Multiple further surgical procedures to effect local disease control can be very effective palliative treatment. Reirradiation is also becoming a viable treatment option with marked improvement in short-term survival with suggestions of altered tumour oncological potential (Bouffet et al., 2012).

A range of different strategies of oncological therapy for relapsed ependymoma are also available though there is little evidence that these are effective.

Controversies

Proton beam vs. radiotherapy

The more recent availability and increasing use of proton beam radiotherapy may also yield more improvement in overall outcome. Proton beam radiotherapy delivers an equivalent dose of radiation of equal efficacy to standard photon-based treatment with a lower dose to surrounding structures. The major perceived advantage of proton bean radiation therapy is reduced incidence of radiation-induced side effects, which in the paediatric population may significantly reduce long-term morbidity (MacDonald et al., 2008). Radiosurgery is currently only used in the context of relapsed disease but may, in the future, be used together with conventional radiotherapy paradigms. Unfortunately, both proton beam and radiosurgery are not yet fully assessed with only one significant clinical trial reported which showed reduced systemic complication rates in children treated with craniospinal proton beam radiotherapy (Yock et al., 2016).

Haemangioblastoma

Ammar Natalwala and Donald MacArthur

History and epidemiology

Haemangioblastomas (HBLs) are uncommon, highly vascular, and benign tumours that account for 1 to 2.5% of all intracranial tumours. This specific tumour entity was first described in 1872 by Hughlings and Jackson, while the term 'haemangioblastoma' itself was coined by Cushing and Bailey in 1928 to describe vascular tumours of the CNS which had previously been known as 'vascular gliomas'. This description differentiated these tumours from CNS telangiectasia or cavernous and venous angiomas (Weil et al., 2003). In 1895 the German ophthalmologist Eugen von Hippel had presented a first case of angiomatosis retinae and in 1926, the Swedish pathologist Arvid Wilhelm Lindau described the clinical syndrome (now known as Von Hippel-Lindau syndrome or VHL) that combined retinal angiomas and cerebellar HBLs. He described CNS haemangioblastomas based on a series of criteria including 'unmistakable neoplasticity' with 'composition of blood vessel elements' and a 'tendency towards cyst formation' (Hussein, 2007).

Approximately 30% of CNS HBL cases are associated with VHL, whereas 70% occur sporadically. VHL disease is clinically heterogenous with the other associated tumours being retinal angiomas, renal cysts, renal cell carcinomas (RCC), pancreatic tumours, phaeochromocytomas, endolymphatic sac tumours of the middle ear, and epididymal cysts (Bründl et al., 2014). CNS HBLs, in association with VHL, are diagnosed at a younger age compared to spontaneous HBLs (i.e. they present in the second and third decade of life versus fourth and fifth decades).

Clinical presentation

Symptomatic tumours usually present due to compressive effects from the tumour or occasionally due to haemorrhage within it or paraneoplastic effects (such as polycythaemia). The mean time to diagnosis has been reported from 7 weeks to 13 months but this can vary depending on the type of HBL and is usually shorter in cases of VHL. These tumours have solid and cystic components and it is generally the cystic HBLs that cause more compressive symptoms. Solid HBLs may grow slowly and patients can remain asymptomatic for many years. Asymptomatic HBLs in patients with VHL are frequently detected by imaging surveillance.

Headache is the main symptom in 95% of cases involving cerebellar and brainstem HBLs. Vomiting, ataxia, vertigo, diplopia, and nystagmus are the next most common symptoms. Less commonly, patients present with neck pain, nausea, dysarthria, or cranial nerve deficits. Patients with spinal HBLs often have long tract signs with pain and associated syringomyelia in 50% of cases (Hussein, 2007). Spinal HBLs are more common in younger men and are usually thoracic and intramedullary. Despite being slow growing tumours, HBLs can cause life-threatening complications (Richard et al., 2000). For example, patients can present with obstructive hydrocephalus depending on the size and location of the tumour and spontaneous massive haemorrhage has been reported.

As a paraneoplastic effect, HBLs are the only brain tumours associated with polycythaemia (seen in 9–20% of intracranial tumours, but not in spinal lesions) due to the unregulated secretion of erythropoietin (EPO) (Hussein, 2007). The molecular genetics involved in this process are discussed later in this chapter.

Pathology

Location

HBLs can occur anywhere in the CNS but have a preponderance towards infratentorial structures and represent 7.5% of all adult posterior fossa tumours and 4% of adult spinal cord tumours (Bründl et al., 2014). **Figure 30.1** outlines the common locations for HBLs overall and in patients with VHL. Infratentorial HBLs are often found at the dorsum cerebelli, obex, and dorsal root entry zone of the spinal cord. Supratentorial HBLs are rare. A systematic review by Mills and colleagues investigated 132 such cases and found 60% had VHL disease (Mills et al., 2012). Other locations for HBLs include spinal nerve roots where the tumour can be intradural extramedullary, extradural, or a combination of these. They often have an intrafascicular origin and thus cannot be completely resected without sacrificing the nerve root. HBLs outside the CNS have also been reported in the literature including within the orbit, intestine, and retroperitoneum.

Radiological and macroscopic appearance

HBLs are usually well circumscribed and do not always have a true capsule. Thus, they can sometimes infiltrate adjacent brain

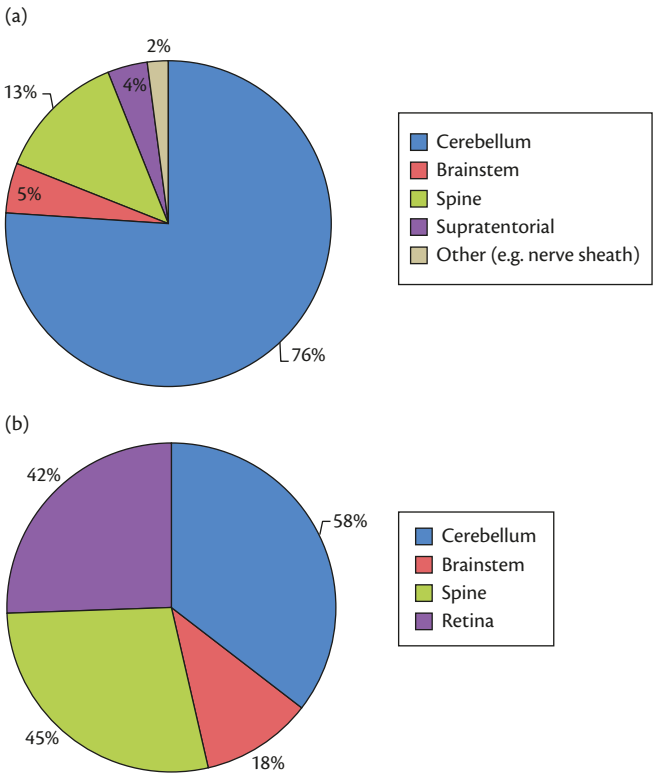

Fig. 30.1 (A) The most common locations of HBLs overall in the CNS and (B) the distribution of HBLs in patients with VHL (tumours often found in more than one location).

Percentages are based on averages from reports in the literature (Ammerman, 2006; Gläsker, 2005; Hussein, 2007; Kanno, 2014; Padhi et al., 2011).

parenchyma. They avidly enhance on postcontrast CT and T1-weighted MRI. T2-weighted images and fluid-attenuated inversion recovery (FLAIR) sequences are used to investigate peritumoural oedema around cysts associated with HBL (Wind and Lonser, 2011). Sun and colleagues report distinct radiologically different groups of HBLs; cystic with an enhancing large cyst and tumour nodule, non-enhancing cyst wall but evenly enhanced tumour nodule, solid HBL comprising of multiple small solid tumours and solid tumour with single or multiple cysts (Sun et al., 2015). These are outlined in Figure 30.2. Knowledge of these subtypes may aid diagnosis based initially on radiological imaging.

Cystic HBLs are often found in the cerebellum and on cross-section they are comprised of yellow xanthochromic or grey proteinaceous fluid and a dense red coloured mural nodule, usually 0.5 to 2.5 cm in diameter (Richard et al., 2000). The formation of cysts in HBL can be intra- or peritumoural (Hussein, 2007). Studies report intratumoural cyst formation occurs mainly due to intratumoural necrosis, whereas peritumoural cysts develop as a result of a tumour interstitial process that generates oedema (Jagannathan et al., 2008). Cystic HBLs without a mural nodule visible are rare, solid HBLs and those with internal cysts are often found in the spinal canal (Richard et al., 2000).

Solid tumours tend to be larger, more vascular, and more commonly involve the brainstem. The main growth pattern for HBL is described as 'saltatory' growth that is characterized by periods of quiescence (2.1 ± 1.6 years) and interspersed periods of rapid growth (1.1 ± 1.3 years). Lonser et al. also reported linear and exponential growth patterns in HBLs associated with VHL (Lonser, 2014).

Histology

HBLs are benign, WHO grade I tumours (Fig. 30.3). They are highly vascular, being composed of a rich capillary network with interspersed large, polyhedric lipid-laden stromal or 'Zwischenzellen' cells (Richard et al., 2000). Based on the relative proportion of these two components, HBLs may be divided into reticular (capillaries predominate) and cellular (stromal cells predominate) subtypes. Recurrence rates are reported to be higher in cellular subtypes (25%) compared to reticular (8%). There may be frequent mast cells (Hussein, 2007). The vascular spaces within the tumour are variably sized and may be poorly developed towards the centre of the lesion. The stromal cells are typically bland but there may be striking nuclear atypia which is thought to be degenerative in nature and is not prognostically important. Mitotic figures are infrequent. Foci of extramedullary haematopoiesis are seen infrequently and are likely to be due to production of EPO by the stroma cells. The brain adjacent to HBLs may show prominent gliosis which may be piloid, containing frequent Rosenthal fibres. This presents a diagnostic pitfall for the unwary, particularly in small biopsies, and should not be interpreted as evidence of a pilocytic astrocytoma.

Stromal cells are not a component of the normal CNS and the histogenesis of HBL remains controversial. They are thought to arise from haemangioblast progenitor cells. Stromal cells lack specific organelles or cell attachments and have been shown to differentiate into erythrocytes and vascular endothelial cells.

Pathologically, the key differential diagnosis of HBL is metastatic renal cell clear cell carcinoma, which is also common in VHL (Hussein, 2007). Other entities that can enter the differential include paraganglioma and angiomatous meningioma. In addition to the morphological differences, a panel of immunohistochemical stains, including CD10, D2–40, epithelial membrane antigen, inhibin-α, and S100, will usually allow a firm diagnosis to be reached.

Molecular tumour genetics and risk factors

VHL is inherited in an autosomal dominant manner (Asthagiri et al., 2010). It has more than 90% penetrance by the age of 65 years. The VHL gene is a tumour suppressor gene located on the short arm of chromosome 3 and widely expressed in fetal and adult tissue. It encodes the VHL protein (pVHL) which is an E3 ubiquitin ligase that targets hypoxia inducible factor alpha (HIF-α) and as such regulates the expression of many hypoxia induced genes including those responsible for angiogenesis (vascular endothelial growth factor or VEGF) and erythropoiesis (EPO). The pVHL can also stabilize other binding proteins leading to HIF-independent activity such as extracellular matrix regulation, apoptosis, microtubule stability, cilia formation and gene transcription and in these respects is considered to be involved in tumour suppression (Hsu, 2012). The expression of VEGF protein induces recruitment of abundant reactive vascular cells into the tumour and therefore seems to be responsible for the hypervascularity of these lesions (Hussein, 2007).

VHL patients harbour germline mutations or deletions of one copy of the VHL gene. It is believed that familial tumours arise from cells where a somatic mutation of the wild-type VHL gene leads to biallelic inactivation (Gläsker, 2005). VHL gene mutations are also found in a fraction of sporadic HBLs (10–44%). Shankar et al found

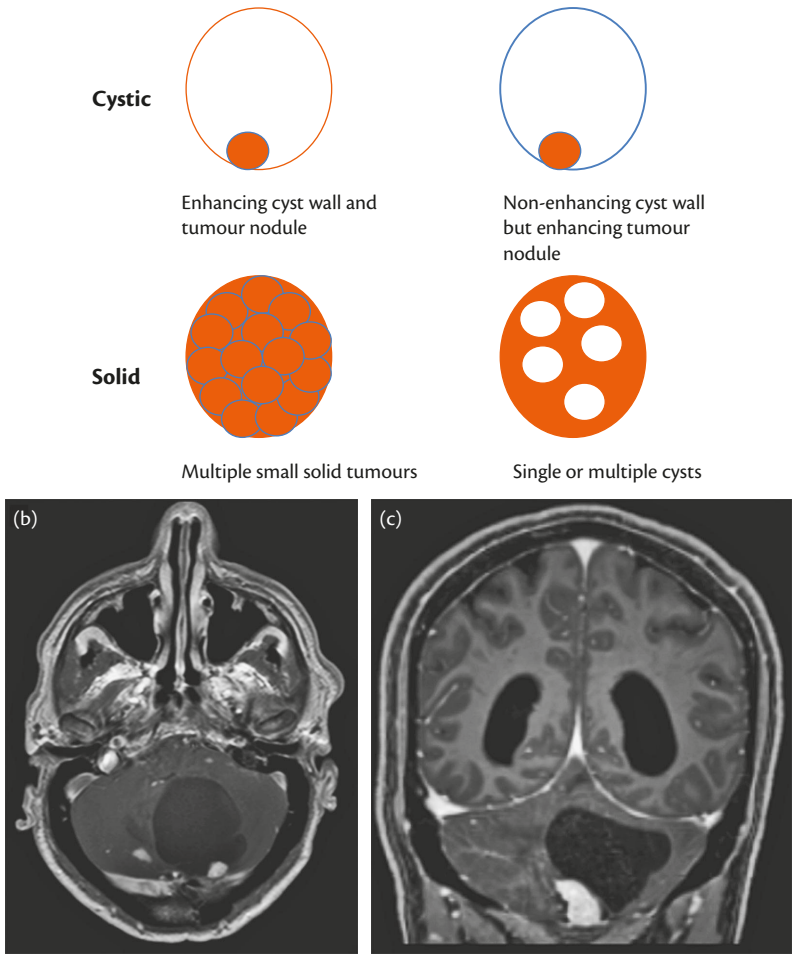

Fig. 30.2 (A) Diagram depicting different morphological subtypes of HBL and appearance on contrast enhanced MRI imaging (based on description reported by Sun et al., 2015). (B and C) Axial and coronal images, respectively, showing typical MRI appearances (T1 postcontrast) of posterior fossa HBLs in a 52-year-old man with known VHL. Image B shows an enhancing mural nodule on the left and associated cyst (non-enhancing cyst wall) as well as a solitary nodule adjacent to this on the right (as well as other smaller nodules).

a markedly high prevalence of recurrent somatic mutations (50%) and loss of heterozygosity (LOH) of the gene locus on chromosome 3p (72%). Together, these alterations accounted for biallelic inactivation of VHL in 47% and an inactivating alteration in at least one allele in 78% of sporadic HBLs (Shankar et al., 2014). Genotype–phenotype studies have identified several different VHL subtypes with different tumour profiles and this is discussed in more detail in a separate chapter.

Treatment

Current treatment options for HBL include surgery to resect the tumour with or without preoperative endovascular embolization, stereotactic radiosurgery (SRS), and radiotherapy. Complete surgical resection is the mainstay of treatment and for accessible tumours can be curative with minimal morbidity and mortality (Hussein, 2007). The optimal timing of treatment is uncertain, however, if there is progression of neurologic symptoms, evidence of tumour or cyst growth, or haemorrhage then intervention is considered by most neurosurgeons.

Surgery

HBLs, in particular the solid type, are often compared to arteriovenous malformations (AVMs) and the surgical principles involved to obtain complete resection without significant bleeding are similar. Surgeons should avoid entering into the tumour or attempting biopsy as piecemeal resection can lead to problematic bleeding (Hussein, 2007). Surgical resection is more straightforward in HBLs following the margins of gliotic tissue, with a wide exposure, circumferential dissection, and *en bloc* removal. As with AVMs, the feeding artery should be occluded prior to occlusion of the draining veins to avoid bleeding secondary to venous outflow obstruction in a hyperdynamic circulation. Multiple feeding arteries are often present as well as more than one abnormally thick draining vein which can make it difficult to differentiate vessels. The mural nodule in cystic HBLs which will usually be identifiable by its reddish or orange colouration must be removed completely in order to prevent recurrence. An attempt may be made to remove an enhancing cyst wall; but Gläsker has suggested that often a non-enhancing cyst wall represents simple reactive gliosis without tumour cells, and it can be left untreated (Gläsker et al., 2010). Depending on location, some solid HBLs may require extended

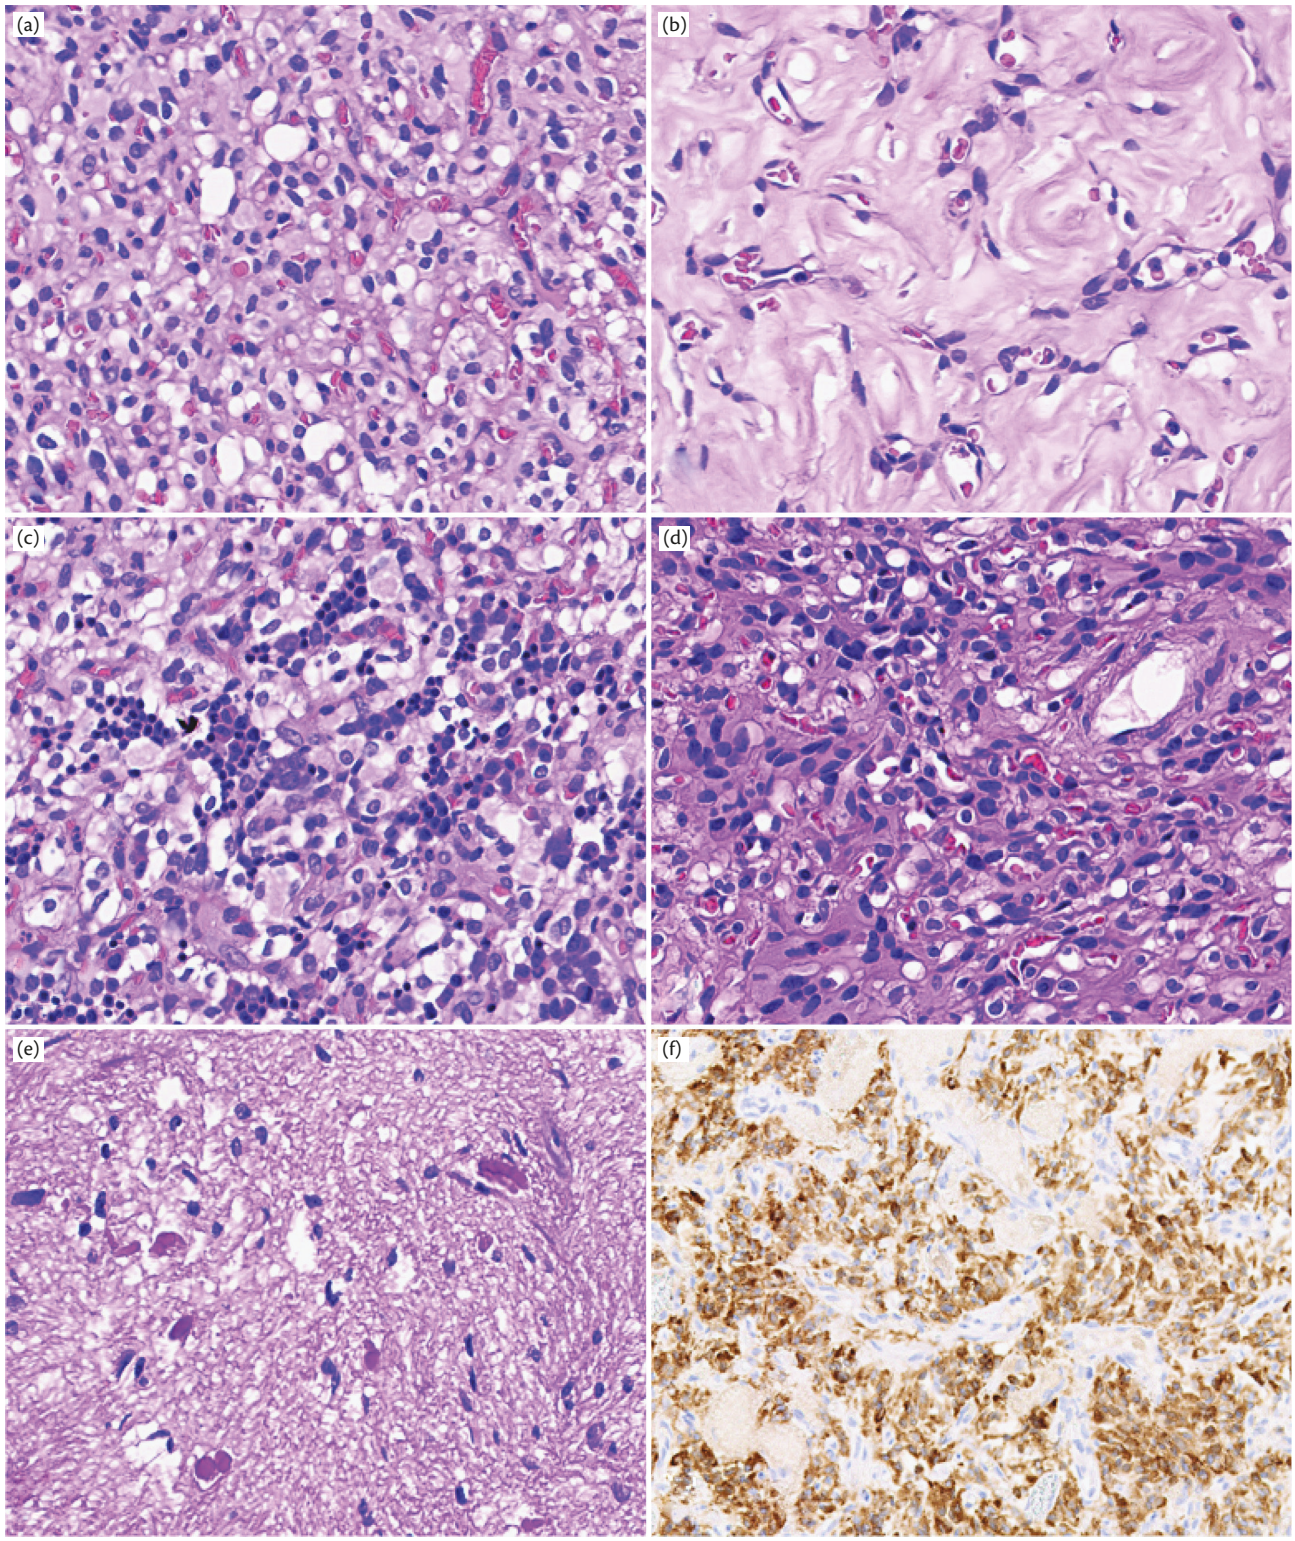

Fig. 30.3 (A) HBL (WHO grade I) is composed of capillaries and stromal cells with variably vacuolated cytoplasm (H&E, objective ×20). (B) The proportion of the two components can vary markedly and it is not unusual to see collagenized, paucicellular areas (H&E, objective ×20). (C) Foci of extramedullary haematopoiesis, thought to be due to production of EPO by the stroma cells, can be seen and may be associated with secondary polycythaemia (H&E, objective ×20). (D) Nuclei atypia, which is presumed to be degenerative, may be striking but is of no prognostic significance (H&E, objective ×20). (E) There may be piloid gliosis, with prominent darkly-stained Rosenthal fibres, in the adjacent brain (H&E, objective ×40). (F) Stromal cell immunoreactivity for inhibin-α is helpful in distinguishing HBL from mimics such as metastatic renal cell carcinoma (anti-inhibin-α immunohistochemistry, ×10). Thank you to Dr Simon Paine (Consultant Neuropathologist, Nottingham University Hospitals) for providing histopathology advice and images.

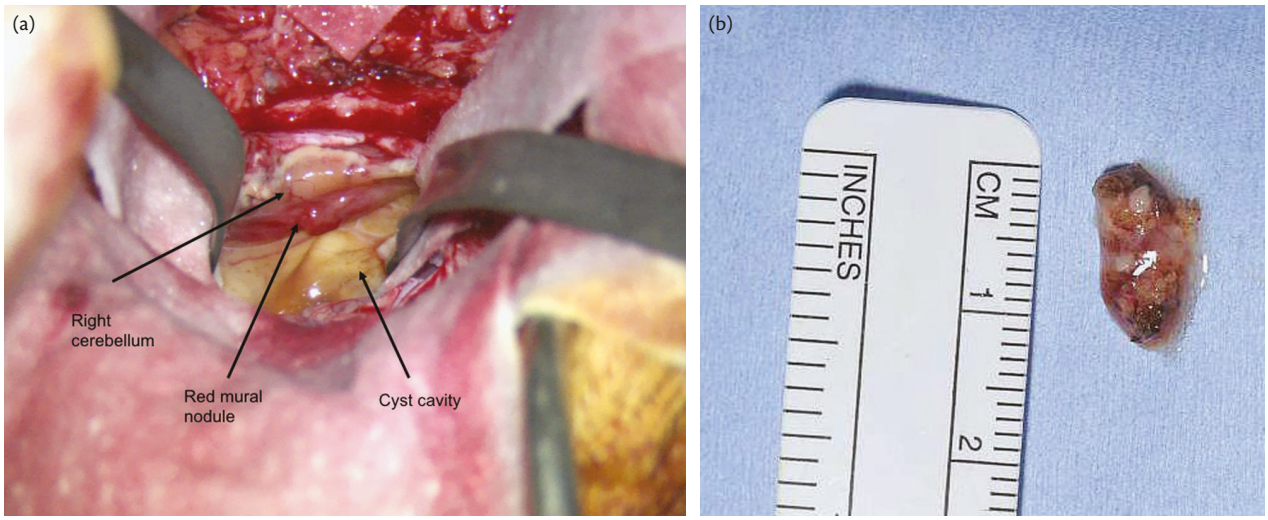

Fig. 30.4 (A) Intraoperative image showing the mural nodule within an opened cyst cavity in the right cerebellum. (B) The mural nodule was resected *en bloc*.

skull base approaches (Dow et al., 2002). The most common surgical approaches include midline suboccipital and retromastoid craniotomies, with or without a C1 laminectomy. Particular care must be taken with brainstem HBLs as they have a subpial attachment and attempts to resect can lead to heavy bleeding and CNS injury (Hussein, 2007). Electrophysiological monitoring may have a role in resection of HBLs of the brainstem, cerebellopontine angle (CPA), and spine. Figure 30.4 shows the intraoperative appearance of HBL.

Some groups advocate preoperative embolization to facilitate surgery by reducing the vascularity of HBLs and subsequent intraoperative bleeding, although these procedures themselves carry a risk of haemorrhage, infarction, and swelling causing secondary hydrocephalus. A range of embolic agents are available but liquid agents such as N-butyl cyanoacrylate (NBCA) and Onyx have the best durability and penetration and are often the methods of choice. However, these agents can migrate and inadvertently cause venous obstruction and thus infarction or haemorrhage (Shin et al., 2014). Cornelius and colleagues report this to be more frequent in cerebellar HBLs (43%) compared to brainstem or spinal HBLs (5.6%) (Cornelius et al., 2007). Figure 30.5 shows pre- and postembolization angiograms of a treated HBL.

Intraoperative indocyanine green videography has been reported as a useful adjunct to surgery by some authors to identify tumour related blood flow and target feeding vessels more easily. Similarly, intraoperative ultrasound has been recommended to help find the

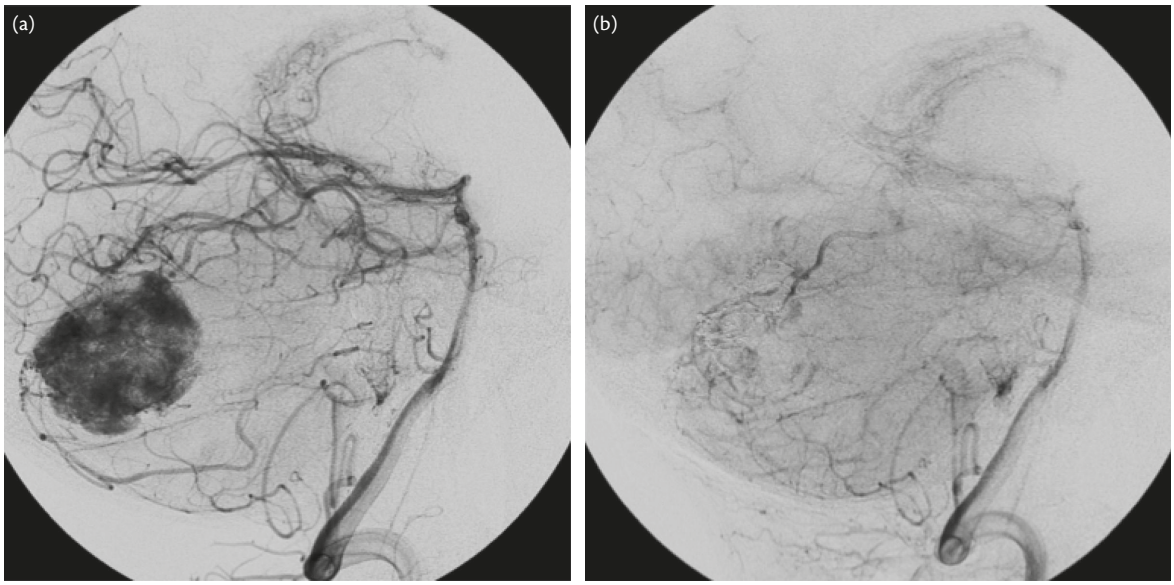

Fig. 30.5 Preoperative endovascular treatment of a left cerebellar HBL in a 53-year-old patient. The medial component of the tumour was supplied by the right posterior inferior cerebellar artery (PICA) and lateral component by left superior cerebellar artery (SCA). (A) A vascular blush is seen postcontrast injection pre-embolization. (B) The distal vermian branch of the right PICA was occluded using NBCA and the postembolization image shows reduced vascularity of the tumour. Thank you to Dr Robert Lenthall (Consultant Interventional Neuroradiologist, Nottingham University Hospitals) for providing interventional radiology advice and images.

plane between tumour and brain parenchyma or the spinal cord particularly in HBLs with a poorly defined outer capsule.

Non-surgical treatment

When surgery is not possible, other treatment options including SRS, radiotherapy, and other salvage systemic treatments may be used.

SRS is generally preferred for recurrent and multiple HBLs or when they are in eloquent or high-risk areas with a low chance of achieving gross total resection. It can often be difficult to know which lesion (if multiple) is causing the symptoms. The presence of a cystic component probably negatively impacts on control rates (Matsunaga et al., 2007). Kano et al. recently reported outcomes for 186 patients with 517 HBLs who underwent SRS across 19 centres in North America and Japan with 15–18 Gray (Gy) dosing (Kano et al., 2015). At a median 5 years follow-up, 20 died of intracranial disease progression and nine of other causes. Factors predicting longer survival were younger age, absence of neurological symptoms, fewer tumours, and higher Karnofsky Performance Status (KPS). Tumour control rates were 89% at 5 years and 79% at 10 years. Some 41% of VHL-associated HBL patients had new tumour recurrences and 16% of the sporadic cases had recurrence at the original tumour site with the specific 5-year recurrence rate being 43% versus 24% in VHL-associated and sporadic HBL, respectively. Thirteen patients (7%) had adverse radiation effects with one patient dying due to this. SRS has also been reported as a preoperative adjunct to significantly reduce vascularity permitting safe resection (Kamitani et al., 2004).

External beam radiotherapy (EBRT) has also been used to treat HBLs. One study investigated the use of EBRT over 20 years in HBL and found local control rates of 57% in fractions totalling 50 Gy versus 33% when less than 50 Gy was delivered (Smalley et al., 1990). Simone et al. explored the effect of infratentorial craniospinal irradiation for advanced HBL associated with VHL; seven patients with 84 HBLs were treated (43.2 Gy in 24 fractions). After treatment, the mean tumour volume was increased by 25% and the total number of tumours also increased to 91 (8.3% more). However, the overall tumour growth rate was lower than reported for the natural history of HBL. Mean follow-up time was 73.8 months (Simone et al., 2011).

Salvage systemic therapy has been tried for patients with recurrence despite surgery and irradiation. Capitanio et al. describe treatments including chemotherapy agents (interferon-alpha-2a or IFN-2a), tyrosine kinase inhibitors, selective VEGF inhibitors, monoclonal antibodies (bevacizumab), and thalidomide. These data are based on case reports and phase II trials, showing stabilization of CNS HBLs and improvement in symptoms but without any change in radiological appearance. Further studies will be needed to elucidate a role for antiangiogenic agents in treatment of HBLs (Capitanio et al., 2013).

Screening for VHL

The presence of more than one haemangioblastoma, early age at diagnosis or the presence of other manifestations of VHL disease should all serve as indications for genetic screening for germline VHL mutations. As well as whole CNS imaging, abdominal ultrasound, or MRI, 24-hour urine for catecholamines, and retinal imaging with ophthalmoscopy and fluorescein angiography is required. The Melmon and Rosen diagnostic criteria for VHL require the presence of one retinal, CNS, or visceral lesion if there is a family history of VHL. Without a family history the requirement includes two CNS HBLs or one CNS HBL and one visceral lesion excluding unilateral papillary cystadenoma of the epididymis and renal cysts which are common findings in the general population or papillary cystadenoma of the broad ligament.

Prognosis

General recurrence rates for HBL are reported between 20% and 33%. The clinicopathological factors that positively correlate with recurrence of these tumours include younger age (<30 years at time of diagnosis), presence of multicentric tumours of the CNS at initial diagnosis, tumours with lower frequencies of cyst formation and lower proportions of lipid-laden stromal cells (Hussein, 2007). Solid HBL tumours also had higher rates of recurrence. VHL patients develop new CNS HBL during follow-up at a rate of having a new tumour every 2.1 years (Conway et al., 2001). Propensity for new tumour growth is far higher in VHL compared to sporadic cases (93% vs. 44%, respectively). While HBLs are considered to be benign tumours, the tumour cells can migrate causing recurrence in distant parts of the brain.

Cerebellar HBL has a good prognosis following complete resection where survival at 5 years is more than 50% (Sun et al., 2015). Following complete resection, it is unlikely HBLs will recur and so chemotherapy and radiotherapy are rarely used postoperatively. Weil et al. in 2003 reported 12 cases of brainstem HBLs that underwent surgical resection and found that fewer preoperative neurological symptoms predicted better postoperative outcome. Tumour and cyst size did not affect outcome. All 12 patients were better or neurologically stable postoperatively and at long-term follow-up (>36 months) only 1 of the 12 had deteriorated.

Surgical outcomes reported by Jagannathan et al. in 2008 for HBL patients with VHL show 88% stability or improvement in symptoms postoperatively with 12% having new cerebellar signs that resolved over an average of 9 days. Long-term follow-up (median 84 months) showed that 7.5% worsened and 10% died. Hydrocephalus resolved in 94% and 6% needed a shunt. Mills and colleagues reported five-year progression-free survival (PFS) for gross total resection (GTR) and subtotal resection (STR) to be 100% and 53%, respectively, for supratentorial HBLs. GTR had been possible in 77% of the cases.

A recent single-centre study focussing on spinal HBLs examined 92 cases over 5 years (60 sporadic and 32 VHL-associated) that underwent 102 operations to resect 116 HBLs. Forty-one per cent were intramedullary tumours and GTR was achieved in 94%. Forty-one per cent had functional improvement, 44% remained stable, and 15% deteriorated. Mean follow-up time was 50 months. The main risk factor predicting outcome was STR. Seventy-seven per cent of patients had an associated syrinx that reduced postoperatively in 83% following tumour resection. Ventral and intramedullary tumours did worse overall in terms of clinical outcome (Deng et al., 2014).

In SRS, 5-year PFS for all CNS HBLs ranged from 63% to 85%. Other studies report 5-year tumour control rates between 71% and 96% for SRS but radiation necrosis can be a serious side effect particularly in the brainstem (Rachinger et al., 2009). Local control rates for SRS drop to 61% at 10 years and 51% at 15 years (Wind and

Lonser, 2011). Kano et al. (2008) report overall survival after SRS to be 94% at 3 years, 90% at 5 years and 74% at 10 years, and local tumour control rates of 92%, 89%, and 79%, respectively. Factors improving local control were VHL-associated HBL, solid and small tumours, and a higher margin dose. Thirteen patients (7%) had adverse radiation effects and one died as a result.

PFS for fractionated radiotherapy for all CNS HBLs ranges from 33% to 90.5% with better outcome attributed to high-dose radiotherapy (57% PFS vs. 33%; fractions ≥50 Gy vs. <50 Gy, respectively) (Mills et al., 2012). Koh et al. report 5-year PFS rates of 80% for VHL-associated HBL and 48% for sporadic HBL in patients received EBRT (Koh et al., 2007).

Reported mortality rates range from 4% to 8% (Conway et al., 2001; Padhi et al., 2011; Bründl et al., 2014). Ten-year outcome data by Bründl and colleagues shows 83% GTR and 17% STR with 75% of these patients having improvement or no change in symptoms after surgery. Their postoperative complications include bleeding (17%), hydrocephalus requiring shunting (4–11%), CSF infection (13%), ischaemia (8%), CSF leak (8%), new diplopia (4%), new hemiparesis (4%), bulbar syndromes, and tetraparesis (8%). Brainstem HBLs have the most unfavourable prognosis (Bründl et al., 2014). San Pedro and colleagues looked at 44 cases of HBL and report that spontaneous macroscopic bleeding is rare compared to asymptomatic microscopic intratumoural haemorrhage. Tumour size, spinal radicular location, and solid subtype of HBLs were associated with higher rates of bleeding. Gläsker et al. report HBLs less than 1.5 cm in diameter to have virtually no risk of bleeding.

Controversy

Age limit for screening for VHL with a single haemangioblastoma

In the absence of an existing family history of VHL, factors favouring a diagnosis of VHL in a patient with a newly diagnosed HBL are younger age of onset (mean age 29 for VHL-associated HBL versus 48 for sporadic HBL; see Maher, 2011), HBL outside the cerebellum (very unusual in sporadic cases but seen in up to 50% of VHL cases), and multiple HBLs (seen in up to 90% of VHL cases, and enabling a clinical diagnosis of VHL).

Some 97% of VHL patients will have presented by age 60 (Maher et al., 1990) but nonetheless, a first diagnosis of VHL has been made at 73 years of age (Kanno et al., 2014). Most authorities now suggest, in keeping with the French VHL study group (Richard et al., 1998), that all patients with apparent sporadic HBL should be investigated for evidence of VHL disease. The frequency of VHL gene mutations in patients presenting with an apparently isolated HBL is reported to be 4–14% (Catapano et al., 2005). However, somatic mosaicism particularly for a patient with a *de novo* mutation may mean that the mutation is not carried in the peripheral blood leukocytes resulting in a false negative genetic test (Butman et al., 2008). On this basis there is a case for keeping early onset HBL patients under close surveillance even if mutation analysis is negative. On the other hand, for older patients (>50 years of age) with negative initial investigations the risk of familial VHL disease appears small (Woodward et al., 2007) but still present.

SRS for haemangioblastomas

In a disease where HBLs are frequently multiple and may occur in the brainstem rather than just the cerebellum there are obvious attractions to a treatment which can avoid the need for multiple neurosurgical interventions and deal with lesions in inaccessible areas. However, the results of studies describing 'tumour control' need to be looked at critically in the context of a tumour which has a well-recognized saltatory growth pattern in the great majority of cases with periods of growth lasting on average 13 months and periods of quiescence lasting 2 or more years (Ammerman et al., 2006).

SRS for HBL is recognized as having a complication rate of 7–20% with adverse effects including worsened headaches due to peritumoural oedema which may necessitate prolonged corticosteroid administration or even surgery to resect the treated lesion (Asthagiri et al., 2010). The apparent early effects of SRS for HBL can be misleading in up to 25% (Asthagiri et al., 2010) with some tumours shrinking initially and then later progressing, while others may enlarge before regressing. The longer-term effects remain uncertain.

In contrast, for accessible lesions conventional surgery appears to offer excellent tumour control and almost immediate symptom control. Symptomatic HBLs should clearly be considered for treatment with surgery or if this does not seem feasible or acceptable to the patient, for SRS. Interventions such as SRS should be used judiciously for asymptomatic lesions found on screening scans. In one 10-year observational study, while 97% of HBLs grew radiologically, only 50% of them required treatment in this time for symptoms (Ammerman et al., 2006), while 45% of the tumours which ultimately became symptomatic over time and required treatment were not present at the time of first scan.

Surgical approaches to posterior fossa tumours

Jacques J. Morcos, Osaama H. Khan, and Ashish H. Shah

Introduction

Lesions of the fourth ventricle and foramen magnum can be difficult to manage surgically due to their proximity to critical brainstem structures. Understanding the anatomy of the fourth ventricle, lower cranial nerves, and basilar cisterns remains paramount for deciding surgical approaches to this location. Detailed preoperative workup and planning are necessary to minimize surgical morbidity and maximize tumour resection.

This chapter provides an overview of the relevant anatomy and surgical techniques for lesions in the posterior fossa, specifically the fourth ventricle the foramen magnum. We will split this chapter into two main sections: microsurgical approaches to the fourth ventricle and skull base approaches to the foramen magnum.

Preoperative planning for posterior fossa lesions

When presented with a lesion in the posterior fossa, a detailed understanding of the pathology and involved structures is fundamental. Preoperative imaging (CT/MRI) should be evaluated for proximity to cranial nerves, surgical accessibility, vascular involvement, and the presence of hydrocephalus. Any hydrocephalus may need to be addressed prior to surgery with a ventriculostomy or a ventriculoperitoneal shunt (Tamburrini et al., 2008). A ventriculostomy is placed if the obstructive hydrocephalus is expected to be reversible after tumour resection or if CSF diversion is deemed helpful in relaxing the cerebellum during the surgical approach. A ventriculoperitoneal shunt is selected if the hydrocephalus is unlikely to be reversible. If there is a suspicion of a hemangioblastoma or other vascular lesion, preoperative angiography may also be helpful. For some vascular lesions, to facilitate surgery preoperative embolization may be used, it is uncommon for hemangioblastomas to be amenable to embolization because their arterial feeders may be too fine for selective catheterization (Standard et al., 1994; Sakamoto et al., 2012).

Deciding on a surgical approach depends mainly on the size and location of the lesion. For lesions near the fourth ventricle, two main surgical approaches are used, the suboccipital transvermian and the suboccipital telovelar approach. The transvermian approach is less desirable because of the potential downside of disrupting intercerebellar tracts, and clearly requires a corticotomy in order to access the fourth ventricle. The approach may be preferred to reach the superior pole of the fourth ventricle, when the lesion has not created its own space and surgical corridor (Tanriover et al., 2004). In contrast, the telovelar approach may be more suited to lesions near the foramen of Luschka and Magendie, or in larger more cranially placed lesions that have created their own surgical path.

Anatomy of the fourth ventricle

Lesions within the fourth ventricle are especially challenging for neurosurgeons because there are few structures around the pathology that could be considered non-eloquent (Lassiter et al., 1971; Alvisi et al., 1985; Liu et al., 1998). A thorough understanding of the anatomy of the fourth ventricle is essential to approaching these tumours. Here we highlight some key aspects of the surgical anatomy of this region.

The most common surgical view of lesions in the fourth ventricle is from a midline posterior suboccipital approach. At the superior end of the exposure, the posterior cerebellar incisura forms a cleft between the cerebellar hemispheres, ultimately leading to the vermis. The portion of the vermian surface, dorsal to the roof of the fourth ventricle, is divided into two main portions, the pyramid, and the uvula (which lies in between the cerebellar tonsils). Just deep to the uvula, the fourth ventricle runs from the cerebral aqueduct to the foramen of Magendie. Rhoton divides the roof of the fourth ventricle into two main components, superior and inferior. The inferior portion of the roof of the fourth ventricle is composed of two separate layers (tela choroidea and inferior medullary velum). This inferior portion can be accessed through the superior portion of the cerebellomedullary fissure, a complex cleft that extends between the ventral surface of the cerebellum and the dorsal medulla. The inferior medullary velum forms a thin membrane that extends laterally from the nodule to the flocculus, the inferior medullary velum, and the nodule form the cranial aspect of the inferior half of the fourth ventricular roof, while the tela choroidea forms the

caudal end. The inferior medullary velum is contiguous with the superior medullary velum rostrally and the tela choroidea caudally.

The tela choroidea is an arachnoid membrane that transmits the vessels of the choroid plexus into the fourth ventricle. Both foraminae of Luschka and Magendie fenestrate the tela choroidea in the subarachnoid space. This anatomy becomes especially relevant when discussing the telovelar approach.

Operative technique

Suboccipital craniotomy

The midline suboccipital craniotomy is the mainstay surgical approach to lesions of the fourth ventricle and posterior fossa. We prefer the prone position and only use the sitting position in exceptional circumstances. A Mayfield cranial frame holder is used with the head flexed and translated posteriorly to allow for visualization of the pathology. Careful attention must be paid to ensure that the head is not flexed excessively to block jugular venous outflow. In the prone position, patients should be padded carefully to avoid pressure related injuries during these procedures, and the plane of the table is usually tilted head up approximately 10 degrees to promote venous drainage

Once the midline incision is made, we generally carry it from 2 cm above the inion to the level of the C2 spinous process. We are careful not to disrupt the pericranium above the inion as it may often be used as a dural patch during closure. Dissection in the deep subcutaneous plane is carried out laterally just below the level of the superior nuchal line. This is done with the specific aim of creating space to allow a transverse cut in the superior nuchal line and ensure a watertight muscular closure. The cuff does not need to be wider than 5–10 mm. It is not necessary and counterproductive to extend this separation between the deep subcutaneous tissue and the muscular epimysium all the way inferiorly as this dissection does not improve the eventual exposure and, worse, it creates dead space for a potential pseudomeningocele. Next, we look for the midline fatty avascular midline muscular raphe and incise it down to C1, creating a T-shaped mobilization of the musculature. We then place fishhooks symmetrically, retracting the muscles laterally and, very importantly, downwards. This compresses the muscles and skin edge down, therefore minimizing the depth of the exposure, an advantage that will be appreciated during the microsurgical portion of the case, when the angles of surgical freedom are maximized. Meticulous subperiosteal dissection is carried out along the posterior arch of C1. Monopolar cautery is never used here for the fear of injuring the V3 segment of the vertebral artery in the sulcus arteriosus. This off-midline region is best exposed through a repeating sequence of spreading and cutting the fascia with scissors, or cautiously using gauze at the tip of a periosteal elevator to improve frictional mobilization of the periosteum without shearing the vertebral arteries. Similarly, one needs to make sure prior to working along C1 that there are no congenital anomalies such as a bifid arch, for the fear of traumatizing the cord. The lip of the foramen magnum is then exposed with an angled curette. The craniotomy size and exact location varies with the pathology, but a typical bone flap is midline 3 × 3 cm in size, with additional drilling of the lip of the foramen magnum to each side towards the occipital condyle without reaching them. The bone flap can be created with one or rarely two small holes, or when the dura can be easily dissected, with no initial holes at all, but rather using the lip of the well dissected foramen magnum as a starting position for the foot plate of the drill. After the craniotomy is done, and depending if the lesion extends to below the foramen magnum, the arch of C1 is resected, again with special attention to the vertebral arteries and surrounding venous plexus. Venous bleeding is easily stopped with powdered gelfoam mixed with thrombin. In younger patients with less adherent dura, we generally place tack-up sutures to minimize the risk of a postoperative epidural hematoma. The dura is then open in a Y-shape, with the vertical limb slightly to one side of midline, in order to avoid troublesome bleeding from a sometimes sizeable occipital sinus. The latter can be controlled pre-emptively with vascular clips. CSF is obtained from the cisterna magna and then the microscope is brought into the field.

Telovelar approach

Once haemostasis is obtained and the dura tented, the tonsils may be gently mobilized laterally from the uvula to expose the inferior half of the fourth ventricular roof, the tela choroidea, and inferior medullary velum. This mobilization is not achieved by self-retaining retractors which we feel are generally counterproductive. Rather, the tonsils are freed up through extensive sharp arachnoidal lysis, including preservation and separation of the tonsillar loops of the posterior inferior cerebellar arteries (PICA). Careful dissection from the tela at the level of the foramen of Magendie to the velum allows visualization of nearly the entire fourth ventricle. Additional dissection through the inferior medullary velum superiorly can expose tumours within the superior part of the fourth ventricle and fastigium (Tanriover et al., 2004). The superior and middle cerebellar peduncles are at a high risk of injury when opening the velum superiorly as they form the lateral walls of the fourth ventricle at that level. As the dissection is carried out cranially, small arterial branches (choroidal) from PICA are divided to allow untethering of the cerebellum. The telovelar approach is generally performed on the same side as the larger part of the tumour. Once maximal dissection is carried out, and if necessary, then a self-retaining retractor can be placed to 'hold' (rather than 'create') the exposure attained, with the tonsil held up and laterally. This is also the point during the surgery when appropriate head flexion achieved during positioning is appreciated. **Figure 31.1** demonstrates the telovelar approach.

Transvermian approach

The transvermian approach to the fourth ventricle has been the more traditional approach to this region, involving transecting the inferior vermis. The vermian incision is intended to expose the nodule and underlying telovelar surface. A midline incision can be carried out through both the nodule and tela choroidea medially with careful attention to avoid injuring the telovelotonsillar segments of the PICA bilaterally. Adequate exposure in the transvermian approach allows visualization of the entire surface of the fourth ventricular floor, which is approximately 4 cm from the obex to the Sylvian aqueduct (Tanriover et al., 2004). However, the transvermian approach is limited in its exposure of the lateral recesses and foraminae of Luschka. Additionally, it involves undesirable neural incision.

When comparing the transvermian and telovelar approaches, there is some limitation with the telovelar approach in the operative angle to the rostral end of the exposure but the benefit of preserving critical cerebellar structures outweighs this slight operative nuisance. It has been proposed that the telovelar approach may produce

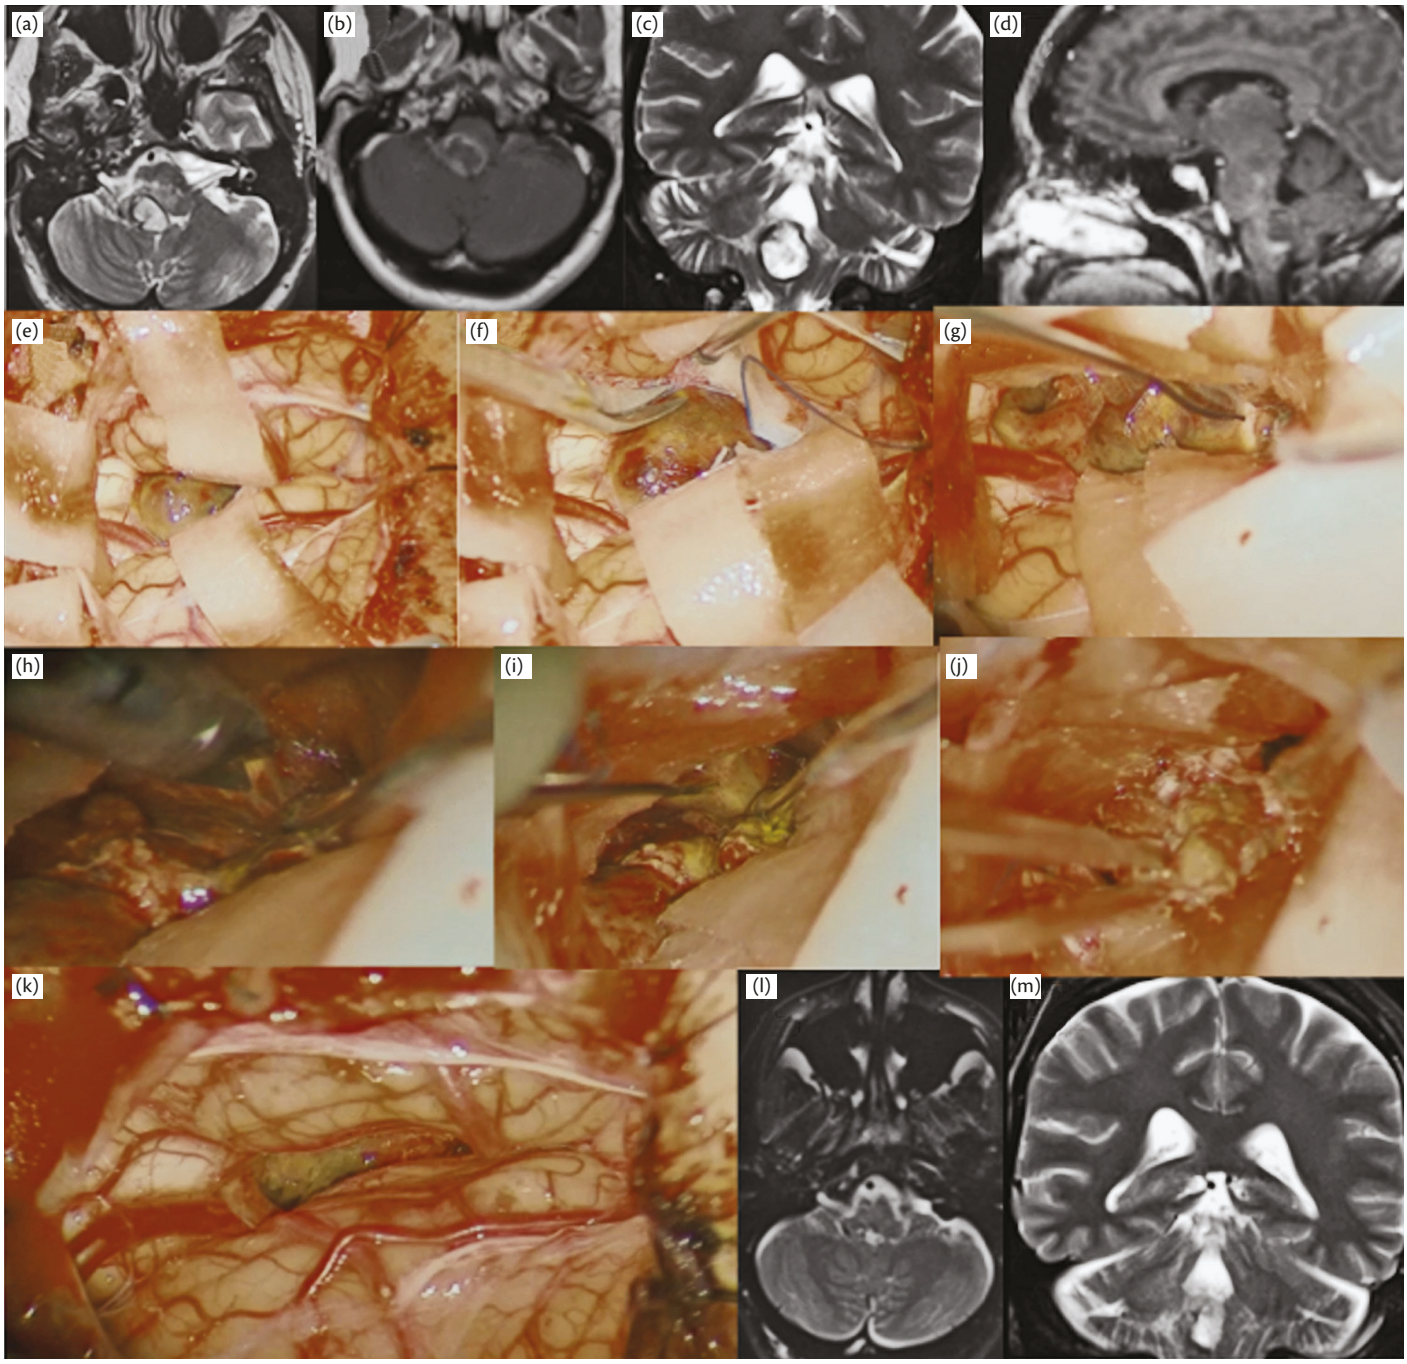

Fig. 31.1 Telovelar approach to a brainstem cavernous malformation. A 35-year-old female presented with a new onset dysphagia, diplopia, and right-sided dysmetria. An MRI (A—axial T2, B—axial T1 with contrast, C—coronal T2, D—sagittal with contrast) reveals a fourth ventricular cavernous malformation. A suboccipital craniotomy with wide dural opening (E) was performed through a right telovelar approach (E). The cavernous malformation can be appreciated protruding between the tonsils. The facial nerve stimulator is used not only to map out the facial colliculus (G) but also as a dissection tool (I). Sharp dissection (H) is used to remove the lesion (J) in its entirety (K). Postoperative axial (L) and coronal (M) MRI confirms complete removal of the malformation.

a lower incidence of cerebellar mutism and ataxia due to the preservation of the vermis and nodule (Tanriover et al., 2004; Deshmukh et al., 2006).

Tumours of the fourth ventricle

The telovelar approach to the fourth ventricle was first described by Matsushima in 1992 to avoid transecting midline cerebellar structures (Matsushima et al., 1992). Since then, the operative approach has become widely adopted to gain access to the lateral recesses and floor of the fourth ventricle. Nevertheless, its efficacy for large fourth ventricular lesions has been brought into question by some authors. Recently, Tomasello et al. reviewed the extent of resection of large fourth ventricular lesions and his group was able to achieve approximately 90% resection for most tumours (Tomasello

et al., 2015). Lesions near the foramen of Luschka and superolateral recesses such as ependymomas and choroid plexus papillomas were especially accessible using the telovelar approach (Lee et al., 2012; Tomasello et al., 2015). In large rostral tumours and those with brainstem involvement the efficacy of the telovelar approach was limited as the working angle was less favourable compared to the transvermian approach. Nevertheless, aggressive surgical resection should be mitigated in circumstances where there is clear brainstem infiltration or high-grade pathology (El-Bahy, 2005). Our philosophy is to use the telovelar approach as a default, and only add a small caudal vermian split if the exposure proves insufficient.

Anatomy of the foramen magnum

The foramen magnum (from the Latin, meaning 'great hole') is located at the base of the skull in the occipital bone. The dura, medulla oblongata, spinal branches of the accessory nerve, vertebral arteries, posterior spinal arteries, and the apical ligament of the dens and tectorial membrane pass through it.

The hypoglossal canal lies inferior and medial to the jugular foramen. Its floor is comprised of the occipital condyles, the anterior-medial wall by the basi-occiput (clivus), the posterior-lateral wall by the squamous portion of the occipital bone, and the roof by the jugular tubercle. This canal transmits the twelfth cranial nerve, a meningeal branch of the ascending pharyngeal artery, and the hypoglossal venous plexus. Foraminae also exist for the mastoid and condylar emissary veins.

The vertebral artery arises from the subclavian artery and has four segments; V1 from its origin to the foramen transversarium of the sixth cervical vertebra, V2 from the C6 to the C2 foramen, V3 from the C2 foramen transversarium to the dural ring, and V4 from the dural ring to the vertebrobasilar junction. The cervical segment runs up and backward between the longus colli and scalenus anterior muscles to reach the transverse foramen of the sixth cervical vertebra. The foraminal segment of the artery ascends through the transverse foramina of the upper six cervical vertebrae, turning upwards and laterally to enter the transverse foramen of the atlas. The Atlantic segment of the vertebral artery curves backward and medially behind the lateral mass of the atlas and onto the upper surface of the posterior arch of the atlas (sulcus arteriosus). This portion is accessible through the suboccipital triangle and is surrounded by a plexus of veins. Branches from this part are to the suboccipital muscles. It then enters the dura below the posterior atlantooccipital membrane. The branches of V4 are the posterior meningeal, anterior spinal, and the posterior inferior cerebellar artery. From a surgical perspective, it is very important to realize that the PICA may arise extradurally (from V3 instead of V4) and therefore be at risk of coagulation injury during the approach.

The V4 segment ascends ventral to the roots of cranial nerves IX, X, XI, and XII. It usually gives off the PICA before joining the contralateral V4 to form the basilar artery at the lower border of the pons. PICA is divided into five main segments from proximal to distal: anterior medullary, lateral medullary, tonsillomedullary, telovelotonsillar, and cortical (Lister et al., 1982). The basilar artery gives rise to the anterior inferior cerebellar arteries (AICA), which pass to the inferior surface of the cerebellum and come into close relationship with cranial nerves VII and VIII in the cerebellopontine angle. The basilar artery then gives rise to the superior cerebellar arteries (SCA) and the posterior cerebral arteries (PCA), which form the posterior axis of the circle of Willis. Other branches are the pontine and, occasionally, labyrinthine arteries.

The orientation of the muscle anatomy of the suboccipital region is important to appreciate when deciding on surgical approaches. This region is protected by strong suboccipital musculature. The sternocleidomastoid and the digastric muscles arise from and deep to the mastoid tip, respectively. The occipital artery runs posteriorly deep to the mastoid tip. The splenius capitis and longissimus capitis lie deep to sternocleidomastoid. Posteriorly, in the midline lies the trapezius and deep to this arises the semispinalis capitis. After these muscles are reflected off the superior nuchal line, the suboccipital triangle is exposed. This triangle is bordered by the obliquus capitis superior and inferior and the rectus capitis posterior major. Within the triangle lie the dorsal ramus of the first cervical nerve and the vertebral artery with its venous plexus. The triangle is crossed by the great occipital nerve.

Dissection in this triangle allows mobilization of the vertebral artery and exposure of the occipital condyle, which can be drilled away to gain access to the foramen magnum and anterior brainstem, if necessary.

Tumours of the foramen magnum

Historically, access to lesions of the anterior cervicomedullary junction was difficult. In the early part of the twentieth century, neurosurgeons failed numerous times to safely excise lesions in this location through mostly posterior-based approaches (Elsberg and Strauss, 1929; Flores et al., 2013). However, in the 1980s, a new surgical technique (far lateral craniotomy) described by Heros and George independently helped facilitate surgical resection of these lesions (Heros, 1986; George et al., 1988). Over the last three decades, the far lateral craniotomy has been a mainstay approach for surgical access to this region.

The far lateral approach is mainly used for foramen magnum meningiomas, and its efficacy for gross total resection has been widely reported. Recent series conclude that a far lateral craniotomy may be able to achieve gross total resection in nearly 60–90% of cases. Komotar et al. recently concluded that the extent of the resection was limited by large tumour size, neural or vascular invasion, firm tumour consistency, and prior radiation (Komotar et al., 2010). Aggressive surgical approaches to the foramen magnum may also increase the risk of operative morbidity. In cases where there is a small residual tumour, gamma knife radiosurgery to the postoperative tumour bed may be a safe adjuvant therapy to prevent tumour progression.

Operative technique

Far lateral approach

The far lateral approach is an ideal approach to extra-axial lesions spanning the level of the lower third of the clivus, foramen magnum, or C1, and when the tumour is located anteriorly or anterolaterally to the neural axis. The approach may also be used in intra-axial lesions located anterolaterally in the medulla and lower pons. **Figure 31.2** demonstrates the far lateral approach.

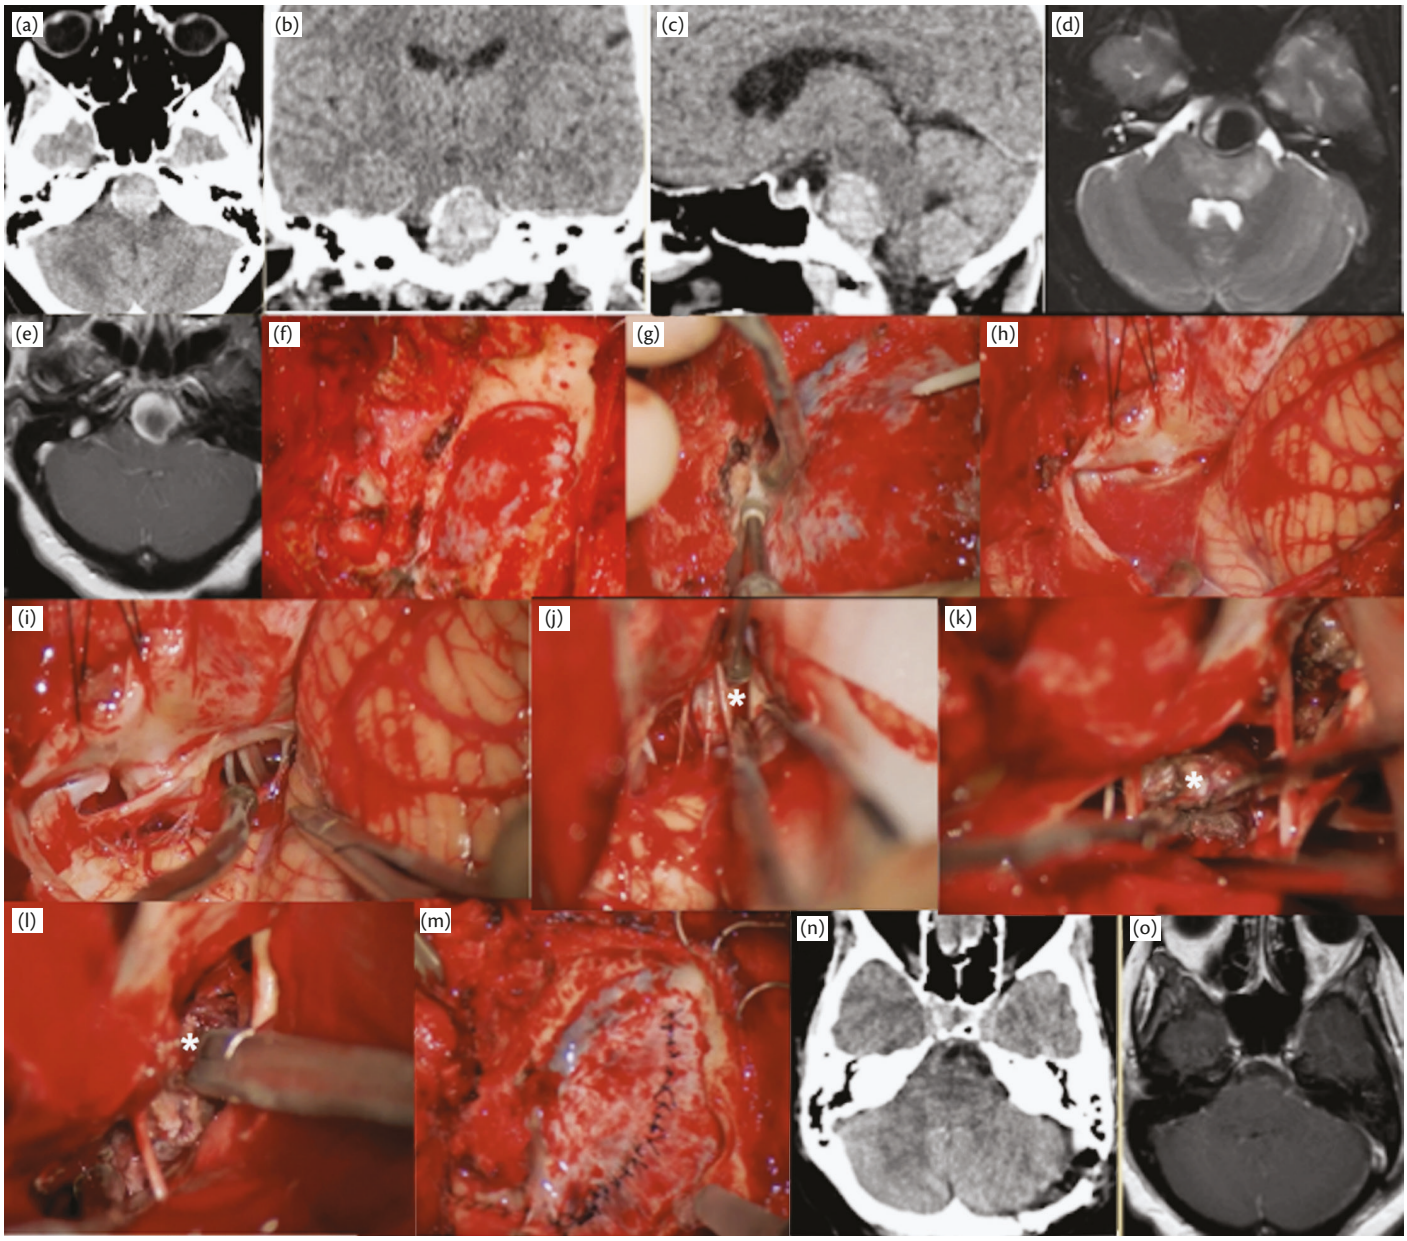

Fig. 31.2 Far lateral approach to jugular tubercle meningioma. Case illustration of a 54-year-old female presenting with a sixth nerve palsy. The CT scan (axial (A), coronal (B), sagittal (C)) shows a partially calcified lesion, the MRI (axial T2 (D) and T1 with contrast (E)) demonstrates a fluid level and enhancement. A retrosigmoid craniotomy (F) was performed with the left side up in a three-quarter prone position with drilling extended into a 'far lateral' craniotomy (G). The dura (H) is held out under traction to optimize visualization and wide arachnoid dissection (I) is performed. The tumour (*) is visualized (J) deep to the lower cranial nerves and debulking of the tumour (K) can be appreciated as well as tumour removal (L) in a piecemeal fashion. A watertight dural closure (M) is performed and a postoperative axial CT (N) and axial MRI with contrast (O) shows complete tumour resection.

Lesions that are posterior or posterolateral do not require this approach as they are more easily resected through a simple suboccipital or retrosigmoid approach. For the far lateral approach, the idea is to come in at an angle that avoids the cerebellum and points medially and often superiorly (Elhammady et al., 2012). This is why we position the patient in the three-quarters prone position with the ipsilateral side up. The head is placed with four movements: neck flexion, rotation towards the floor, tilting towards the floor, and finally upwards or posterior translation. The combination of these four moves achieves an opening of the angle between the shoulder and the head and a partial opening of the occiput to C1 joint, which makes visualizing the condyle easier. This manoeuvre places the ipsilateral cerebellar hemisphere in a position where gravity will help it fall away from the lesion. The incision is hockey stick in shape, starting in the midline from C2 to above the inion, and then curving laterally to the tip of the mastoid. The same soft tissue principles apply here as for the midline suboccipital craniotomy, although the approach here is unilateral. A cuff is preserved at the superior nuchal line for closure. The myocutaneous mass is retracted with fish hooks lateroinferiorly. Generally, the bone flap has a tear drop-like shape because it is narrower at the foramen magnum than at the upper edge. Again, a 3 cm height is usually enough but individual

tailoring can be done. The flap can be taken close to the sigmoid sinus if a retrosigmoid vantage point is also necessary. After the bone flap is lifted, the remaining lip of foramen magnum leading to the juxta-condylar bone is drilled with a matchstick or round drill bit. Since the occipital condyles are located anterior to the transverse equator of the foramen magnum, the drilling of the juxta-condylar bone does not need to extend into the condyle. The 'far lateral' designation of this approach implies that the condyle is not drilled. In exceptional circumstances, such as in lesions infiltrating the condyle, a true 'transcondylar' approach may be necessary. After this thorough drilling, the ipsilateral hemi-arch of C1 needs to be removed, with similar techniques and precautions as were described in the suboccipital approach. The dura is then ready to be opened in a U-shaped flap based laterally and held with traction sutures. A sign of adequate drilling is when there is no bony protrusion seen tenting the dural flap at its base. That base should be as flat as possible, otherwise the microsurgical view will be suboptimal laterally.

One of the main goals once the dura is opened and the brain relaxed with CSF egress, is to correctly identify microanatomical structures including the vertebral artery (VA) as it pierces the dura, the attachments of the first two dentate ligaments and the lower cranial nerves. The spinal contribution of cranial nerve XI is posterior to the dentate ligament. The V3 segment of the vertebral artery pierces the dura at the most superior dentate ligament. The rostral dentate ligaments are divided to allow for better visualization of anteriorly based tumours, such as a foramen magnum meningioma. The arachnoid of the lateral cerebellomedullary fissure is then thoroughly excised to allow untethering of the cerebellar hemisphere. Once the anatomy and tumour are clearly delineated, an effort to devascularize and detach the tumour must be made. It is important to note that foramen magnum meningiomas should be approached based on their relationship to the V3 segment (Flores et al., 2013). If the meningioma arises distal (above) the vertebral artery, then dissection should start rostrally, and likewise if the lesion arises below the VA, the tumour plane should be defined inferiorly. Most of these operations are done with the benefit of intraoperative monitoring of lower cranial nerves, somatosensory evoked potentials, and motor evoked potentials. If there is no developed arachnoid plane between the tumour and vascular structures, it may be best to leave a small carpet of residual tumour. The dura must be closed in a watertight fashion to reduce the risk of a postoperative CSF leak and pseudomeningocele, through the use of an autologous pericranial patch if needed (Flores et al., 2013).

The most common morbidities after the far lateral approach are a cranial nerve palsy, pseudomeningocele, or hydrocephalus. The incidence of lower cranial nerve palsies after a far lateral approach ranges from 30% to 40% depending on the surgical series; however, most (80%) improve within the first few months after surgery (Komotar et al., 2010; Talacchi et al., 2012). Craniocervical instability may also occur in cases where there is significant (>50%) drilling of the occipital condyle. The need for postoperative fusion may be correlated to the degree of bony involvement, location, and size of the lesion. Lastly, development of a pseudomeningocele or CSF leak from the wound may also be potential complications after resection of foramen magnum lesions. Meticulous wound closure and a watertight dural closure can help avoid these complications.

Intraventricular tumours

Paul Grundy and Vasileios Apostolopoulos

Introduction and general principles of management

Some 1.2% of the primary brain tumours have an intraventricular location, according to the Central Brain Tumour Registry of the US (CBTRUS 2006–2010 statistical report, N = 326 711; Ostrom et al., 2013). They represent a diverse group of tumours of variable histological origin; however, most are low-grade tumours. The radiological differential diagnosis can be challenging but is usually narrowed by considering the imaging features of the tumour, the patient's age, the location of the tumour within the ventricle, the clinical presentation, and associated medical conditions (e.g. tuberous sclerosis). Symptoms suggestive of raised intracranial pressure secondary to hydrocephalus are a common presentation, but increasingly frequently they are being diagnosed as an incidental finding. Characteristic patterns of growth have been observed and are recognized as typical for various types of intraventricular tumours. Depending on their pattern of growth and size intraventricular tumours can be confined in one ventricle or can extend into the adjacent ventricle (e.g. central neurocytoma) or into an adjacent cistern through outflow foramina (e.g. fourth ventricular ependymoma). Large tumours can extend through the ependymal wall out into the parenchyma (e.g. large meningiomas, or choroid plexus tumours). Indeed, for extremely large tumours it can sometimes be difficult to differentiate whether they are parenchymal tumours extending into the ventricle or vice versa (**Fig. 32.1**). The management of intraventricular tumours needs to be tailored to the individual case but as a rule the management of hydrocephalus is the first consideration. For third ventricular tumours, neuro-endoscopy can obtain both cerebrospinal fluid (CSF) diversion (endoscopic third ventriculostomy +/– septostomy) and a biopsy. CSF diversion should be carried out first as the biopsy can cause bleeding from the tumour with reduced visibility. CSF and plasma tumour markers should be sent if germ cell tumours are suspected. Imaging of the whole craniospinal axis is indicated for tumours with known potential of CSF dissemination (**Table 32.1**). All cases should be discussed at a neuro-oncology MDT meeting before definite surgical treatment is planned unless delay would harm a patient. Conservative management with serial imaging follow-up maybe the best option if the patient is asymptomatic, the tumour is not growing, or the patient is not fit for surgery. For older and unfit patients and when tumour is considered low grade with an indolent clinical course, CSF diversion alone maybe the best alternative (e.g. subependymoma of the fourth ventricle in older people).

Classification (anatomic, pathological, topographic)

Different intraventricular tumours tend to occur in specific parts of the ventricular system largely because the cell populations they originate from exist preferentially in certain parts of the ventricular system (**Table 32.1**). This knowledge is helpful to narrow the differential radiological diagnosis. Intraventricular tumours may originate from the ependyma or subependyma lining the walls of the ventricular system, septum pellucidum, or choroid plexus. Colloid cysts are related to misplacement of endodermal elements at the embryonic telencephalon/diencephalon interface. Many apparently intraventricular tumours are intraparenchymal tumours exophytic into the ventricles, for example, large astrocytic tumours can grow into the ventricle from the frontal lobe, the corpus callosum, or thalamus, and brain stem gliomas can be exophytic into the fourth ventricle.

Medulloblastomas are usually vermian tumours (although in young adults they can also grow within the cerebellar hemispheres) but frequently present as large tumours filling much of the fourth ventricle. Not infrequently large sellar and suprasellar tumours grow upwards into the third ventricle. Similarly, pineal region tumours can grow from the pineal region into the posterior third ventricle. More details about tumours growing in specific parts of the ventricles will be provided next.

Anterior body and frontal horn

Tumours here most commonly derive from the ventricular walls (ependymoma, subependymoma) or the septum pellucidum (central neurocytoma). Primary septal tumours (astrocytoma, lymphomas, and germinoma) are extremely rare. Metastatic melanoma of the septum has been also reported (Cipri et al., 2009).

Large intraparenchymal, high grade astrocytic tumours can become exophytic into the ventricles and many obliterate the foramen of Monro, or cut-off the posterior lateral ventricle and cause obstructive

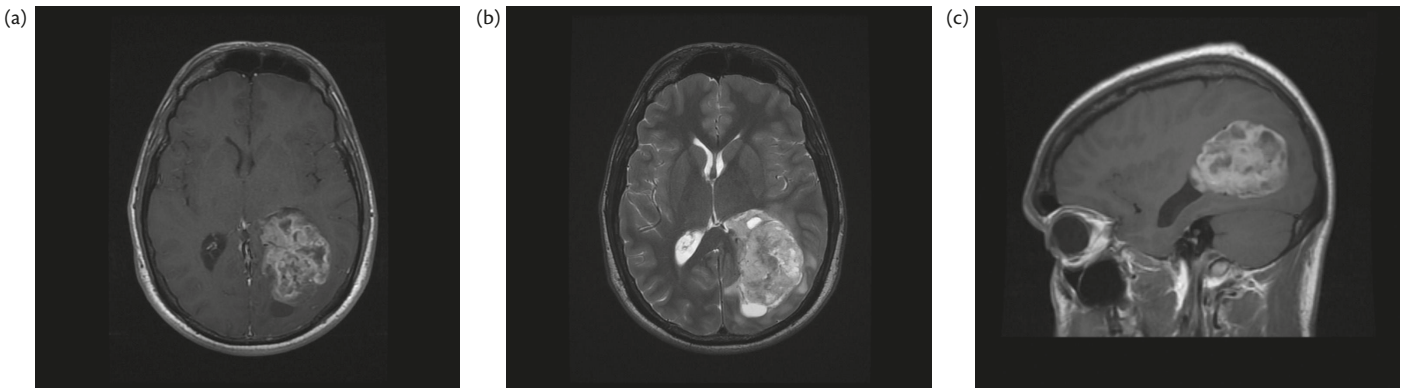

Fig. 32.1 Ganglioglioma with appearances suggestive of intraventricular location, thought preoperatively to be a meningioma. Exophytic intrinsic gliomas may grow into the adjacent ventricles. Axial (A) and sagittal (B) T1 MRI with gadolinium and axial T2 (C).

Table 32.1 Intraventricular tumours—quick review table

Location	Attachment	Cells of origin	Tumour	WHO	MRI features	Commonest location, associated conditions, pt population	CSF seeding, potential of recurrence
Lateral ventricles	Walls of the ventricle	Ependymal cells (glial cells with ependymal differentiation)	**Ependymomas**	II, III	Well defined, lobulated, Heterogeneous +– calcifications, haemorrhage, cysts, Iso@T1, hyper@T2, enhancement	Fourth ventricle if supratentorial can also be extraventricular, NF2,	Possible, can recur if not completely excised
		Subependymal glial cells	**Subependymomas**	I	Well defined, lobulated hypo@T1, hyper@ T2, most are non-enhancing although some enhancement possible	Usually in the fourth ventricle, older pts than with ependymomas	Never, cured if completely excised
		Mixed neuronal and giant cell astrocytes within subependymal nodules in TS	**Subependymal giant cell astrocytomas**	I	Well circumscribed, other subependymal nodules, Hypo-iso@T1, hyper@T2, avid enhancement	Lateral ventricle near the foramen of Monro, children with tuberous sclerosis	Never
	Septum pellucidum	Precursor neuronal cells	**Central neurocytomas**	II, III	Wide attachment on the septum pellucidum, well circumscribed, lobulated, can contain cysts, calcifications, rarely haemorrhages Iso@T1, Iso@T2, heterogeneous enhancement,	Lateral ventricle near the foramen of Monro, young adults	Unlikely, can be cured if completely excised, have higher recurrence rate higher recurrence if atypical
		Astrocytes	**Astrocytomas**	II, III, IV			Unlikely, Likely to recur
	Trigone	Arachnoid cap cells within choroid plexus	**Meningiomas**	I, II	Lobulated, homogeneously enhancing	slightly more common on the left	Unlikely
		Choroid plexus	**Choroid plexus tumours (CPP I, CPP II, CPP III)**	I, II, III	Lobulated avidly enhancing	Trigone, young adults	Rare for CPP I, II. Frequent for CPC III. Whole spine MRI recommended
		Lymphocytes	**Lymphomas**			Rare, usually multiple	Unlikely
Third ventricle	Foramen of Monro	Paraphysis elements from foramen of Monro	**Colloid cyst**	I	Hyper@T1, iso/hypo@T2, no enhancement	Anterior third ventricle, foramen of Monro	Never, cured if completely excised, can recur if incompletely removed
		Choroid plexus	**CPP, CPC**		Hyper@T1, iso/ hypo@T2, no enhancement	Rare	Rare for CPP I, II. Frequent for CPC III. Whole spine MRI recommended

Table 32.1 Continued

Location	Attachment	Cells of origin	Tumour	WHO	MRI features	Commonest location, associated conditions, pt population	CSF seeding, potential of recurrence
		Arachnoid cap cells – Vellum Interpositum	**Meningiomas**			Rare	Never
	Suprasellar	Squamous cells – Rathke's cleft	**Craniophangiomas**		Refer Chapter 26		Unlikely, tend to recur if incompletely removed
		Germ cells	**Germ cell tumours (germinomas and non-germinomas)**		Isointense or slightly hyperintense for T1 and T2 and homogenous enhancement	Pineal/suprasellar, children/young adults	Likely
	Posterior third ventricle	Intra-axial tumours from the thalamus can become exophytic into the posterior third ventricle, but most commonly tumours in this area originate from the pineal region (see relevant chapter). Obstructive hydrocephalus is a usual initial presentation that needs to be treated as a first priority.					
Fourth ventricle	Walls/floor of the ventricle	Ependymal cells	**Ependymomas**	II, III	Well defined, lobulated, Heterogeneous +- calcifications, haemorrhage, cysts, Iso@T1, hyper@T2, enhancement	Fourth ventricle if supratentorial can also be extraventricular, NF2,	Possible, can recur if not completely excised
		Subependymal cells	**Subependymomas**	I	Well defined, lobulated hypo@T1, hyper@ T2, most are non-enhancing although some enhancement possible	Usually in the fourth ventricle, older pts than with ependymomas	Never, cured if completely excised

hydrocephalus for the whole ventricle or cause enlargement of the trapped posterior part of the ventricle (encysted ventricle).

Central neurocytomas originate from precursors of neuronal cells that exist within the septum pellucidum. They are isointense to grey matter on T1 and T2 and show heterogeneous enhancement. Typically, they have a wide attachment on the septum pellucidum and can grow to a significant size within the lateral ventricle (Fig. 32.2). Occasionally they can also grow into the third ventricle through the foramen of Monro. They are well circumscribed, can be lobulated, contain cysts, and have heterogenous signal and flow voids, and they can also contain calcifications. They occasionally encase the columns of Fornix, in which case complete surgical excision maybe contraindicated to preserve memory. Details of this tumour will be discussed later in this chapter.

Subependymomas are well circumscribed non-enhancing benign tumours most frequently seen in the fourth ventricle but they can also be encountered within the lateral ventricle as non-enhancing, or minimally enhancing tumours attached on the lateral wall of the lateral ventricle. Surgical resection is indicated if they become symptomatic or progressive on imaging. Within the lateral ventricle complete excision and surgical cure can be usually achieved. The management of these tumours needs to be tailored to the patient age and general fitness. Conservative management for older and asymptomatic patients is a reasonable management option.

Subependymal giant cell astrocytomas (SEGA) are tumours of mixed glial and neuronal differentiation arising from subependymal nodules and are common in patients with tuberous sclerosis. They appear as iso or hypointense on T1 and hyperintense on T2 and demonstrate avid enhancement. They grow slowly usually in the area of the foramen of Monro, leaving the overlying ependyma intact. If they reach a significant size can cause obstructive hydrocephalus. The usual practice is close surveillance with serial imaging and clinical follow-up, if the patient is asymptomatic. Surgical excision is indicated if continuous growth is demonstrated on serial scans or the patient develops hydrocephalus. Stereotactic radiosurgery for smaller lesions has also been suggested by some authors.

Recurrence of SEGAs after surgery has been found to be low in patients treated with mTOR inhibitors. These medications down regulate the mTOR signalling pathway of the cell cycle found to be overactive in many cancers. In SEGAs these drugs not only reduce the recurrence rate of SEGAs but can also lead to shrinkage of other tumours associated with tuberous sclerosis, such as angiofibromas and angiomyolipomas. However, the benefits of this treatment should be balanced carefully with significant and potentially debilitating side effects including Immunosuppression and recurrent infections, significant anaemia, thrombocytopenia fatigue, nausea, and diarrhoea (Campen and Porter, 2011).

Ependymomas in adults are more frequent in the fourth ventricle (60%), but they can also be seen within the lateral ventricle. They can theoretically grow anywhere in CSF spaces within the craniospinal axis (third ventricle, aqueduct), and they are also one of the commonest intramedullary spinal cord tumours. They are well circumscribed tumours that enhance and frequently contain calcifications. They are usually isointense or hypointense to the white matter on T1 and hyperintense on T2.

Astrocytomas can be exophytic into the ventricles from the surrounding brain parenchyma. However rarely they can grow as primary septal tumours.

Posterior body–trigone

Meningiomas are the commonest intraventricular tumour in the trigone of the lateral ventricle, but only represent 4% of all intracranial

Fig. 32.2 Central neurocytoma of lateral ventricle, axial T2 (A) and coronal T1 (B) with gadolinium showing typical appearances involving septum and fornices and here protrusion into the third ventricle and dilatation of left lateral ventricle.

meningiomas. They are more common in adults with a slight predilection for female patients for reasons not completely understood, also with a slight predilection for the left side. They are thought to originate from arachnoid cap cells trapped within the choroid plexus during embryonal life. They may reach a large size and cause symptoms suggestive of high intracranial pressure but they can also be incidental. They appear as large homogeneously enhancing tumours usually with a significant feeding vessel that on MRI is seen to enter the tumour, usually a branch from one of the choroidal arteries (Fig. 32.3). Intraventricular meningiomas can also occur at a much lower frequency in the posterior third ventricle (arachnoid cap cells from vellum interpositum) or in the fourth ventricle (arachnoid cap cells within the choroid plexus). Treatment options (depending on the size and clinical picture) include surgery, SRS, or surveillance.

Choroid plexus tumours arise from the choroid plexus and located most commonly in the lateral ventricle in children and the fourth ventricle in adults. Most frequently they occur in children younger than 15 years, but can also occur in the first year of life. Histologically they can be choroid plexus papillomas (CPP—WHO I), atypical choroid plexus papillomas (CPP—WHO II) or choroid plexus carcinomas (CPC—WHO III). The radiological appearances for all these types of choroid plexus tumours are similar but the prognosis differs significantly. Most they appear as avidly enhancing tumours with lobulated margins and flow voids and they can frequently reach a large size. When they reach a large size, they can breach through the ependyma into the surrounding parenchyma. They tend to present with hydrocephalus both due to increased CSF production and due to obstruction. The best management regardless the WHO grade of the tumour is gross total resection. Preoperative embolization should be considered as it can reduce intraoperative bleeding which can be catastrophic. Postoperative radiotherapy is used for CPCs but the single most important prognostic factor is the presence or not of residual tumour. The prognosis for CPC is considered generally poor. CPPs can be cured it completely excised. The location, size, and enhancement characteristics of the choroid plexus tumours can occasionally make difficult to differentiate from meningiomas in this area. CSF seeding is rare for the CPP I, II, but individual cases have been reported. CSF seeding is frequent for CPCs. Whole spine MRI before any definite management decision is therefore mandatory.

Third ventricle

Anterior third ventricle

Foramen of Monro

Colloid cysts are the commonest third ventricular tumours. The true incidence of colloid cysts cannot be calculated with accuracy as a

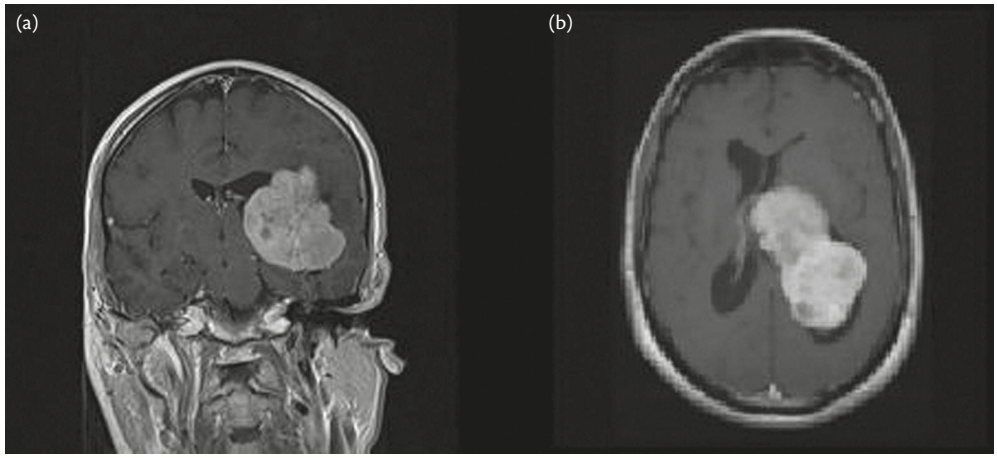

Fig. 32.3 Intraventricular meningioma within trigone of lateral ventricle. T1 weighted MRI in coronal (A) and axial (B) planes.

significant proportion of these tumours are asymptomatic therefore underreported (Pollock and Huston, 1999). They are benign lesions consisting of epithelial-lined cysts filled with gel—density material which contains mucin, cholesterol, and hyaloid substances. The relative proportion of the components of the contained material can vary from case to case causing a wide variety of different appearances on imaging and different consistency at surgery.

On CT they appear typically as hyperdense and less commonly iso or hypodense unilocular lesions filling the anterior third ventricle with or without associated hydrocephalus. On MRI they can be hypo-iso or hyperintense with no enhancement on T1 but most commonly hypointense on T2. They can be diagnosed as an incidental finding or present with acute, intermittent, or chronic obstructive hydrocephalus (intermittent headache, drop attacks). Although the origin of these cysts is not completely elucidated it is thought that they derive from abnormal folding of the primitive neuro-epithelium which in this area separates the telencephalon from the diencephalon. Sudden death is rare but has been reported. While traditionally this was thought to be related to acute obstructive hydrocephalus caused by mobile tumours ('the ball-valve mechanism'), theories of cardiac involvement secondary to acute hypothalamic dysfunction have become more and more prominent (Turillazzi et al., 2012).

As a general principle, symptomatic colloid cysts should be removed. According to level II evidence 98% of asymptomatic colloid cysts will remain clinically silent on long term follow-up (Pollock and Huston, 1999). The risk of observation for asymptomatic cysts was also found to be higher for patients younger than 50 and cysts larger than 1 cm (Pollock et al., 2000).

Surgical options include open surgery via a transcortical or transcallosal approach, endoscopic excision, or frameless stereotactic aspiration. There are pros and cons for each. The open approaches have a higher chance to achieve complete excision of the cyst but may carry a higher risk for seizures or forniceal injury. The size of the ventricles can be a limitation for the endoscopic approach. The viscosity of the cyst content can also be a limiting factor for the stereotactic or endoscopic aspiration. If incompletely aspirated colloid cysts can recur.

Extension of a sellar mass, most likely a large pituitary adenoma, has typical appearance on MRI for pituitary tumours, bitemporal visual field disturbance, and hormone disturbance on endocrine profile.

Suprasellar tumours extending into the ventricles—most commonly craniopharyngioma but also germinoma—please see more details in Chapter 27.

Optic pathway and hypothalamic gliomas—most often affects the paediatric population. More details in Chapters 38 and 88.

Meningiomas from the skull base extending upwards. More details in Chapter 14.

Posterior third ventricle

1. *Pineal region tumours* can grow into the posterior third ventricle. Please refer to the relevant chapter on these tumours.
2. *Meningiomas* from the tentorial edge (included in the differential diagnosis of the pineal region tumours).
3. *Arachnoid cysts*—might be difficult to be spotted easily on first look. They can cause triventricular hydrocephalus. If they are symptomatic, they can be managed with endoscopic fenestration.
4. *Dermoid cysts*—rare.

Fourth ventricle (adults)

1. *Ependymomas*—enhancing lobulated tumours more common in young adults that tend to grow outwards through the foramina of ventricular outflow (Fig. 32.4). The main treatment is surgical but when these tumours originate from the floor of the fourth ventricle radical excision needs to be balanced carefully with the significant risk of lower cranial nerve palsies. In such cases, if a good dissection plane is maintained between the tumour and the floor of the fourth ventricle it is likely that postoperative cranial nerve palsies (likely to occur) are likely to improve gradually over time (although full recovery cannot be guaranteed). All this should be discussed carefully with the patient before the operation. Preoperative imaging of the whole craniospinal axis is mandatory due to the risk of CSF dissemination. The difficulty of correlating histologic grading and clinical significance in ependymomas is well documented. The new WHO CNS tumour classification in 2016 has not elucidated this further. However, a new entity, the RELA fusion-positive ependymoma (common with supratentorial ependymoma in children), was included.

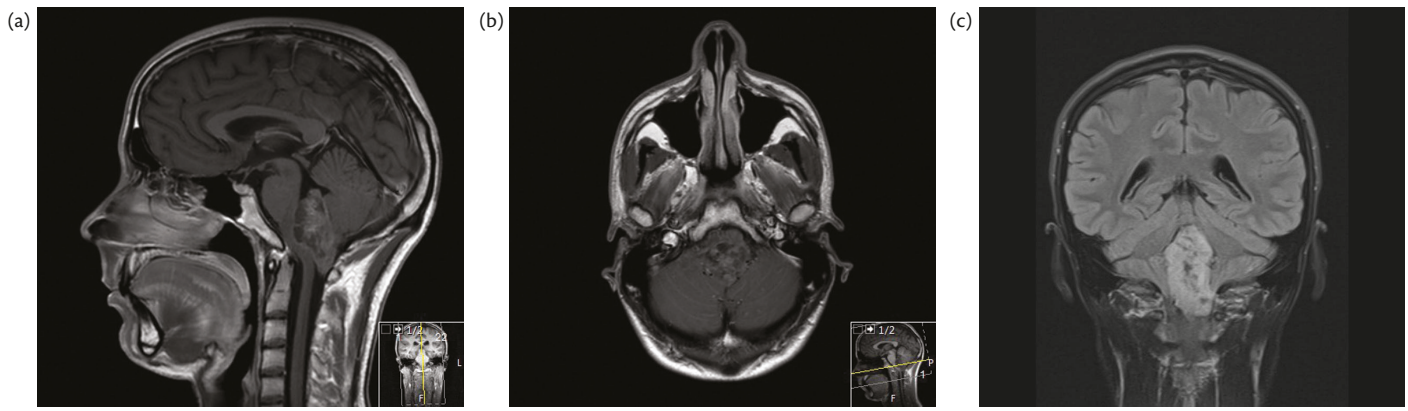

Fig. 32.4 Ependymoma of fourth ventricle, sagittal (A) and axial (B) T1 with gadolinium and coronal (C) FLAIR showing typical appearances with patchy contrast enhancement, compression of brainstem, growth through foramen of Magendie and involvement of posterior inferior cerebellar artery branches.

Also, the previously recognized entity of cellular ependymomas was deleted from the classification as it was considered identical with the standard ependymomas.

2. *Subependymomas*—non-enhancing (or sometimes containing enhancing components) lobulated tumours commoner in middle age and older patients and often is an incidental finding. If small and asymptomatic or if the patient is not fit to undergo surgery, they can be managed conservatively. Occasionally CSF diversion might be necessary, but often patients are managed conservatively due to the indolent clinical course of these tumours. Resection should be considered for younger patients with larger or symptomatic tumours but is often deliberately subtotal to avoid injury to floor of the fourth ventricle.
3. *Medulloblastomas*—originate from the cerebellar vermis and most commonly occur in the paediatric population but can rarely occur in young adults (location in the cerebellar hemisphere possible). They usually present with acute obstructive hydrocephalus. The 2016 WHO CNS tumour classification provides a very useful presentation of the usual combinations of the well-established histological subtypes of these tumours (desmoplastic/nodular, medulloblastoma with extensive nodularity, large cell, and anaplastic) and four now established genetic subtypes (WNT activated, SHH activated, group 3 subtype, and group 4 subtype) (Louis et al., 2016). The management should be prioritized and considered carefully; the management of acute hydrocephalus, imaging of the whole craniospinal axis and CSF sampling, MDT discussion, surgery for the primary tumour (aim for maximal tumour resection, establish histological, and molecular subtype) and further oncological treatment depending on the stage of the disease and the age of the patient. Locally established protocols usually apply. At the time of presentation, a significant percentage of the patients have already secondary deposits in the spine. Secondary deposits or CSF dissemination at the time of presentation, subtotal excision of the primary tumour and younger age are all well recognized factors of poor prognosis (more details in Chapter 28).
4. *Choroid plexus tumours*—the fourth ventricle is an unusual location for these tumours, but they can occur here as avidly enhancing lobulated tumours. The main treatment is surgical. If subtotally resected they can recur.
5. *Exophytic brain stem gliomas*—usually pontine gliomas. More common in children (more details in Chapter 7).
6. *Cysticercosis*—should be included in the differential diagnosis if the patient comes from or travelled in to endemic areas.

Clinical presentation

The clinical presentation of intraventricular tumours depends on their location, size, and progress rate. Rapid progression can cause acute hydrocephalus (severe headache, drowsiness, nausea, and vomiting) that require CSF diversion before the definite management of the tumour. Slow growing tumours however are asymptomatic for a long time before they become symptomatic and usually present with a chronic, NPH-like clinical picture (cognitive decline, gait disturbance, and incontinence). The management of these patients should focus on the surgical management of the tumour as this can also address the resulted hydrocephalus. Incidental diagnosis particularly of low-grade intraventricular tumours has become increasingly frequent nowadays due to the wide availability of imaging. Certain intraventricular tumours can reach a significant size and can cause symptoms from direct mass effect on periventricular neural structures. Large tumours in the left lateral ventricle have been associated with memory and speech disturbance. Large tumours on either side can cause motor deficit, and if they have a significant extraventricular extension into the parenchyma they can also cause epilepsy. Visual disturbance can occur either as a result of the long-standing high intracranial pressure or various visual field deficits can occur due to the direct pressure on the visual pathways. Tumours of the posterior third ventricle and pineal region can also present with Parinaud's syndrome as well as acute hydrocephalus. Large posterior fossa tumours usually present with acute obstructive hydrocephalus and depending on their size and extension with balance disturbance. The slow and gradual onset and progress of symptoms of low-grade tumours can rarely be accelerated by intratumoural haemorrhage, which leads to sudden deterioration (Ogbodo et al., 2012).

Management

If an intraventricular tumour causes obstructive hydrocephalus with deteriorating neurological state CSF diversion should take the priority. For third ventricular tumours, bilateral drainage of the ventricles should be considered if the tumour obstructs both foramina of Monro, although this is not always necessary. The ventricles can be drained by inserting an external ventricular drain, or depending on the working diagnosis, Endoscopic third ventriculostomy can be carried out first followed by endoscopic biopsy of the tumour (e.g. posterior third ventricle/pineal region tumours). Endoscopic third ventriculostomy can potentially be a CSF diversion option for all cases when blockage of the ventricle happens at posterior third ventricle or below.

For patients with slow growing tumours with chronic hydrocephalus, the management of the tumours can take the priority. However, in these cases if a decision is made for the patient to be managed conservatively, a ventriculoperitoneal (VP) shunt can be inserted to treat hydrocephalus. This is a commonly followed management plan for older patients who are diagnosed with lower grade intraventricular lesions and are not fit to undergo excision of the intraventricular tumour.

For tumours with a potential of CSF dissemination (**Table 32.1**), enhanced MRI of the whole spine and CSF sampling preoperatively is mandatory to stage the tumour adequately.

Tumour markers from the blood and CSF should be sent for pineal region tumours. CT of the whole body should be considered if suspected metastases.

Central neurocytoma

Low-grade tumours, most common in young adults. When initially described in 1982 (Hassoun et al., 1982) were graded WHO I tumours but due to the high recurrence rate of some histological subtypes were subsequently upgraded to WHO II tumours. They

usually present with gradual onset of symptoms suggestive of raised intracranial pressure due to hydrocephalus. Apart from headaches a clinical picture of chronic hydrocephalus with cognitive decline, gait disturbance, and incontinence is common. When very large the patients can also present with symptoms due to direct mass effect of the tumour on the periventricular structures. Intratumoural haemorrhage can lead to sudden deterioration of symptoms that leads to diagnosis. They have generally a good prognosis, but if incompletely excised they can recur. They are usually located in the lateral ventricle originating from the septum pellucidum and occasionally extend into the third ventricle. They show mild to moderate enhancement and can contain cysts, calcifications, and flow voids.

Epidemiology

Rare tumours reported in different series to represent up to 0.5% of brain tumours.

Pathology

Well differentiated tumours with neuronal differentiation. Due to their clear cytoplasm, they can mimic other clear cell tumours. The presence of synaptophysin and the neuronal nuclear antigen are used to confirm the diagnosis. Cytoplasmic vacuolations of this tumour give the tumour the 'fried egg' appearance, like that seen in oligodendroglioma.

The MIB-1 labelling index when more than 3% was associated with a worse prognosis for local control and survival (Rades et al., 2004). These tumours are called atypical central neurocytomas.

Despite their usual benign nature, malignant transformation of central neurocytomas has been reported (Amagasa et al., 2008).

Treatment

Due to low occurrence rate of these tumours there is no enough data to support large prospective studies. The highest level of evidence available on the management of central neurocytomas tumours comes from meta-analyses. The largest meta-analysis reported (N = 438) on the management of central neurocytomas concluded that in all cases gross total resection should be attempted if considered safe (Rades and Schild, 2006). In this study the tumours were divided in typical and atypical central neurocytomas based on the MIB-1 labelling index greater than 3% and the presence or not of atypical histological features. In 351 of the patients with typical neurocytomas it was found that the addition of radiotherapy after gross total resection has achieved the same 5-year survival but slightly higher (100% vs. 87%) local control rate. However, taking into consideration the risks of radiotherapy is not generally recommended. Radiotherapy has however proven beneficial in patients with typical neurocytomas who underwent subtotal resection as it improved both the 5-year survival and local control to almost the gross total resection (GTR) levels (see **Box 32.1**).

For the management of atypical central neurocytomas in a meta-analysis for treatments applied for 85 atypical neurocytomas, it was concluded that after GTR five-year survival was slightly lower when compared to typical neurocytomas (93% vs. 100%), but the local control rate was significantly lower (57% vs. 87%). The addition of radiotherapy was not found to improve the survival or local control and therefore is not recommended.

Box 32.1 Management of central neurocytomas (typical and atypical)

Grade 1c recommendations

- Attempt GTR if safely feasible (applies for typical and atypical central neurocytomas)
- STR + RT = GTR control rates/survival—applies for typical central neurocytomas where GTR is considered high risk
- RT after STR of typical neurocytomas is recommended at 50–54 Gy
- RT after GTR of atypical central neurocytomas not recommended
- RT after STR of atypical central neurocytomas is recommended at 55–60 Gy

Grade 2c recommendations

- Do not use RT after GTR in typical central neurocytomas
- Biopsy, CSF diversion, and RT are sometimes effective for typical central neurocytomas

CSF, cerebrospinal fluid; GTR, gross total resection; RT, radiation therapy; STR, subtotal resection.

For subtotal resection the 5-year survival and local control are very low, but improve dramatically with postoperative radiotherapy (survival 43–78% and local control 7–70%).

An interhemispheric-transcallosal or transcortical approach can be employed for the surgical resection of these tumours. The interhemispheric-transcallosal approach provides easy access to the ventricles with no risk of seizures and very low risk of disconnection syndrome.

A summary for the management of central neurocytomas can be seen in **Box 32.1**. See **Figure 32.5** for the histopathological features of typical central neurocytoma.

Prognosis

Much depends on the proliferative potential of the tumour and the degree of resection achieved.

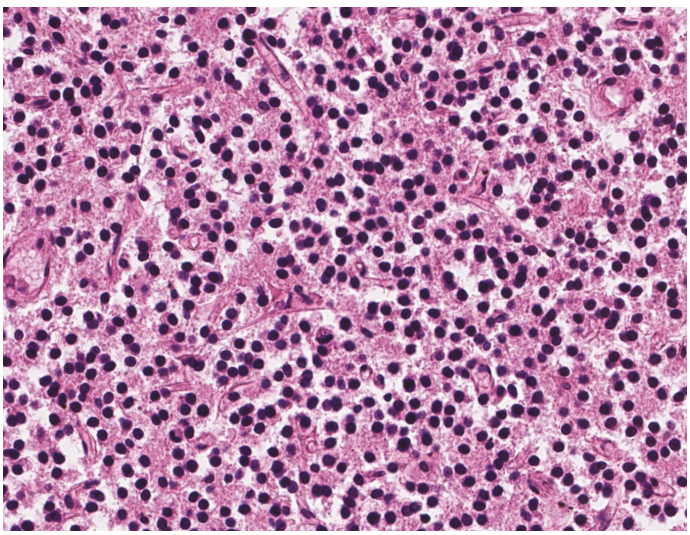

Fig. 32.5 Histopathological features of central neurocytoma. Neurocytic cells with uniformly round nuclei are typical features. Occasional poorly formed rosettes may occur as in this example. Strong immunoreactivity for synaptophysin would be expected.

Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

Colloid cysts

Asim Sheikh and Paul Chumas

Introduction

Colloid cysts are benign, mostly intraventricular tumours accounting for 0.5 to 2% of all intracranial mass lesions. They are most commonly found in the anterior portion of third ventricle at the level of foramina of Monro and, if symptomatic, usually present with obstructive hydrocephalus of the lateral ventricles. The original description historically linked them with sudden death in the pre-CT era. They are also known as neuroepithelial cysts (**Figs. 33.1, 33.2, 33.3,** and **33.4**).

Management options include treatment of hydrocephalus alone, aspiration of the cyst contents and removal of the cyst endoscopically or via a microsurgical approach.

Epidemiology

Cushing described an asymptomatic case of a colloid cyst. Interestingly, a colloid cyst was reportedly found on autopsy of Harvey Cushing himself (Fulton, 1946). Due to most colloid cysts being asymptomatic, it is difficult to ascertain the exact incidence of this benign lesion (Fulton, 1946). With the advent and ever-increasing availability of modern imaging techniques, more asymptomatic colloid cysts are being diagnosed. The prevalence is estimated at 1 in 8500 persons based on autopsy as well as MR imaging series (de Witt Hamer et al., 2002). A study in Finland calculated symptomatic colloid cyst incidence at 3.2 per million per year over a 14-year observation period, accounting for 2% of all intracranial tumours (Hernesniemi and Lievo, 1996). Vandertop estimated that one case becomes symptomatic per million-person years (de Witt Hamer et al., 2002). Age at diagnosis ranges from intrauterine until 76 years of age (Gaertner et al., 1993; Romani et al., 2008) but the most common age of diagnosis is between 20 and 50 years old. Although presumed to be congenital, they are rarely reported in children (Macdonald et al., 1994; Maqsood et al., 2006).

Pathogenesis

Colloid cysts are normally located anteriorly in the third ventricle at the level of foramen of Monro in the coronal plane, although they can also be located more posteriorly in the third ventricle, roof, or floor of the third ventricle, the columns of the fornix or in the choroid plexus (Fries and Perneczky, 1994) (**Fig. 33.5**). Other rare locations include the lateral ventricles, the septum pellucidum, fourth ventricle and prepontine region (Ciric and Zivin, 1975; Shima et al., 1976; Jan et al., 1989; Maurice-Williams and Wadley, 1998; Jeffree and Besser, 2001; Killer et al., 2001; Jaskólski et al., 2003). Most are found as an isolated lesion, but multiple cysts have also been described (Maurice-Williams and Wadley, 1998). Their size can range from few millimetres up to 9 cm in diameter (Shuangshoti and Netsky, 1966).

Histologically, cysts are made up of either a single layer of pseudostratified columnar epithelium with or without cilia, or cuboidal low columnar epithelium (Leech et al., 1982) (**Figs. 33.6, 33.7,** and **33.8**). Mucus goblet cells are also commonly seen, with a mucin positive mucicarmine on periodic acid-Schiff staining. The epithelium and surrounding capsule together form the wall of the cyst. The wall can be variable in its thickness, the contents of the cyst are an amorphous material believed to be mucin discharge from epithelial cells and cellular desquamation. The content consistency is also very variable, from liquid to viscous, and may be semisolid or solid. This is an important consideration when planning treatment options (Bosch et al., 1978).

Colloid cysts have historically been referred to by various other names including neuroepithelial cells, neurenteric cysts, and primary actinomycoma (Powers and Dodds, 1977; Graziani et al., 1995). They are thought to arise from neuroepithelial cells including those of the choroid plexus, ependymal and embryonic paraphysis. A more recent hypothesis suggests they may be of non-neural origin (Takahiro et al., 1992). Although most cases are sporadic and isolated, several familial cases have also been described with a suggested autosomal recessive inheritance pattern (Ibrahim et al., 1986; Akins et al., 1996; Nader-Sepahi and Hamlyn, 2000; Joshi et al., 2005). Screening may be of value in cases where two or more family members are affected.

Pathologically, colloid cysts can either enlarge due to production of colloid material, causing obstructive hydrocephalus or have sudden enlargement due to intracystal haemorrhage when they may compress nearby structures. Sjovall in 1910 suggested intermittent blockage of CSF flow at the level of the foramen of Monro may occur due to the pendular attachment of the cyst to the tela choroidae

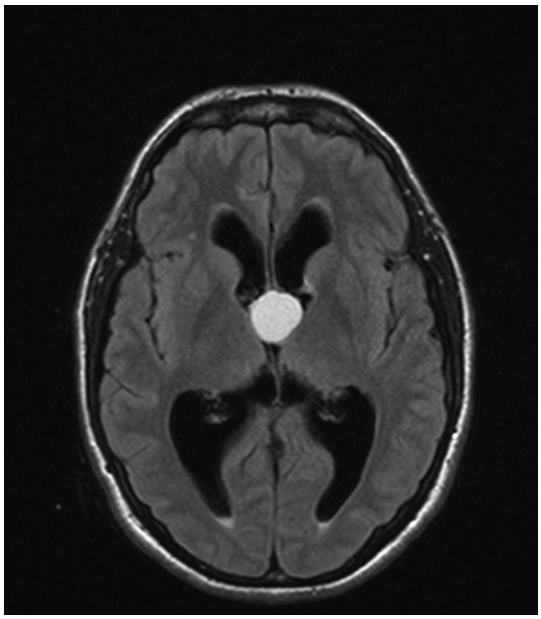

Fig. 33.1 MRI T2W FLAIR image of colloid cyst.

(Sjovall, 1910). Colloid material production can cause both increase in the size of the cyst and local inflammation. A sudden increase in size can be due to acute haemorrhage within the cyst and can produce rapid and often serious neurological deficit (Malik et al., 1980; Beems et al., 2006). Nearby structures can also be compressed by cyst enlargement, for example, local pressure on the fornices can lead to long-term memory problems (Aggleton et al., 2000). Direct compression of the lateral walls of the third ventricle with resultant compromise of the hypothalamic cardiovascular regulatory centres has been postulated as a cause of acute deterioration (de Witt Hamer et al., 2002). A change in posture may cause direct compression of the internal cerebral veins and lead to increased intracranial venous pressure (Hamlat et al., 2004). Acute deterioration may also be seen after a lumbar puncture.

Presentation

There are a wide variety of symptoms that patients may present with, however there are none which are specifically pathognomonic. Symptoms can either be due to acute intermittent raised intracranial pressure, presumed to be from intermittent obstruction to CSF flow from mobile pedunculated cysts or they can be from (permanent) hydrocephalus due to longstanding partial CSF outflow obstruction. There are also a growing number of patients who present with incidentally found cysts.

The commonest symptoms are headaches (68%), gait disturbance (47%) and short-term memory loss (37%). Nausea, vomiting (37%) and blurred vision (24%) are also commonly seen (Little and MacCarty, 1974). The commonest signs are evidence of papilloedema (47%) and gait disturbance (32%). A quarter of

patients will have no signs demonstrable on examination (Little and MacCarty, 1974).

Headache duration, location, and character is variable. A recent study aimed to categorize patients into three groups. One, presenting with headache as the main symptom (72%), another with memory loss with or without signs of raised intracranial pressure and the last group with paroxysmal symptoms while being asymptomatic between attacks (Pollock et al., 2000). However, this distinction is difficult and a combination of symptoms is possible.

It is also worth discussing the often-overestimated risk of sudden death associated with colloid cysts. In the pre-CT era, colloid cysts were associated with a high risk of sudden death due to presumed mobility of the cysts causing acute CSF outflow obstruction. This was most likely associated with interventions such as lumbar punctures and ventriculography. It is possible, however, to

have decompensation and death occurring in patients with chronic hydrocephalus as well. Hypothalamic cardiovascular centre reflex mechanisms may also be responsible for acute deterioration due to direct pressure from the cyst (de Witt Hamer et al., 2002).

Diagnostic imaging

Historically, pneumoencephalography was the mainstay of diagnosis for third ventricular tumours. The advent of CT and then of MRI has made it easier to diagnose colloid cysts. Isodense lesions on CT can pose diagnostic challenges (Powell et al., 1983).

CT imaging shows colloid cysts to be well circumscribed lesions at the level of the foramen of Monro with associated hydrocephalus and periventricular lucency in acute CSF obstruction. Cysts are commonly hyperdense, but may also be isodense or hypodense (Ganti et al., 1981; Hine and Chui, 1987). Cysts that are hypodense on CT, usually have fluid contents and thus there is an option to treat

these with aspiration (El Khoury et al., 2000). Some cysts show moderate peripheral enhancement although this is uncommon.

On MRI, most cysts appear homogenously hyperintense on T1-weighted images and hypointense on T2 images (Maeder et al., 1990). Presence of cholesterol esters may cause the central portion to be low in intensity on T2-weighted images. Rarely, inspissated debris may form a dependent nodule that can be seen on CT and MRI scans.

Intraventricular haemorrhage occasionally mimics a colloid cyst on CT scans and MRI. Subependymomas, central neurocytomas, and subependymal giant cell astrocytomas may occur in the same area as a colloid cyst on imaging studies, but these entities can be distinguished by their shape, contrast enhancement, and signal intensity.

Natural history

Colloid cysts account for less than 2% of intracranial lesions (Little and MacCarty, 1974). A long-term follow-up of such rare tumours is therefore not widely available. Pollock published a series of 155 patients spanning 24 years of observation (Pollock et al., 2000). Four factors were found to be positively associated with symptomatic lesions, younger age group (below 44 years), larger cyst size (more than 13 mm), ventricular dilatation, and increased intensity on MRI T2-weighted images.

The natural history of colloid cysts is related to the rate of cyst growth, development of CSF obstruction, and the fact that cyst size becomes stable as patients age. The natural history can be classified into three groups. Firstly, asymptomatic patients where cyst growth stops prior to CSF obstruction and ventricular dilatation. A second group, also asymptomatic, where an initial rapid growth of the cyst causes ventricular dilation but subsequent cyst stability and lack of growth maintains a symptom free course. Lastly, the group where an enlarging cyst causes CSF obstruction and ventricular dilatation, which in turn causes symptoms. This group commonly has hyperintense T2 characteristics on MRI.

Spontaneous rupture of cysts is also known to occur (Motoyama et al., 2002) and they can reduce in size spontaneously (Hattab et al., 1990).

Management

The current practice of the senior author is complete microsurgical excision of colloid cysts in young symptomatic patients. The majority of 'incidental' cysts are actually found after a scan done for headaches. This poses a real dilemma to ascertain whether these are truly incidental or contribute to a symptom complex.

In a small proportion of elderly patients or those not fit for a prolonged anaesthetic, CSF diversion alone may be considered reasonable. While a conservative approach with radiological surveillance may be appropriate for asymptomatic small sized cysts.

We look at the different management options in detail here.

Conservative management

The majority of colloid cysts either present with symptoms or become symptomatic soon after discovery and hence require treatment. For patients to be managed conservatively with colloid cysts, they must have a radiological diagnosis that is clear, no hydrocephalus, no significant symptoms and the size of cyst should not be more than 10 mm in size (de Witt Hamer et al., 2002; Hamlat et al., 2004). Thus, for small incidentally found colloid cysts, a conservative approach to management is reasonable.

CSF diversion procedures and pellucidotomy

Patients presenting acutely with ventricular dilatation and who are otherwise not surgical candidates for microsurgical removal of colloid cysts, may require urgent CSF diversion. This can be undertaken by placement of bilateral external ventricular drain or shunts. Alternatively a unilateral shunt with endoscopic pellucidotomy may be utilized. Placement of a unilateral shunt alone risks contralateral ventricular dilatation and may result in a deteriorating neurological status.

Rarely, colloid cysts located in the posterior third of the third ventricle may result in triventricular dilatation. In these cases, endoscopic third ventriculostomy can be performed (Hopf et al., 1999).

Percutaneous stereotactic aspiration

Percutaneous aspiration of colloid cyst contents remains a valuable treatment option. Historically, Gutierrez-Lara et al reported on free hand aspiration of colloid cysts in 1975 (Gutierrez-Lara et al., 1975). This method was then refined by use of stereotactic frame (Bosch et al., 1978). The simplicity of aspiration has a definite appeal.

The advantages of aspiration include that it is simple and relatively safe to perform, and it can be used in patients with normal or small ventricles from an earlier shunting procedure (Bosch et al., 1978). While there is a higher recurrence rate, total or subtotal aspiration may be the only treatment required in some patients (Mathiesen et al., 1993).

The disadvantages of aspiration includes a higher recurrence rate (Mathiesen et al., 1993) which can occur as late as 6 years after an aspiration procedure. Aspiration is not always possible because the contents may be too viscous, high cyst viscosity is evident from hyperdensity on CT and is seen in two-thirds of cases (Rivas and Lobato, 1985; Kondziolka and Lunsford, 1992). Furthermore, the capsule may be too tough or a small cyst may deflect away from the aspirating needle (Kondziolka and Lunsford, 1992). Early attempts at aspiration had a high morbidity from vascular injury and mechanical trauma. Spillage of contents while aspirating may cause ventriculitis or aqueductal blockage (Antunes et al., 1980). For these reasons, percutaneous aspiration has now been confined to a very limited group of patients.

Endoscopic aspiration

Endoscopic aspiration of cyst contents was first described by Powell et al in 1983. Deinsberger in 1994 showed that endoscopic aspiration of colloid cysts is safe and if the cyst wall is opened widely, has low recurrence rates (Deinsberger et al., 1994).

Endoscopic excision of cysts

Numerous published series advocate the endoscopic excision of colloid cysts.

The advantages of the endoscopic approach over open surgery are shorter operating times (mean 110 minutes vs. mean 206 minutes for microsurgical excision), lower complication rates owing to the

Table 33.1 Comparison of microsurgery and endoscopy as the primary surgical procedure in colloid cyst management

Parameter	Microsurgical	Endoscopic	Significance *P* value
Age (mean in years)	40.0	40.5

smaller cortical incision, and therefore a lower risk of postoperative seizures (Lewis et al., 1994). A 13-year follow-up of endoscopically removed colloid cysts showed a recurrence rate of only 6.3% (Levine et al., 2007). The rate of mortality and shunt dependency is similar in both groups. Hence some centres are offering this technique as the treatment of choice.

However, another recent study reviewed the available literature on endoscopic vs. microsurgical excision of colloid cysts (Sheikh et al., 2014). This study concluded that microsurgical removal of colloid cysts appears to result in a significantly higher rate of complete radical resection, decreased rate of recurrence, and fewer reoperations than endoscopic removal. This may be related to the advantage of performing two-handed microdissection of the cyst wall from critical adherent structures to achieve true gross total resection. Tables 33.1 and 33.2 provide comparative data on the techniques.

The technique of endoscopic excision of a colloid cyst is performed under general endotracheal anaesthesia, the patient is positioned supine with the head supported in a horseshoe head support. A head up position of approximately 15° is used. A linear incision is made just in front of the coronal suture in the mid-pupillary line and a burr hole is made. The dura is opened and ventricular cannulation is carried out with a No.14 French peel away introducer and stylet. Either a rigid or a flexible endoscope is inserted through the peel away catheter. Flexible scopes are useful for colloid cyst excision when the cyst is attached more posteriorly or to inspect the third ventricle and aqueduct for any debris.

The foramen of Monro is identified and usually found to be obstructed by the colloid cyst. The vascular cyst wall is coagulated with endoscopic bipolar or monopolar electrodes. Some centres have also utilized potassium titanyl phosphate (KTP) 600 μc laser fibres to coagulate and perforate the cyst capsule. The contents are then aspirated, adequate irrigation is maintained using lactated ringer's solution in a pulsed or continuous fashion. A pair of 1 mm punch biopsy forceps may be used to remove the cyst capsule and colloid material. The third ventricle and aqueduct are inspected for any debris or blockage at the end of the procedure.

A ventricular access device is left in the tract left by the endoscope and connected to an Ommaya reservoir that can be later converted to a shunt if required. Gel foam is placed at the cortical opening to help prevent a CSF leak.

Microsurgical approaches to cyst removal

Transcortical, transventricular approach

Most colloid cysts are located in the anterior third of the third ventricle and can be removed using a transcortical, transventricular approach as described by Dandy in the 1930s (Dandy, 1933).

Anterior third ventricular lesions are approached via a precoronal suture craniotomy, while more posterior lesions are approached via more frontally based openings allowing a more oblique posterior trajectory through the foramen of Monro. In the 1930s, Dandy resected part of the frontal lobe to access the third ventricle. This is now refined to a mere 10–15 mm cortical opening either transgyral or preferably trans-sulcal. Large tumours can be approached via an ipsilateral approach while smaller cysts can be accessed with a contralateral approach. Although this can be used in patients with normal ventricles, it is ideally used when hydrocephalus is present.

The common postoperative complications include epilepsy (9.3%), meningitis (3.3%), wound infections, and memory problems due to fornix injury. Total removal was possible in 87 of 88 reported cases (98.8%). Charalampaki et al. have described 100% removal of colloid cysts with an endoscopically assisted transcortical-transventricular technique (Charalampaki et al., 2006).

Table 33.2 Postoperative complications comparison

Treatment	Seizures	Memory deficit	Intravent haemorrhage	Venous infarct	Intracerebral haematoma	Subdural haematoma	Arterial infarct	Hemiparesis	Meningitis	Overall
Endoscopy n = 666	0.3%	5.0%	1.2%	0%	0%	0.2%	0.3%	0.9%	2.7%	10.5%

Interhemispheric, transcallosal approach

The advantages of this approach are that it can be utilized in the absence of hydrocephalus, the access is through a relatively atraumatic corridor in the midline and via a small callosotomy, which gives a direct route to the colloid cyst.

However, the technique is technically more demanding and nearby vascular structures are vulnerable to damage. These include the superior sagittal sinus, cortical bridging veins, the anterior cerebral, and pericallosal arteries. Transient hemiparesis can be seen afterwards. A disconnection syndrome can be avoided by keeping the callosotomy less than 2 cm long in the anteroposterior (AP) dimension. Mutism can result from bilateral retraction of the supplementary motor areas within the cingulate gyri and fornix damage causing memory difficulties is a constant risk.

The interhemispheric, transcallosal approach is carried out under general anaesthetic with the head held in pins. The neck should be flexed and the operating table positioned in a 15° head-up position. Neuronavigation is helpful in planning the craniotomy site and trajectory by locating an avascular corridor away from cortical bridging veins. The typical craniotomy flap crosses the midline and is 4 cm anterior and 2 cm posterior to the coronal suture. The approach to the corpus callosum is down the falx and between the cingulate gyri. The Calloso-marginal and pericallosal arteries are identified and taking care to avoid placing a retractor directly on the vessels, may be gently retracted with the ipsilateral hemisphere on each side. An anterior callosotomy of 2 cm or less is made to access the lateral ventricle. The ventricle laterality is determined by the orientation of the choroid plexus, thalamostriate vein, and foramen of Monro before one of the following trajectories is utilized.

A paraforniceal approach may be adopted for smaller lesions presenting through the foramen of Monro that can be directly approached through the foramen and excised without the need to enter the third ventricle.

An interforniceal approach may be used for larger lesions and those located more posteriorly or where there is an associated cavum septum pellucidum. Dissection progresses between the two leaves of the septum pellucidum and the two fornices to access the third ventricle through the velum interpositum between the internal cerebral veins. The biggest disadvantage of this technique is the vulnerability of the fornices to bilateral injury, which can lead to severe antegrade amnesia (Sweet et al., 1959). In patients with larger cysts, the fornices may be splayed open by the cyst, making it easier to access by this route (**Figs. 33.9, 33.10,** and **33.11**).

A subchoroidal approach is used to avoid forniceal damage. The foramen of Monro can be enlarged posteriorly via subchoroidal dissection through the taenia thalami. This was popularized by Lavyne and Patterson (1983). This approach is limited by the terminal portion of the thalamostriate vein and although some authors have described division of the thalamostriate vein this needlessly risks venous infarction within the thalamus and is therefore not recommended.

A transchoroidal approach which similarly is fornix sparing can be adopted by dissecting past the choroid plexus on the medial side through the taenia fornices (Wen et al., 1998). This avoids the thalmostriate vein as it drains into the internal cerebral vein, however, the internal cerebral vein is still at risk within the velum interpositum. The fornix must also be protected with this approach.

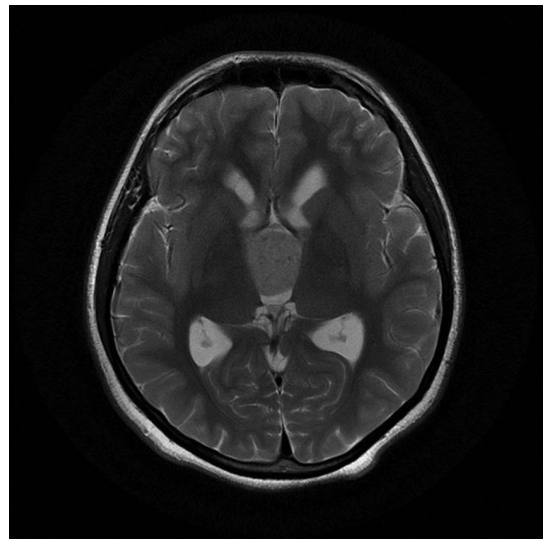

Fig. 33.9 Large colloid cyst with forniceal columns pushed apart.

The main disadvantage of both subchoroidal and transchoroidal approaches is the potential risk to the thalamostriate and internal cerebral veins. However, with large tumours, the choroidal fissure may be splayed by the underlying cyst which facilitates access.

Frontal translamina terminalis approach

This approach utilizes either a subfrontal dissection or paramedian interhemispheric route to the lamina terminalis. It is advantageous to utilize this approach for third ventricular colloid cysts in the anterior third ventricle or those encroaching into the suprachiasmatic recess (Desai et al., 2002).

There is currently no literature available on combining endoscope-assisted cyst excision with an approach through the lamina terminalis, although it has been shown to be feasible in cadaveric studies (Abdou and Cohen, 2000). This may be an area for development in the future.

Fig. 33.10 Sagittal T2-weighted MRI of large colloid cyst.

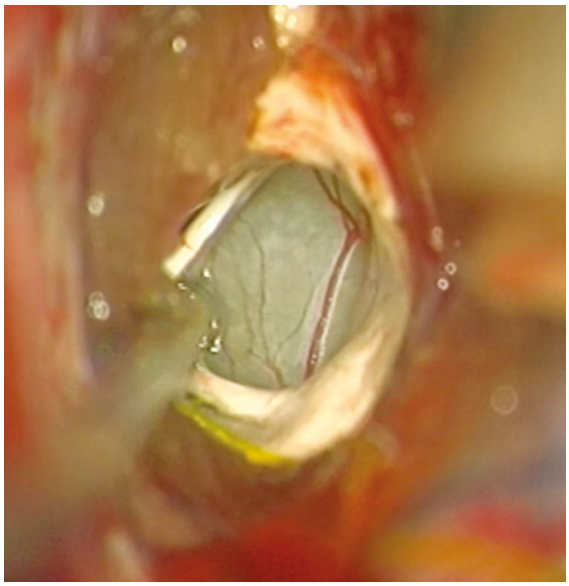

Fig. 33.11 Interhemispheric transforniceal approach. The left lateral ventricle has been accessed and the septum pellucidum then split to view the colloid cyst in this patient, with the preoperative scan findings seen in Figures 33.9 and 33.10. Controversies in management

Smaller cysts, less than 1 cm in size which are picked up incidentally, pose a clinical dilemma. It can be challenging to determine whether these cysts are truly incidental or not because a vast proportion of the CT scans performed are in fact requested due to episodes of headache. A careful clinical evaluation is required that may sometimes, include a period of intracranial pressure (ICP) monitoring. It may be difficult to counsel patients on the importance of reporting headaches, as a sign of incipient hydrocephalus, when they have had headaches of sufficient severity to warrant neuroimaging in the first place. This may therefore lower the threshold for surgical intervention, depending on the psychological state of the patient.

The frequency of radiological surveillance required for patients with conservatively managed cysts, such as the very small incidental cysts with no symptoms, unrelated headaches, or classic migraine, is not clear.

Choosing between an endoscopic and microsurgical approach is also an area of controversy. Both techniques have their pros and cons as described earlier and in Tables 33.1 and 33.2. While the endoscopic approach offers a smaller craniotomy and cortical tract, it is necessary for the ventricles to be sufficiently enlarged and it may be difficult to remove all the cyst capsule and therefore the recurrence rates are higher. In general terms, the choice of the procedure type (endoscopic vs. microsurgical) comes down to the experience/expertise of the surgeon and his/her frank discussions with the patient. With regards the route for microsurgical approaches (transcortical or transcallosal)—again this largely comes down to surgeon preference. While some surgeons argue the transcortical approach gives a better angle of approach to tackle most colloid cysts, the ventricles need to be sufficiently enlarged and the risk of epilepsy is increased. In contrast, an interhemispheric approach can be used in patients with small or large ventricles. Taking into account patient preference, our unit policy is to offer microsurgery in younger fit patients where there is likely to be more tolerance of a major procedure and where long-term cyst control is of greater importance. Endoscopic approaches being reserved where the cyst anatomy and morphology are favourable and are appropriate in a slightly older age group where the complications of surgery may not be so well tolerated. Finally, cyst aspiration or CSF diversion alone is generally used in the least fit patients or older people where long-term control is a less significant factor. However, the most important factor in the choice of any of these approaches is operator experience.

Choroid plexus tumours

Jonathan Roth, Rina Dvir, and Shlomi Constantini

Introduction

Choroid plexus tumours (CPT) are rare intraventricular tumours that originate from the choroid plexus epithelium. According to the 2007 and 2016 WHO classification, there are three tumour subtypes (Wrede et al., 2009; Menon et al., 2010; Dudley et al., 2015; Louis et al., 2016):

- Choroid plexus papilloma (CPP), which is benign and compose roughly 40–60% of CPT
- Choroid plexus carcinoma (CPC), which is malignant and compose roughly 30–50% of CPT
- Atypical choroid plexus papilloma (ACPP), which is an intermediate subtype and compose roughly 10–30% of CPT

Typically, CPT are considered more prevalent in the infantile age group; however, CPT may present in adulthood too.

In this chapter, we discuss the main diagnostic, genetic, and treatment-related aspects of CPT.

Epidemiology

CPTs occur mainly in infants before the age of 2 years (Lam et al., 2013); however, it may occur in older children and adults (Turkoglu et al., 2014). Their prevalence, pathology, and anatomical distribution differ between age groups (Lam et al., 2013). CPT represent 2–5% of paediatric brain tumours, as opposed to 0.4–0.8% of adult brain tumours. CPT often present as congenital/neonatal tumours and comprise 10–20% of brain tumours diagnosed during the first year of life (Serowka et al., 2010; Lang et al., 2012; Sun et al., 2014b).

Pathology also differs between age groups. CPC and ACPP are more common in the infantile age group, with a median age for CPC of 3 years old. There is a slight male predominance, possibly linking CPT to an x-linked mutation (Menon et al., 2010; Dudley et al., 2015).

CPT typically occur in the ventricular system since they arise from the choroid plexus. In children, they are typically located in the lateral ventricle, mostly at the atrium (**Fig. 34.1**). Third ventricular CPT are rare, occurring mostly in infants (Gupta et al., 2013) (**Fig. 34.2**). In adults, most CPT occur in the posterior fossa, mostly in the fourth ventricle (Bostrom et al., 2011). While CPPs are almost always confined to the ventricular system, CPCs are not usually limited in that way. CPC may reach very large sizes, often presenting as a large hemispheric tumour in an infant.

CPC is associated with worse overall survival (OS) compared to CPP and ACPP (Lam et al., 2013; Dudley et al., 2015). OS at 5 years for CPP following complete resection ranges between 84% and 100% (Wrede et al., 2009; Lam et al., 2013; Dudley et al., 2015). In contrast, CPC is a highly malignant tumour with a dismal prognosis despite multimodal treatment, with OS at 5 years of about 26–70% (Wrede et al., 2009; Lam et al., 2013; Dudley et al., 2015). Most ACPP have an OS rate similar to CPP, however a small subgroup displays the biological behaviour and prognosis of CPC (Wrede et al., 2009).

Presenting symptoms

CPP are one of two entities leading to overproduction of CSF (the other being choroid plexus hyperplasia (CPH)). CPP may produce up to 5 litres per day (Fujimura et al., 2004; Cataltepe et al., 2010; Nimjee et al., 2010), often with a high protein level. Thus, CPP may lead to hydrocephalus secondary to several causes: CSF overproduction, CSF pathway obstruction, and CSF malabsorption. Many of the patients with CPT present with hydrocephalus (Pencalet et al., 1998; Bettegowda et al., 2012; Sun et al., 2014b) (**Figs. 34.2, 34.3, 34.4,** and **34.7**).

Signs and symptoms of increased intracranial pressure secondary to hydrocephalus in infants include increased head circumference, upward gaze limitation, general hypotonia, bulging fontanel, vomiting, and failure to thrive (FTT). In older children and adults, symptoms often include headaches, nausea/vomiting, visual decline, and focal signs depending on the exact location (Lang et al., 2012).

As CPC are often large invading tumours, they may present with symptoms secondary to a hemispheric mass effect (leading to elevated intracranial pressure and seizures) (**Fig. 34.3**). APCC are more closely related to CPP than to CPC (**Figs. 34.2** and **34.4**). They are often of intermediate size, located in the ventricle, and generally do not invade the surrounding hemisphere. They are more prevalent in the infantile age group, but may present in adulthood too.

Diagnosis

CPTs are located mostly within the ventricular system. As stated earlier, most CPP in the paediatric age group arise in the lateral ventricle, mostly at the atrium, as opposed to CPP in adult patients, which are located most commonly in the fourth ventricle (Figs. 34.1, 34.3, 34.4, 34.6, and 34.7). CPT have been described in the third ventricle (Mishra et al., 2014) and cerebellopontine angle (CPA) (Menon et al., 2010; Prasad et al., 2014), originating from the local choroid plexus (Figs. 34.2 and 34.5). CPP may also occur extraventricularly, in the pineal region (Sasani et al., 2014), brainstem (Xiao et al., 2013), sellar/suprasellar region (Bian et al., 2011), and brain parenchyma (Imai et al., 2011).

The classical radiological appearance of CPP is of a cauliflower-like lesion, isointense on T1, with brisk and homogeneous enhancement (Fig. 34.1). However, in rare instances they may not enhance (Pratheesh et al., 2009). They are often isohyperintense on T2 (Figs. 34.1, 34.5, 34.6, and 34.7). On CT they are usually isodense with mild calcifications. CPP may rarely be cystic with mural nodules (Emami-Naeini et al., 2008). ACPP generally resembles CPP radiologically (Figs. 34.2 and 34.4).

CPC often have a large, non-homogenous enhancing appearance. Leptomeningeal spread (or drop metastasis) is rare in CPP (about 5%). However, it may occur in ACPP and CPC in up to 50% of cases, thus a spinal MRI is indicated (Menon et al., 2010, Wrede et al., 2009) (Fig. 34.3). It is unclear if surgery is a risk factor for drop metastasis (Sun et al., 2014b).

Of major importance is the blood supply. The choroidal vessels are often engorged, leading to large deep-seated veins—including thalamostriate, atrial vein, internal cerebral vein, and vein of Galen. These arteries and veins are usually located on the deep/medial aspect of the tumour. Peripherally located draining ependymal veins are also common, especially in large and high-grade CPT. Digital subtraction angiography (DSA) often shows an early tumour blush, with prominent choroidal arteries.

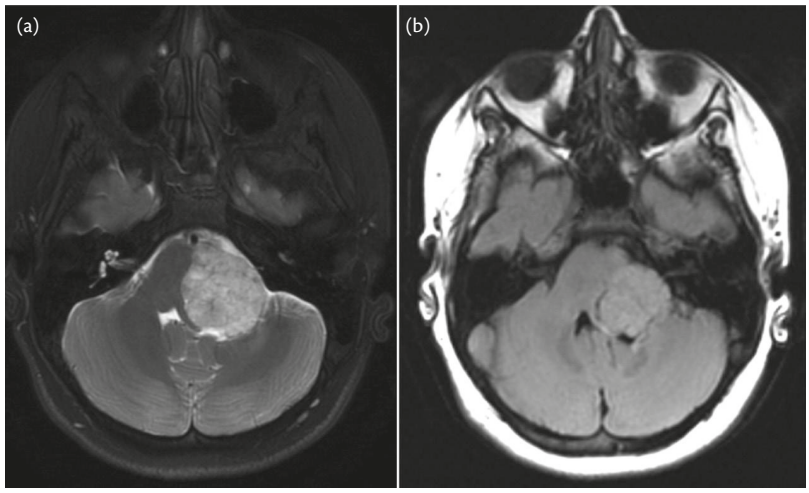

Fig. 34.5 A 12-year-old child with a CPP. Axial T2 (A) and T1 (B) MRI scans, showing a CPA lesion. The lesion was completely resected.

Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

Hydrocephalus is commonly seen secondary to the various mechanisms stated here earlier.

Pathology

CPC display the classic histopathological signs of malignancy such as a high mitotic index, cellular atypia, and brain invasion (Fig. 34.8). In contrast, CPP are benign papillary neoplasms resembling non-neoplastic choroid plexus (Fig. 34.9). Nevertheless, despite the obvious histological differences, there is a histological continuum between choroid plexus hyperplasia (CPH), CPP, ACPP, and CPC (D'Ambrosio et al., 2003). However, genetic and molecular studies in CPT are limited. Although rare, malignant transformation of CPP and ACPP to CPC has been described (Jeibmann et al., 2007).

While CPH is a non-tumoural pathology with no growth potential, differentiation between CPH and CPP may be difficult (D'Ambrosio et al., 2003; Cataltepe et al., 2010). Various measures have been used to differentiate between the two pathologies, including MIB-1 proliferative index (in CPH it is close to 0, while in CPP it ranges between 0.2 and 17). Histologically, CPT are differentiated from normal choroid plexus by EAAT-1 expression. EAAT-1 is a glial glutamate transporter that is commonly seen in CPT, and is absent in normal choroid plexus (Beschorner et al., 2009).

Since 2007 (and remaining in the 2016 version), the WHO described an intermediate group—*atypical CPP* (ACPP) (Louis et al., 2016). These tumours resemble CPP but with increased mitotic activity (≥2 mitoses/10HPF) (Jeibmann et al., 2006). ACPP tend to occur in younger patients compared to CPP and CPC (Wrede et al., 2009; Lam et al., 2013). OS for ACPP is similar to OS for CPP in young children, but is considered a poor prognostic factor in children older than 3 years old (Thomas et al., 2015).

CPC is one of the characteristic paediatric tumours of Li-Fraumeni syndrome (LFS), a familial cancer predisposition syndrome characterized by a high frequency of malignant tumours at a young age. TP53 germline mutations are the genetic hallmark of

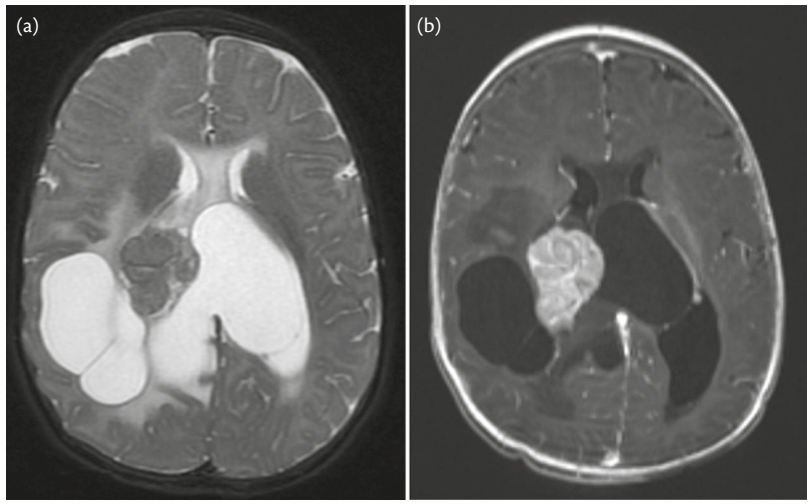

Fig. 34.7 A 5-month-old child with CPP. Axial T2 (A) and T1-Gad (B) MRI scans, showing a ventricular tumour with an accompanying cyst. The tumour was completely resected.

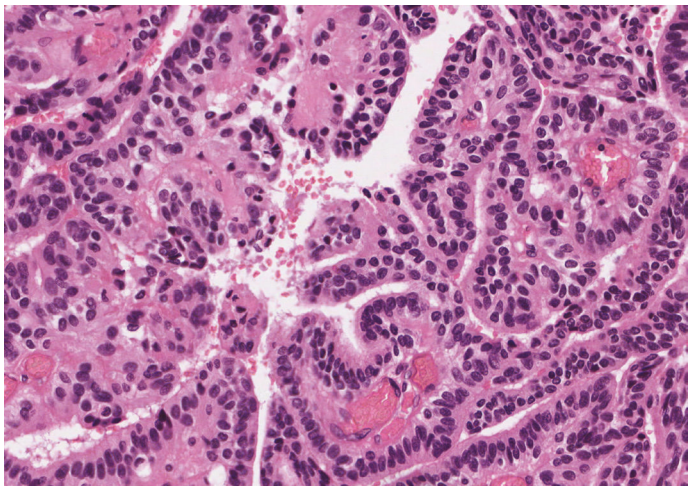

Fig. 34.8 Atypical choroid plexus papilloma—atypical examples such as this display raised mitotic activity and variable loss of the papillary pattern.
Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

LFS. Patients with CPC should be screened for Li-Fraumeni syndrome (TP53 germline mutations) (Gozali et al., 2012; Giacomazzi et al., 2013).

Genetic and molecular studies have shown similarities between CPP and ACPP (Merino et al., 2015). It has been suggested that ACPP represents an immature variant of CPP, characterized by increased proliferative activity, whereas CPC seem to represent a genetically distinct tumour (Japp et al., 2015). CPC is highly correlated with TP53 mutations, where more copies of mutated TP53 are associated with increased CPC aggressiveness and a worse rate of survival (Merino et al., 2015). These mutations can either be part of a germline LFS or somatic TP53 mutations in the tumour tissue itself.

CPC and ATRT (atypical terato-rhabdoid tumour) may show similar histological appearances. However, INI1 protein staining is positive in CPC and negative in ATRT, differentiating between the two (Stevens et al., 2009; Sun et al., 2014b).

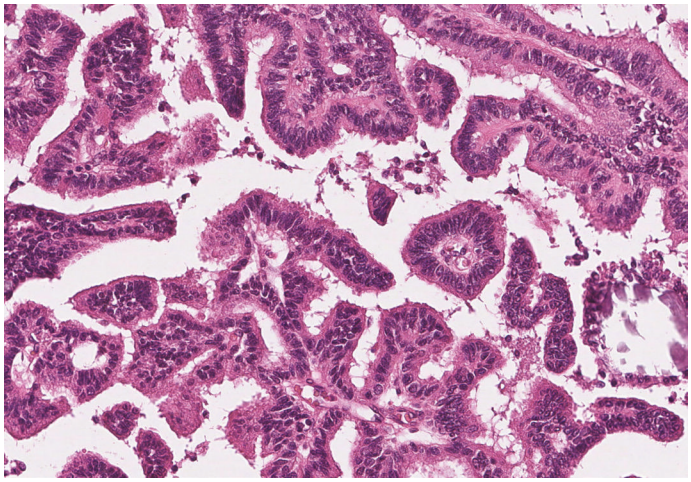

Fig. 34.9 Choroid plexus papilloma—a papillary architecture composed of epithelium overlying fibrovascular cores. Mitotic figures are rare in this grade I example.
Courtesy of Dr Kieren Allinson, Department of Pathology, Addenbrooke's Hospital, Cambridge.

Treatment

Complete surgical resection (gross total resection, GTR) is the cornerstone of treatment for CPP, ACPP, and CPC, in both paediatric and adult patients (Wrede et al., 2009; Safaee et al., 2013; Koh et al., 2014; Sun et al., 2014a; Dudley et al., 2015). Various series have shown a significant correlation between complete resection, overall survival, and progression-free survival (Sun et al., 2014a; Dudley et al., 2015). GTR is more commonly achieved in CPP (80–100%) compared to ACPP (63%) and CPC (47–62%) (Pencalet et al., 1998; Wrede et al., 2009). Tumour recurrence following GTR is estimated at about 30% in ACPP, and about 6% in CPP (Jeibmann et al., 2007).

As CPT are more common among infants and are often extremely vascular, several technical points need to be addressed in order to improve patient safety and decrease blood loss and patient morbidity.

Preoperative embolization

Preoperative embolization (PE) has been described in a small number of series, with encouraging results. Super-selective embolization of the feeding arteries via the anterior or posterior choroidal arteries, using various materials such as microspheres, NBCA, onyx, and histoacryl glue, has been shown to significantly reduce blood loss and improve the surgeon's resection control and extent of resection (Takahashi et al., 2009; Trivelato et al., 2012; Haliasos et al., 2013b; Wang et al., 2013). Interestingly, PE was found to reduce CSF production following surgery; however, it did not reduce the need for permanent CSF diversion (Haliasos et al., 2013a). In a single case report, embolization was performed in a three-month-old baby to treat a third ventricular tumour suggestive of being a CPP (Wind et al., 2010). Following embolization, the tumour completely involuted.

Age was not found to limit the ability to safely enter the feeding vessels and embolize the tumours, with PE performed in babies even in the neonatal period and during first few months of life (Otten et al., 2006; Hartge et al., 2010; Wind et al., 2010).

Surgical resection

Anaesthesia-related factors include preoperative preparation of sufficient blood products. At surgery, large venous access lines (as well as a central line if necessary), and an invasive arterial-line should be placed. Major blood loss and the need for massive transfusions is a major point to be addressed, especially among infants (Piastra et al., 2007).

Positioning of the patient should allow good venous drainage with no compression on the jugular veins. The head should be raised above the level of the heart. The surgical corridor should be comfortable. These cases may be extremely bloody, and a small 'minimal-invasive' approach may restrict the surgeon's comfort as well as the patient's safety.

The surgeon must attempt early identification and control of the feeding vessels. Nevertheless, often, especially in large tumours, the vessels are exposed only after a major debulking of the tumour has been performed. Thus, in such cases, an efficient technique should be applied, including removing parts of the tumour, coupled with blood products as needed, and tamponade every few minutes to reduce blood loss. Continuous surgeon-anaesthesiologist updates are paramount in such cases, to alert the surgeon once hypovolemic

signs arise, and alert the anaesthesiologist regarding any major bleeding. The very large tumours (especially CPC) may necessitate many blood product transfusions. Tranexamic acid (TXA)—an antifibrinolytic agent—has been suggested to reduce operative blood loss in small children with CPT (Phi et al., 2014).

Luckily, most CPP are soft and easily aspirated by suction. Thus, a relatively fast tumour removal may be achieved, exposing the feeding vessels, and allowing for their coagulation and control. It is important to 'protect' the surrounding ventricle (especially the regions of the foraminae of Monro) from blood spillage, to avoid casts of blood in the ventricular system. Following tumour resection, it is important to inflate the ventricular system with irrigation, as following CSF drainage may trigger subdural hematomas and collections (Pencalet et al., 1998). Some surgeons have advocated 'sealing' the corticectomy opening with fibrin glue (Pencalet et al., 1998).

Surgical approaches to the ventricular system depend on the exact location as well as size of the tumour and ventricles, and vascular supply. Generally, lesions located at the atrium are often located posterior-laterally, thus limiting interhemispheric approaches. These may be approached transcortically, via the low parieto-occipital junction, taking into account optic radiation fibres, as well as arcuate fibres (especially on the dominant side), or via superior parietal lobule. Another approach to the atrium is the contralateral interhemispheric translingual approach. Other transtemporal/transparietal approaches depend on dominance and cortical mantle over the tumour. Tumours located at the body of the lateral ventricle may be approached via a transcallosal approach. Third ventricular tumours may be approached via a transforaminal with or without a transchoroidal extension, or via a posterior approach, as though to the pineal region. Recently, endoscopic resections of third ventricular choroid plexus tumours have been described (Santos and Souweidane, 2015; Sufianov et al., 2015). CPA lesions may be approached via a retrosigmoid approach, and a fourth ventricular lesion can be approached via a telovelar approach.

CPT of the fourth ventricle may invade the brainstem (Kumabe et al., 2008). Thus, these cases should be operated while using intraoperative monitoring, possibly performing a subtotal resection and adding adjuvant treatment.

It has been shown that hydrocephalus may persist even following complete tumour resection. This may be secondary to prior compromised absorption, in addition to the reaction to surgical blood products. Obstructive hydrocephalus may arise from local adhesions at the foramen of Monro or aqueduct. Also, secondary to major ventricular involvement and spillage of blood products, postoperative fever is common, and may need to be differentiated from infectious causes. Thus, following tumour resection, the ventricular system needs to be irrigated to remove blood clots. An external ventricular drain (EVD) is often placed to allow clearance of CSF over a few days.

In cases presenting with severe hydrocephalus, an early EVD may control the intracranial pressure prior to resection of the tumour. However, especially in small children, severe electrolyte imbalance may follow (Phi et al., 2011).

Radiation and chemotherapy

CPP is generally considered a benign tumour, which does not require treatment after a gross total resection has been achieved. CPC is a highly proliferative malignant tumour that can metastasize along the neuroaxis and generally has a poor survival outcome. The mainstay of CPC treatment is surgery with adjuvant chemotherapy. In selected cases, neoadjuvant chemotherapy is administered prior to definitive surgery. Older children and adults are often treated with chemo-radiotherapy protocols. Several chemotherapy regimens are employed in CPC, including ICE (ifosfamide, carboplatin, and etoposide) (Berrak et al., 2011) and regimens containing multiagent chemotherapy (carboplatin, cyclophosphamide, etoposide, doxorubicin, and methotrexate) (Passariello et al., 2015). ICE has been used also as a neoadjuvant treatment prior to tumour resection, increasing the rates of GTR and reducing blood loss (Lafay-Cousin et al., 2010; Schneider et al., 2015). Some institutions employ myeloablative high-dose chemotherapy with stem cell support either as upfront treatment (Zaky et al., 2015), or as a salvage treatment for relapsed cases (Mosleh et al., 2013). The 5- and 10-year overall survival for CPC following GTR is 70% and 67%, respectively (Dudley et al., 2015).

The benefit of radiation in CPC treatment remains a matter of debate. In a recent population-based study, radiation failed to improve OS of patients with CPC (Cannon et al., 2015; Dudley et al., 2015). However, in another meta-analysis published in 2014, radiation conferred a survival advantage to patients that underwent complete or incomplete resection of CPC (Sun et al., 2014b). In CPC associated with Li-Fraumeni syndrome, radiation has been associated with poorer OS rates (Bahar et al., 2015).

Stereotactic radiosurgery (SRS) has been selectively applied for refractory tumours (Kim et al., 2008). It may also be applied for small and/or distant tumours that recurred following surgery.

Adjuvant treatment of ACPP is controversial. In younger patients, ACPP is not considered a bad prognostic factor. Complete resection followed by 'watch and see' is the accepted regimen (Thomas et al., 2015). In children older than 3 years of age, a close follow-up after GTR is recommended because of the prognostic impact of ACPP (Thomas et al., 2015).

For incompletely resected ACPP, adjuvant chemotherapy is the accepted treatment. Similar to the CPC treatment protocols, various treatment regimens exist, including high-dose chemotherapy and stem cell rescue (Mosleh et al., 2013; Zaky et al., 2015). This protocol postpones radiotherapy usage, depending on the child's age and status of residual tumour.

Favourable prognostic factors for CPC include supratentorial location, GTR of tumour, no TP53 mutation (either somatic or germline), age older than 3 years of age, no tumour dissemination, no tumour recurrence, and adjuvant treatment (Sun et al., 2014b).

Surgical management of intraventricular lesions

Eduardo C. Ribas, Guilherme C. Ribas, and Ramez W. Kirollos

Anatomy of the lateral and third ventricles

Anatomy of the lateral ventricles

Deep inside each cerebral hemisphere, the lateral ventricle is found encircling the thalamus, which is characterized as an ovoid mass. The lateral ventricle is subdivided into openly communicating portions that receive different denominations according to their disposition in relation to the thalamus, the frontal horn corresponds to the ventricular portion located anterior to the thalamus, the ventricular body is the portion disposed over the thalamus, the atrium, or ventricular trigone, is located posterior to the thalamus, the temporal horn of the ventricle is placed beneath the thalamus and the occipital horn corresponds to a variable posterior extension of the atrium, which narrows progressively to one end (Timurkaynak et al., 1986; Rhoton, 2003) (**Figs. 35.1, 35.2, 35.3,** and **35.4**). Between the frontal horn and the body of each lateral ventricle, the interventricular foramen of Monro can be found, connecting each lateral ventricle with the third ventricle.

Each of these five portions has a floor, a roof, a lateral and a medial wall, with the frontal and temporal horns, and the atrium, also having an anterior wall (Timurkaynak et al., 1986; Ribas, 1999; Rhoton, 2003). Besides the thalamus, other structures that delimit the lateral ventricle portions are the corpus callosum, caudate nucleus, hippocampus, fornix, amygdala, the stria terminalis, and septum pellucidum.

The hippocampus is composed by Ammon's horn, characterized as an exuberant intraventricular prominence of the parahippocampal gyrus, and by the dentate gyri, disposed medially along the superior, medial, and flat surface of the parahippocampal gyrus called the subiculum (Williams and Warwick, 1980; Wen et al., 1999). The hippocampus is constituted by allocortex, characterized by three layers of cells, and is covered by the alveus which corresponds to the white matter formed by the axons of the neurons of these different cell layers (Williams and Warwick, 1980; Heimer, 1995; Duvernoy, 1998). It is interesting to note that, as other phylogenetically old nervous structures as the cord and brainstem, the white matter of the hippocampus is disposed externally and not internally.

Macroscopically the hippocampus is formed anteriorly by a head and a body which together constitute the medial aspect of the floor of the temporal horn, and by its tail that ends at the medial wall of the ventricular atrium (Timurkaynak et al., 1986; Rhoton, 2003).

The fornix arises along the hippocampus as the convergence of the alveus' fibres that form initially the thin fimbria of the fornix, which constitutes the most medial structure of the floor of the temporal horn. As the fornix continues posteriorly it encircles the most posterior part of the thalamus, called the pulvinar, assuming a form that resembles a tape called crura (the leg) of the fornix. Both crura of the fornices are connected together by the commissure of the fornix or hippocampal commissure, which are then attached to the inferior surface of the splenium of the corpus callosum. The fimbria of the fornix continues anteriorly and medially with the crura of the fornix turning into the body of the fornix, which is juxtaposed to the body of the contralateral fornix. The most anterior segment of the body of the fornix then detaches from the superior thalamic surface moving again away from the contralateral fornix with an anterior-lateral and inferior course becoming the column or pillar of the fornix. Most of its fibres run posteriorly to the anterior commissure, and penetrates the hypothalamic parenchyma to finally reach the ipsilateral mammillary body of the hypothalamus (**Figs. 35.2** and **35.3**). When detaching from the thalamus each column of the fornix becomes the anterior margin of the interventricular foramen of Monro, the posterior margin of which is formed by the most anterior aspect of the ipsilateral thalamus (Timurkaynak et al., 1986; Nagata et al., 1988; Rhoton, 2003). Given their locations, the crura of the fornix corresponds to the most medial aspect of the anterior wall of the atrium, and the body of the fornix to the most medial aspect of the floor of the ventricular body.

The choroidal fissure is the cleft between each thalamus and each fornix and corresponds to the insertion site of the choroid plexus to these two structures along two small ridges (taenia), respectively, the tenia thalami (or choroidea) and the tenia fornices. It extends between the inferior choroidal point, located just next to the transition between the head and body of the hippocampus at the level of the lateral geniculate body, and the interventricular foramen of Monro, which then corresponds to a widening of this cleft as a result from the detachment of the column of the fornix from the thalamus (Nagata et al., 1988; Rhoton, 2003) (**Fig. 35.3**). Since the choroidal fissure encircles the thalamus, there is no choroid plexus in the frontal and occipital horns (Nagata et al., 1988; Wen et al., 1998).

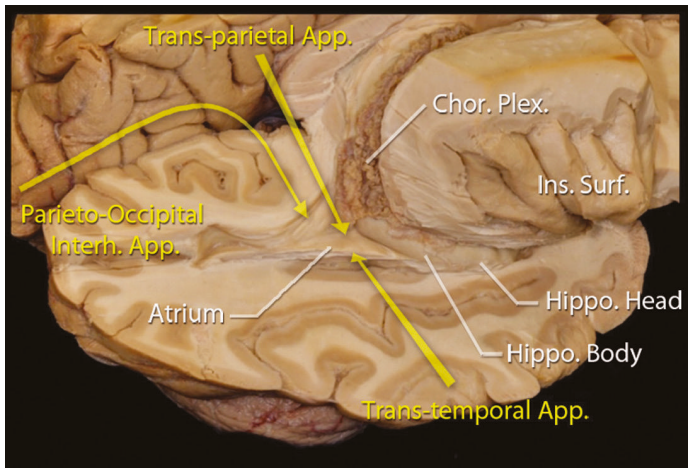

Fig. 35.1 The atrium of the lateral ventricle is exposed by a coronal cut posterior to the thalamus and an axial cut at the level of the temporal horn, and three usual approaches (yellow arrows) to this region are shown.

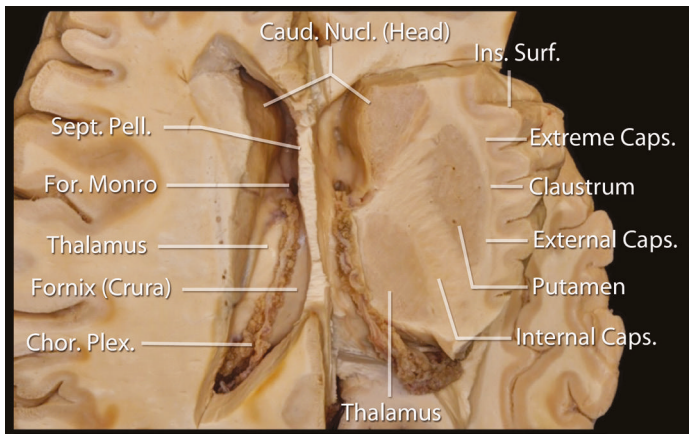

Fig. 35.2 At the left, an axial cut at the level of the roof of the lateral ventricle opens this cavity. At the right, a more caudal axial cut crosses the central core of the brain and reveals its structures: basal ganglia, thalamus, and white matter capsules. Note the proximity of the genu of the internal capsule to the ependymal surface at the level of the foramen of Monro.

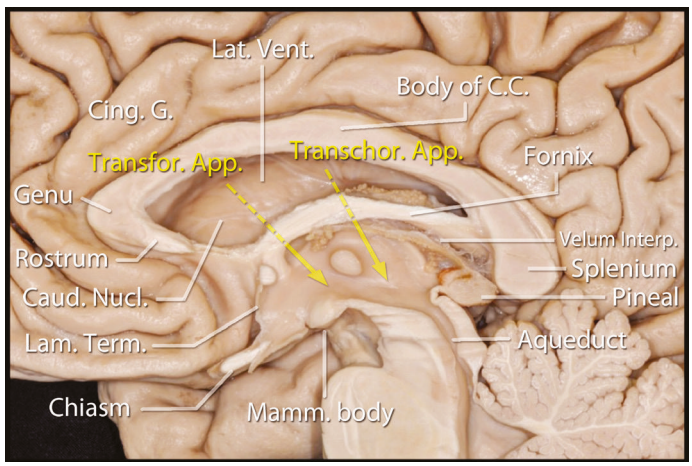

Fig. 35.3 A midline sagittal cut crosses the corpus callosum and exposes the third and lateral ventricle (anterior horn and body). Yellow arrows depict possible surgical approaches to these cavities.

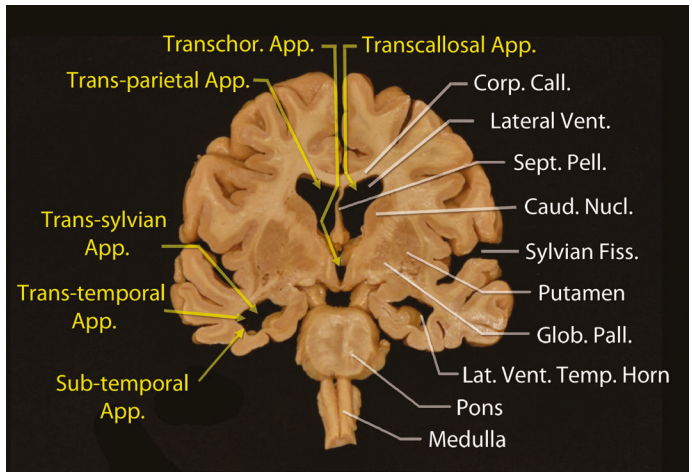

Fig. 35.4 A coronal cut through both hemispheres at the level of the foramen of Monro depicting the various approaches (yellow arrows) to the lateral and third ventricles.

Lateral and parallel to each fornix, the caudate nucleus also encircles the thalamus more laterally, and is constituted by a head, a body, and a tail, which respectively constitute the lateral wall of the frontal horn, the lateral wall of the ventricular body, the most lateral aspect of the anterior wall of the atrium, and the medial aspect of the roof of the temporal horn. The tail of the caudate nucleus ends anteriorly merging with the amygdala, which constitutes the anterior wall of the temporal horn (Wen et al., 1999).

Along the medial side of the caudate nucleus, the stria terminalis is found running over the thalamic-striate sulcus between the thalamus and the caudate nucleus also with a C-shaped configuration. This structure is constituted by a thin bundle of fibres originating at the amygdaloid complex, and ends under the head of the caudate nucleus at a nucleus called 'the bed nucleus of the stria terminalis' (Williams and Warwick, 1980; Heimer, 1995). Within the body of the ventricle the stria terminalis runs underneath the thalamostriate vein.

The upper surface of the thalamus constitutes the floor of the ventricular body, and its posterior surface, called the pulvinar, constitutes the middle portion of the anterior wall of the atrium, between the laterally placed tail of the caudate nucleus and the medially placed crura of the fornix. The medial surfaces of both thalami constitute the lateral walls of the third ventricle (Yamamoto et al., 1981), and their most posterior and inferior surfaces, medial to both choroidal fissures, constitute the roofs of the both sides of the transverse fissure of the brain, which harbour the ambient cisterns and part of the quadrigeminal cistern.

The corpus callosum is distinguished as the largest cerebral commissure, composed of fibres that connect almost all of the cortex in both hemispheres (Fig. 35.3). Exceptions are the anterior portion of the temporal lobes that are connected by the anterior commissure, the primary visual areas, and most of the somatosensory areas which are not interhemispherically connected (Brodal, 1981). Along a midsagittal section the corpus callosum resembles roughly a hook facing forward and downward in relation to the brain. Its anterior portion is thicker and has a curve with an anterior convexity, called the genu of the corpus callosum, which harbours the forceps minor, a bundle of fibres that connects the poles and the anterior aspects of the

frontal lobes. Inferiorly, the genu continues with a thinner horizontal and basal portion known as the rostrum of the corpus callosum, which ends posteriorly at the anterior commissure and interconnects the fronto-orbital surfaces. Posterior to the genu, the body (Heimer, 1995; Rhoton, 2003) or trunk (Williams and Warwick, 1980) of the corpus callosum has an almost horizontal portion with a slight superior curve, and interconnects most frontal and parietal convexities. The trunk of the corpus callosum is continuous with the splenium, the most posterior and thicker portion of the corpus callosum, which harbours the forceps major, a bundle of fibres that connects the posterior parietal and occipital cerebral lobes (Williams and Warwick, 1980).

Morphologically, the corpus callosum can be understood as a set of transverse fibres that cross the midline and fan out in several directions in order to spread throughout both hemispheres. The fibres of the corpus callosum can be seen as a butterfly flapping its wings, where the body of the butterfly corresponds to the midline portion of the corpus callosum and the beat of each wing corresponds to the distribution of its fibres throughout each hemisphere.

Given the morphology of its fibres, the corpus callosum is closely related to the five portions of the lateral ventricles, forming a large part of the walls, lined with ependyma as with other ventricular surfaces.

Anteriorly, the rostrum and genu constitute respectively the floor and anterior wall of both frontal horns, while the trunk constitutes the roof of the frontal horns and of the ventricular bodies.

As the fibres from the splenium of the corpus callosum open up laterally and posteriorly, they constitute on each side the roof and the lateral wall of the atrium and posterior horn. As they extend medially and inferiorly to the atrium and posterior horn, they also constitute the medial and inferior walls of these ventricular portions. Therefore, the fibres of the splenium embrace the whole atrium and posterior horn, encircling them, and participating in the composition of all their walls.

On the medial wall of each atrium, a distinct prominence of the splenium can be seen and is called the bulb of the corpus callosum, and, more posteriorly, already on the medial wall of the posterior horn, another prominence called calcar avis is also usually seen, corresponding to an intraventricular bulging of the deep calcarine fissure.

The septum pellucidum consists of two thin membranes of white matter intermingled with scattered neurons and glial cells that form the medial walls of the ventricular frontal horns and bodies (Williams and Warwick, 1980). In each frontal horn, the respective septum pellucidum membrane is attached superiorly to the upper trunk of the corpus callosum, anteriorly to its genu, and inferiorly along its rostrum. At the ventricular bodies, the septum pellucidum membrane is attached superiorly to the trunk of the corpus callosum and inferiorly to each body of the fornices, which are disposed together medially (**Figs. 35.2** and **35.3**).

Given the rise of the bodies of the fornices as they run posteriorly, to finally end up joining the inferior surface of the splenium, the septum pellucidum progressively decreases in height along the anteroposterior direction, ending thus as a bevel. The posterior end of the septum pellucidum determines the posterior limit of the ventricular bodies and the anterior limit of the atriums (Timurkaynak et al., 1986; Rhoton, 2003).

The floor of each atrium and occipital horn consists of a flat and triangular area called the collateral trigone, the anterior extension of this trigone becomes prominent constituting the collateral eminence that forms the lateral aspect of the floor of the temporal horn. The medial half of the floor of the temporal horn is formed by the hippocampus, which corresponds to the intraventricular bulging of the parahippocampal gyrus, and which posteriorly has its macroscopic insertion on the medial wall of the ventricular atrium (Timurkaynak et al., 1986; Wen et al., 1999; Rhoton, 2003).

Despite the fact that the collateral trigone and eminence correspond to the intraventricular projection of the deep collateral sulcus of the basal surface of the brain, the floor of the atrium and of the temporal horn is placed mostly over the fusiform gyrus. Located medial to the inferior temporal gyrus and laterally to the parahippocampal gyrus, the fusiform gyrus is bounded laterally by the occipitotemporal sulcus and medially by the collateral sulcus (Ono et al., 1990). Between the fusiform gyrus and the floor of the atrium and temporal horn, the inferior longitudinal fasciculus is found.

The main white matter fibre bundles can be identified through fibre dissection (**Fig. 35.5**). The superior longitudinal fascicle is deep to the frontal, parietal, and posterior temporal lobes, and is lateral to the lateral ventricles. The extreme, external, and internal capsules are composed of several white matter pathways which run underneath the insular surface, but as their fibres continue towards the cerebral lobes, pass underneath the insular limiting sulci. The extreme capsule is formed by short association fibres which interconnect adjacent insular gyri and continue towards both opercula. The external capsule is medial to the claustrum and mainly formed by three major fibre bundles (uncinate fascicle, inferior fronto-occipital fascicle, and claustrofugal fibres), and the internal capsule is medial to the putamen and formed by projection fibres (mainly the pyramidal and corticopontocerebellar fibres). The anterior commissure passes underneath the antero-inferior pole of the globus pallidus, and its fibres connect both medial aspects of the temporal lobes.

The white matter that constitutes the lateral wall of the ventricular atrium and temporal horn constitutes the so-called sagittal stratum (Ludwig and Klinger, 1956), which lies underneath the subcortical temporal white matter (u-fibres, temporo-pontine-cerebellar fibres) and which is composed by the inferior fronto-occipital fascicle, anterior commissure fibres, and by the posterior thalamic peduncle which harbours the optic radiation fibres.

The optic radiation fibres originate at the lateral geniculate body region. While its anterior bundle is initially directed anteriorly forming a curve named Meyer's loop (Ebeling and Reulen, 1988) to after bends posteriorly, its central and and posterior bundles have a more straight and posterior course. Finally, these fibres will continue to run posteriorly towards the upper and lower banks of the calcarine fissure (Párraga et al., 2012) (**Fig. 35.5**). Underneath the visual radiation fibres, callosal fibres known as the tapetum (Williams and Warwick, 1980) are found, constituting the more internal and directly related fibres with the ventricular cavity. Fibres of the inferior thalamic peduncle, which is constituted particularly by the auditory radiation (Türe et al., 2000; Williams and Warwick, 1980), are found more anteriorly and superiorly to the temporal horn since they run towards the Heschl gyrus. See **Figure 35.6** for the brain structures related to each lateral ventricle.

Anatomy of the third ventricle

The third ventricle is a single cavity located in the centre of the brain, between the thalami (Yamamoto et al., 1981; Rhoton, 2003). It receives cerebrospinal fluid (CSF) from both lateral ventricles through

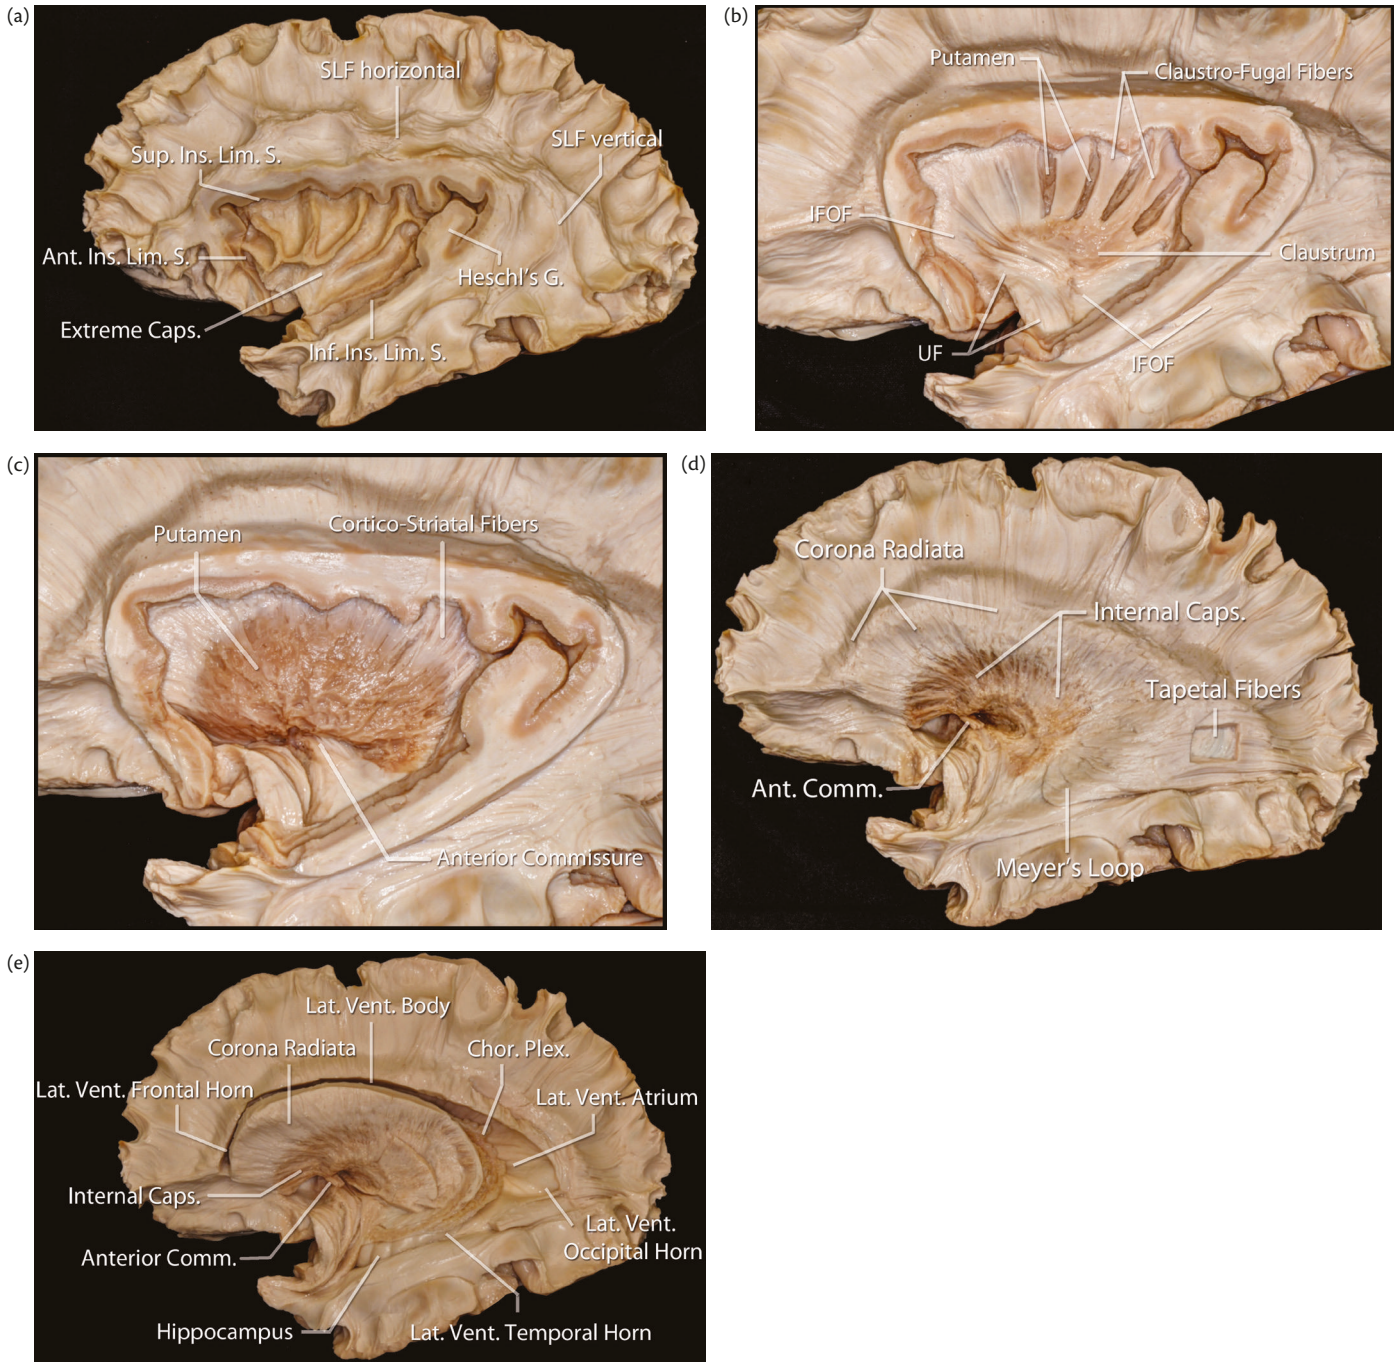

Fig. 35.5 Stepwise lateral fibre dissection of the left cerebral hemisphere demonstrating the insular and peri-insular white mater tracts related to the lateral ventricle. (A) The extreme capsule is made by short association fibres and is exposed after removing the insular cortex. The superior longitudinal fasciculus (SLF) is found outside the insular region, after decortication and removal of the more superficial short association fibres. (B) The inferior fronto-occipital and uncinate fasciculi (IFOF, UF) are found as the dissection progresses at the insular region, and their trajectory to others cerebral lobes can also be identified. (C) The removal of the previous white matter fibres leads to the exposure of the putamen and, inferiorly, anterior commissure fibres. (D) The internal capsule is found after removing the lentiform nucleus; the tapetum is formed by callosal fibres and found deeply, posterior to the insular region. (E) A deep circular cut was made along the outer margin of the insular region, leading to the wide exposure of the lateral ventricular cavity including the frontal horn, body, atrium, occipital horn, and temporal horn.

both foramina of Monro which are located next to each other at the anterior part of its roof, and drains into the fourth ventricle through the aqueduct of Sylvius, the opening of the aqueduct is located in the posterior part of the floor. Some CSF is also produced in this cavity by two small strains of choroid plexus located along the roof.

The anterior wall of the third ventricle is mainly formed by the lamina terminalis, which is a thin membrane that stretches from the anterior commissure (superiorly and posteriorly) to the optic chiasm (inferiorly and anteriorly) that forms a prominence already at the anterior margin of the floor (Yamamoto et al.,

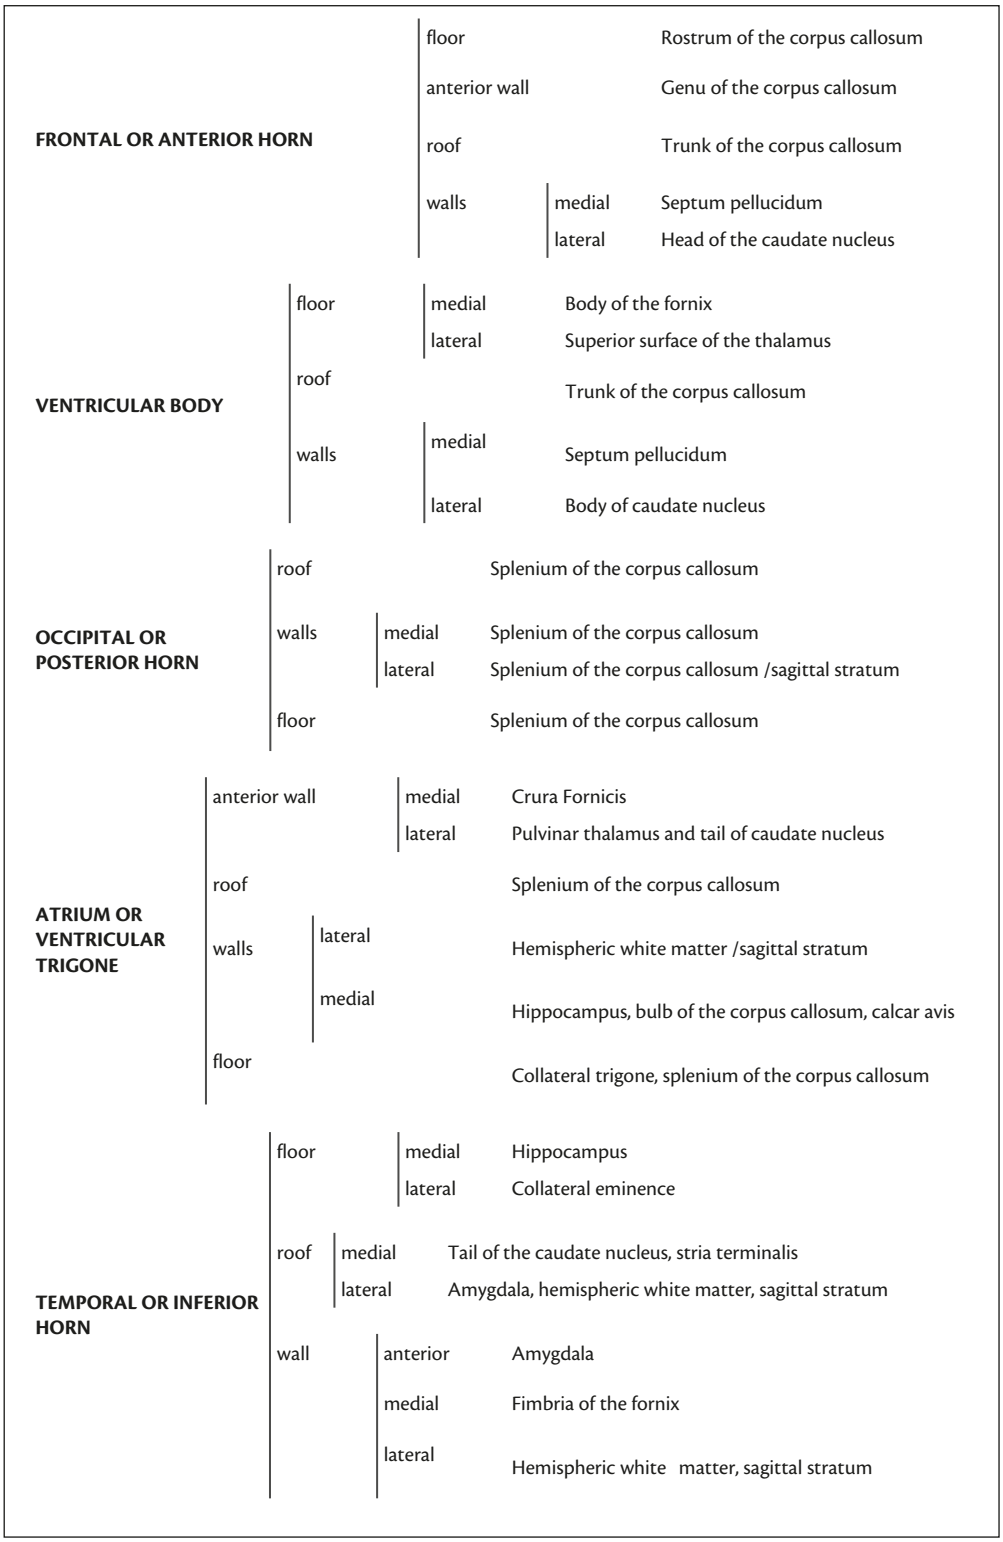

Fig. 35.6 Brain structures related to each lateral ventricle.

1981) (Fig. 35.3). The small recess between the lamina terminalis and the optic chiasm is named the optic recess. While the superior third of the lamina terminalis is hidden posterior to the rostrum of the corpus callosum, the lower two-thirds lie within the lamina terminalis cistern that harbours the anterior communicating artery.

The lateral walls of the third ventricle are mainly constituted by both thalami, with both interventricular foramina of Monro located next to each other at the most anterior and superior aspect of this ventricular cavity.

On each side, the shallow and superiorly concave hypothalamic sulcus extends from the foramen of Monro towards the orifice of the

aqueduct, separating the thalamus from the ipsilateral hypothalamus which is basally continuous with the contralateral hypothalamus, with all these surfaces then assuming a u-shaped configuration. The lateral arms of the u corresponds to the lateral walls, the upper two-thirds, constituted by the thalami, and the lower third by the hypothalamus. The bottom of the u is constituted by the hypothalamus and corresponds to part of the floor of the third ventricle.

The superior limit of each lateral wall is given by the stria medularis thalami which runs along the supero-medial border of each thalamus, from the foramen of Monro to the habenular commissure. This commissure connects both habenulas, which are small eminences located on the dorsomedial surfaces of both thalami, superior to the posterior commissure.

The massa intermedia connects both thalamic medial upper half surfaces, in approximately two-thirds of brains (Yamamoto et al., 1981).

The floor of the third ventricle extends from the optic chiasm to the orifice of the aqueduct of Sylvius, which has the posterior commissure as its superior margin and the mesencephalic tegmentum as its inferior margin, and can be divided into an anterior hypothalamic part and a posterior mesencephalic part. The anterior part is composed, from anterior to posterior, by the optic chiasm, the infundibulum, the tuber cinereum, and the mammillary bodies, while the posterior part already corresponds to the roof of the interpeduncular fossa and is formed by the mesencephalic tegmentum (Fig. 35.3). The infundibulum is continuous with the pituitary stalk, and connects the hypothalamus to the posterior lobe of the pituitary gland (neurohypophysis) through the supraopticoparaventriculo-hypophyseal tract, which transports colloid droplets containing the oxytocin and vasopressin hormones (Nieuwenhuys et al., 2007).

When the floor is seen from above and from inside the ventricle, the infundibular recess can be easily identified between the optic chiasm prominence and the tuber cinereum, and the mammillary bodies appear as two prominences posterior to the infundibular recess. An endoscopic third ventriculostomy should be performed by opening the thin and commonly translucent area between the infundibular recess and the mammillary bodies. Posterior to the mammillary bodies, the floor of the third ventricle has a concave and smooth surface, marked by the triangular-shaped opening of the aqueduct more posteriorly.

When seen from outside within the cerebral basal surface, the floor of the third ventricle is located just posterior to the optic chiasm and between the optic tracts and cerebral peduncles, with the roof of the interpeduncular fossa corresponding to the anterior aspect of the mesencephalic part of the third ventricle floor. While the anterior perforated substance spreads along the basal areas anteriorly to both optic tracts, the posterior perforated substance spreads along all the inferior aspect of the third ventricle floor.

The roof of the third ventricle extends from the foramina of Monro to the habenular commissure, and is formed by four layers of structures, the superior layer comprised by the fornices, then layers consisting of the superior and the inferior tela choroidea, and the space between these two thin membranes which constitutes the velum interpositum cistern.

The superior and neural layer is anteriorly constituted by both bodies of the fornices which run juxtaposed. While the upper sheet of tela choroidea is in intimate contact with the inferior borders of both fornices, the lower sheet of tela choroidea is attached to both stria medullaris that run along the supero-medial thalamic borders.

The velum interpositum cistern in between the tela choroidea layers ends anteriorly at the level of both foramina of Monro, and opens posteriorly into the quadrigeminal or pineal cistern. It harbours the medial posterior choroidal arteries and the internal cerebral veins within small trabeculae (Fig. 35.3).

The internal cerebral veins are formed by the junction of the anterior septal vein and the thalamostriate vein, which usually happens close to their entry point into the vellum interpositum cistern as they pass underneath the fornix through the choroidal fissure, next to the foramen of Monro. The internal cerebral veins exit the velum interpositum cistern posteriorly, over the pineal gland, and join to the basal vein of Rosenthal to form the great vein of Galen.

Two small strands of choroid plexus project downward from the lower sheet of tela choroidea into the third ventricle along both sides of the midline. Each of these choroid plexus strands is continuous along its pedicle with the choroid plexus of the ipsilateral lateral ventricle through the choroidal fissure, which defines the lateral aspect of the third ventricle roof.

The posterior wall extends from the suprapineal recess, located superiorly to the habenular commissure, to the opening of the aqueduct, and includes, from superior to inferior, the suprapineal recess, the habenular commissure, the pineal gland, the pineal recess, and the posterior commissure which is the upper aspect of the opening of the aqueduct (Fig. 35.3).

The pineal gland is found in the quadrigeminal cistern, already outside the third ventricle, and is attached to the posterior wall by a double stalk that projects superiorly to the habenular commissure and inferiorly to the posterior commissure. The pineal recess is anterior to the pineal gland and constitutes an extension of the third ventricle cavity between the upper and lower attachments of the pineal gland. See Table 35.1 for brain structures related with the third ventricle.

Surgery for supratentorial intraventricular tumours

Preoperative planning

Once a diagnosis has been made, decisions to make include whether there is an indication for surgical resection, and if so, whether the goal is gross total resection. Finally, the choice of the appropriate surgical approach can be planned.

Imaging

Preoperative investigations include imaging with MRI to establish the characteristics of the lesion and its anatomical origin and extent. Typical appearances can sometimes be diagnostic such as in colloid cysts of the third ventricle or epidermoids with characteristic restricted diffusion. A high signal on T2-weighted sequences may indicate high-water content and 'soft' consistency while a computed tomography (CT) scan may demonstrate calcification.

For some lesions with propensity for CSF seeding (e.g. primitive neuroectodermal tumours, ependymoma, germ cell tumours), imaging of the entire neuraxis, including the spine, should be completed to plan management.

Tumour markers

The detection of positive tumour markers initially in the serum and subsequently in the CSF, if available, dictate further management. For germ cell tumours in the vicinity of the third ventricle elevation of levels of alpha-fetoprotein (AFP) or human chorionic gonadotropin (ß HCG) restrict the diagnosis to only a few categories that are all managed at least initially with radiotherapy or chemotherapy. See Chapter 36.

Endoscopic procedures

Prior to resection of some intraventricular lesions an endoscopic procedure may serve as an urgent treatment to relief CSF obstruction, obtain a biopsy, or fenestrate a cystic lesion. At the same time CSF can be sampled for tumour markers and cytological examination. For lesions obstructing the aqueduct, a third ventriculostomy is recommended. If the lesion infiltrates the floor of the third ventricle and if obstructing the foramina of Monro then an endoscopic septum pellucidotomy and insertion of a single ventriculoperitoneal (VP) shunt can simplify CSF diversion. In cases where an intended endoscopic biopsy is planned in addition to the procedure to relieve obstructive hydrocephalus, it is recommended to carry out the ventriculostomy first as bleeding from the biopsy site may obscure the endoscopic view required to complete the procedure. The use of a flexible endoscope may facilitate both procedures through the same burr hole.

Decision-making

The indication for surgical resection depends upon patient and lesion factors. Patient factors include age, comorbidities, and the anticipated prognosis. The tumour factors take into account the presence of metastatic and CSF spread and the availability of alternative non-surgical treatment such as in cases of lymphoma or germinoma. In some cases, such as germ cell tumours with positive tumour markers, initial treatment with radiotherapy or chemotherapy is instituted, and surgery is reserved to resect any residual thereafter.

Planning of the surgical approach is important and relies upon evaluation of complex and multiple factors. The approach has to be tailored to achieve the predetermined goal of resection and requires knowledge of the anticipated surgical 'blind spots' and potential morbidity of each approach. In general choosing an approach depends on the planned extent of resection which in turn depends on patient factors including the existence of neurological deficits, the type and prognosis of the lesion, and whether effective adjuvant therapies are available to deal with residual disease. Technically, characteristics such as the size, configuration, extent, and consistency of the lesion help to dictate the most appropriate approach.

Surgical approaches to supratentorial intraventricular lesions

Table 35.2 demonstrates the surgical approaches to supratentorial intraventricular lesions.

Approaches to the body and frontal horn

Transcallosal approach

The patient is positioned supine, with some neck flexion and head elevation, which provides a direct trajectory. Either a coronal incision or a laterally based U-flap is fashioned. Classically, a bifrontal craniotomy across the midline is fashioned with one or two burr holes directly on the superior sagittal sinus (SSS) or if preferred on either side of the SSS and extending one-third posterior to and two-thirds anterior to the exposed coronal suture. This is based on the fact that the callosotomy must be placed anteriorly as the fornices underlie the corpus callosum (CC) posteriorly prior to sweeping anteroinferiorly to form the septum pellucidum (Rhoton, 2002). The craniocerebral relationship indicates that the foramina of Monro are coronally at the level of the coronal suture and that the central sulcus is 5 cm posterior to the coronal suture (Ribas et al., 2006), indicating the location of the pre- and postcentral gyri which should be protected from

Table 35.2 Surgical approaches to supratentorial intraventricular lesions

	Lateral ventricle Body + frontal horn	Lateral ventricle Trigone + atrium	Third ventricle	Third ventricle posterior	Third ventricle anterior

manipulation or retraction. The antero-posterior dimensions of the craniotomy should be adequate to allow the surgeon to choose an area devoid of bridging veins allowing an interhemispheric approach without disruption of these key vessels. Although either lateral ventricle can be entered from this approach, it is easier to expose more of the hemisphere for which the corresponding ventricle is to be entered. Some authors advocate detailed imaging preoperatively of the draining veins such as with computed tomography venogram (CTV) or magnetic resonance venogram (MRV) and the approach can then be tailored with image-guidance to avoid the bridging veins.

The interhemispheric approach (**Fig. 35.4**) requires careful dissection preserving the pial surface deeper to the inferior edge of the falx as the medial frontal lobes can be adherent. The trajectory in the sagittal plane is guided by the fact that the surface markings of the foramen of Monro are in a plane corresponding to the coronal suture intersecting with the superior temporal line, and hence the approach is facilitated by inspection of the inclination of the partially exposed coronal suture during the craniotomy and by the use of image-guidance. Although retraction injury occurs with injudicious placement of brain retractors, excessive 'dynamic retraction' is equally detrimental. Therefore, a strategy of brain relaxation and gentle manipulation is required. In the presence of gross hydrocephalus initial placement of a ventricular drain at the start, without totally collapsing the ventricle, facilitates the approach and allows placement of a brain retractor as a 'holder' if the surgeon wishes to do so.

The CC is exposed and identified by its glistening white colour and the surface vascular pattern. It is ideal to identify both pericallosal arteries and these are dissected and mobilized laterally, each with the corresponding hemisphere so as not to disrupt the supplying branches to the pial surface. With experience and especially where there are dilated ventricles a central white septum in the midline sagittal plane at the attachment of the septum pellucidum can be identified. This allows placing the callosotomy lateral enough to enter the desired lateral ventricle. A large callosotomy is generally not required provided that the trajectory to visualize the intraventricular lesion is correct. The location rather than the size of the callosotomy is important to avoid damaging the fornices. Separation of the fibres of the CC reveals the underlying purple coloured ependyma which once punctured allows CSF egress.

Orientation once the ventricular cavity is entered requires identification of the choroid plexus which is followed to the foramen of Monro. Once the thalamostriate vein is identified the laterality of the ventricle is established (Rhoton, 2002). If no choroid plexus is visible it is likely that this is the frontal horn and if changing the trajectory more posteriorly still shows that the cavity is devoid of choroid plexus, then entry into a cavum septum pellucidum should be suspected.

It is best to perform a septum pellucidotomy avoiding bleeding from the septal vein especially with lesions obstructing the foramina of Monro as a single catheter for CSF diversion may be used later if CSF flow is not re-established. In many cases the lesion may be obstructing the view of interventricular landmarks and hence it is possible to inspect the contralateral ventricle through the pellucidotomy and use this as a reference to establish the relative depth and location of the fornices and deep veins.

Prior to resecting the lesion either identify the location of the fornix and important veins or at least be aware of their relative location. If possible, establish the origin of the lesion aided by preoperative imaging. The lesion may predominantly arise from the septum pellucidum such as a central neurocytoma and some subependymomas, from the choroid plexus such as papillomas or meningiomas or from the ependymal wall such as gliomas or giant cell astrocytomas. The anatomical origin may not be possible to determine in large or bilateral lesions. If accessible, first coagulate and separate the choroid plexus from the surface of the lesion to control a possible source of blood supply. Proceed to piecemeal resection with suction or CUSA surgical aspiration depending on the consistency of the lesion with intermittent haemostasis, as excessive bleeding will preclude visualization within the ventricle. The extent of resection takes into account patient factors such as age, the nature of the lesion and whether adjuvant therapy is available and the preoperative presence of neurological deficits. This may necessitate leaving a small residual adjacent to the fornices or adherent to the major veins. For those lesions arising in the brain parenchyma and which are exophytic into the ventricle care must be taken not to extend the resection in such a way as to injure the surrounding caudate nucleus, thalamus, or the genu of the internal capsule which lies at a level adjacent to that of the foramina of Monro.

In most cases leaving an external ventricular drain for a few days until the CSF clears is advised. It can be placed either at the outset or at the end of the procedure through the callosotomy and tunnelled through the dura and away from the incision. This is followed by meticulous dural closure, replacement of the bone flap with burr hole covers and wound closure.

The pitfalls of this approach include SSS compression by retractors which, if prolonged may lead to thrombosis. Sacrifice of major bridging veins may lead to venous infarction and postoperative epilepsy and a trajectory followed too posteriorly in the sagittal plane risks damage to the fornices. Cingulate gyrus damage may occur if this structure is mistaken for the CC, the area between the pericallosal and callosomarginal vessels is entered rather than the corridor between the two pericallosal arteries, contusion and surrounding swelling of the cingulate gyrus may then result in a postoperative supplementary motor area (SMA) syndrome. Pericallosal artery injury or disruption of its branches to the corresponding hemisphere may cause hemiparesis especially affecting the lower limb. Entering a cavum septum pellucidum rather than the lateral ventricular and confusing which ventricle has been entered can lead to serious damage for example attempted septostomy damaging the caudate or thalamus. Forniceal damage through the approach or during resection should be avoided, if the lesion is adherent or partially infiltrating the fornix, then a subtotal resection is advocated. Finally a pellucidotomy without clear vision and orientation can result in bleeding from a septal vein and if inferiorly placed can damage part of the fornix.

Blind spots of this approach where tumours may be accidentally left include the roof of the contralateral lateral ventricle. It should be noted that for large intraventricular lesions, the foramen of Monro, the fornix, and thalamostriate vein may initially be obscured by the lesion.

Transcortical approach

Alternatively, the body and frontal horn can be approached through a frontal transcortical approach (Rhoton, 2002). The superior frontal sulcus is frequently deep and an initial trans-sulcal approach or an approach through the middle frontal gyrus can provide a trajectory to the ventricle. This approach is facilitated in cases with hydrocephalus. Image-guidance helps to plan the trajectory through the white matter tracts (Szmuda et al. 2014).

Once the ventricle is entered the subsequent operative steps are similar to those just described but bearing in mind the orientation of the operative view from a more lateral to medial trajectory.

Approaches to the atrium of the lateral ventricle

Although the bodies of the lateral ventricles are near the midline, the atria or trigones are off midline cavities located behind both thalami and consequently their access requires off midline approaches. A key anatomical feature to have in mind regarding the atria is that while the most posterior aspect of the splenium within the midline ends covering the pineal or quadrigeminal cistern, its lateral extensions open bilaterally and posteriorly covering both thalamic pulvinars and encircling both atrial cavities and their variable posterior extensions that constitute the occipital horns, already inside the brain parenchyma and hence posterior to the most posterior aspect of the splenium seen along the midline.

Given this anatomical location, only the most superior and anterior tumours of the atrium can be reached through the anterior transcallosal approaches already described to access the frontal horn and the body of each lateral ventricle, with other atrial tumours requiring different transcortical approaches according to their main location, extension, and vascular supply. The principal approaches to the ventricular atrium are the transparietal, the transtemporal, and the alternative parieto-occipito interhemispheric (**Fig. 35.1**).

Planning the trajectory has to take into account not only the cortical entry site avoiding eloquent cortex, but also the trajectory through the white matter tracts. Neurological deficits from cortical injury often recover due to neuronal plasticity, however white matter tract disruption results in a permanent deficit. It is imperative to state that the safest rather than the shortest trajectory should be adopted. The use of image-guidance is very useful in optimizing the orientation of the trajectory to the target but the surgeon should resist the temptation to choose the shortest route through a seemingly thin but eloquent neural mantle.

Transparietal approach

Although sometimes interrupted the intraparietal sulcus is a very evident sulcus that transverses the superolateral surface of the parietal lobe and which, usually, is continuous with the inferior and downward segment of the postcentral sulcus. The actual or projected meeting or transition point of these sulci constitutes the nearest point of the parietal surface to the atrium (Harkey et al., 1989; Ebeling and Steinmetz, 1995; Ribas et al., 2006). Nevertheless, the transparietal microneurosurgical approach to the atrium (**Fig. 35.4**) has to be mandatorily initiated through the transitional site between these two sulci, moving more posteriorly along the intraparietal sulcus allows access to the more posterior part of the atrium, particularly if this cavity is not enlarged.

For this approach the patient should ideally be in the semi-sitting position, and the craniotomy should be done having as its centre the projection of the actual or projected transition point of the intraparietal and postcentral sulci, which is located approximately 6 cm superior to the lambda along the sagittal suture and 5 cm lateral to it (Ribas et al., 2006).

Preoperatively both the shape and interruptions of both sulci, as well as their joining site, can be estimated through careful study of 3D-rendered MRI images, the projection of their joining site on the skull surface can be better estimated with fusion of the CT and MRI images.

Intraoperatively, after identifying the locations of the intraparietal and the postcentral sulci visible segments considering their usual or known courses as carefully seen on the MR images, the identification of their actual or projected meeting or transition point can usually be identified as a variable enlargement of the subarachnoid space, and should also be confirmed with the aid of neuronavigation if available. It is frequent to find veins running along or immediately next to both sulci.

The transparietal approach to the atrium can be done trans-sulcal, subpial, or transgyral, but always considering that the transition site between the postcentral and the intraparietal sulci constitutes the nearest and easiest surface site to more securely reach the atrium, the surgical route has to follow the sulcal orientation which always leads towards the nearest ventricular cavity (Harkey et al., 1989; Ebeling

and Steinmetz, 1995; Ribas et al., 2006) and the approach has to be along a 30° posteriorly oblique radial approach (Ribas et al., 2006). Both neuronavigation and intraoperative ultrasound can be very helpful to confirm the route towards the atrium.

A wide sulcal opening is often needed to expose and allow piecemeal delivery of firm lesions and hence it is advantageous to be able to plan the use of a deep sulcus on preoperative imaging and to anatomically localize this at surgery.

Once the ventricular cavity is encountered the surgical corridor can be enlarged, if necessary, by removing more brain tissue posteriorly along the intraparietal sulcus orientation and preferably medially from the superior parietal lobule, in order to avoid further damage to the superior longitudinal and arcuate fascicles which run mostly laterally to the intraparietal sulcus within the inferior parietal lobule.

The transparietal approach to the atrium just posterior to the postcentral sulcus and along the level of the intraparietal sulcus, hence posterior to the somatosensory cortex, will always cause damage to the parietal u-fibres, the parietal projection fibres (mostly parietopontocerebellar fibres), and the most superior fibres of the optic radiation which cover the atrium and run towards the cuneal margin of the calcarine fissure causing a contralateral homonymous lower quadrantinopia.

While non-dominant parietal damage is more particularly related with left hemi-neglect and anosognosia, spatial disorientation, construction, and dressing apraxias, dominant parietal damage can cause dysphasias, dyslexia, dyscalculia, apraxia, tactile agnosia, and possibly Gerstmann's syndrome (dysgraphia, dyscalculia, finger agnosia and right/left disorientation).

Posterior temporal approach

The approach to the atrium through the distal part of the superior temporal sulcus (Harkey et al., 1989; Ebeling and Steinmetz, 1995; Ribas et al., 2006) is appropriate for more inferior atrial tumours, particularly when these lesions extend towards the temporal horn or receive a significant blood supply from the anterior choroidal artery. This approach can damage the optic radiation that runs along the lateral wall of the atrium. The Wernicke area with its underlying language related fibres is also at risk where it lies predominantly within the posterior aspect of the superior temporal gyrus and within the supramarginal gyrus, in the dominant hemisphere. Awake craniotomy, when feasible, can minimize these risks.

The most distal point of the superior temporal sulcus, prior to its usual trifurcation, lies about 2–3 cm posterior and inferior to the posterior Sylvian point (end of the Sylvian fissure) (Ribas et al., 2006). For craniotomy purposes, this area is located about 3 cm vertically above the meeting point of the horizontal parieto-mastoid suture and the ascending posterior aspect of the squamous suture, which is a site that can usually be palpated as a slight depression over the superior aspect of the mastoid process (Ribas et al., 2006; Ribas and Rodrigues, 2007). Once the horizontal sulcal segment just inferior and posterior to the end of the Sylvian fissure has been identified, an adjoining transparenchymal approach can be performed transsulcal, subpial, or transgyral, 30–40° anteriorly and radially oriented (Ribas, 2005; Ribas et al., 2006) (Fig. 35.1). The ventricular route can be enhanced by the use of neuronavigation and intraoperative ultrasound. Further removal of brain tissue can be performed as necessary to obtain adequate exposure.

Since the Heschl gyrus bounds anteriorly and obliquely the triangular temporal plane, with its inner apex immediately next to the atrium, the opening of the most posterior aspect of the Sylvian fissure can also lead to the atrium. Nevertheless, this opening is technically difficult due to the flatness of the fissure at this level. This approach obliquely requires further removal of the superior temporal intraopercular surface (auditory primary cortical area), and the base of the supramarginal gyrus.

There is a blind spot in large lesions where the vascular pedicle at the attachment of the choroid plexus may not be exposed prior to reducing some of the bulk of the tumour mass.

Alternative approaches

Anatomical operative approaches to the body and trigone of the lateral ventricle which totally avoid the visual white matter tracts include the interhemispheric transcallosal, the posterior interhemispheric approach through the medial parieto-occipital sulcus or through the or isthmus of the cingulate gyrus (described next) and the more recently described supracerebellar infra/transtentorial approach and then subsequently through the collateral sulcus.

The interhemispheric part of the parieto-occipital sulcus is related to the occipital horn rather than the trigone. A posterior approach and a corticotomy in the region of the precuneus or isthmus of the cingulate gyrus would access the trigone but for this deep approach a slack brain is desirable if not essential and the presence of a large mass may preclude its use.

Parieto-occipital interhemispheric approach The parieto-occipital interhemispheric approach to the atrium (Fig. 35.1) as proposed by Yaşargil (Yaşargil, 1996) is unique in the sense that it is the only approach which does not damage the optic radiation. Nevertheless, it is not a direct route, and the surgical corridor is rather limited by the degree of occipital retraction. The mobilization and retraction required to gain access with an interhemispheric approach may be problematic in the presence of a deep solid hemispheric mass.

Since the approach is interhemispheric along the cuneus, ideally the patient should be in the semi-sitting position, the craniotomy along the midline should extend from the lambda, which corresponds to the most distal point of the parieto-occipital sulcus, to the opisthocranion, which is the most prominent cranial point of the occipital fossa and which corresponds to the most distal point of the calcarine fissure. While the opisthocranion is usually located 3–4 cm above the inion, the lambda is usually located between 2 and 4 cm above the opisthocranion (Ribas et al., 2006).

The occipital interhemispheric approach is facilitated by the fact that the cortical parieto-occipital veins usually have an ascending course parallel to the superior sagittal sinus for a few centimetres before joining the sinus (Oka et al., 1985; Yaşargil, 1996). The access should be done between the falx-tentorium transition and the cuneal surface towards the splenium, bearing in mind that the anterior apex of the cuneus, where the parieto-occipital sulcus joins the calcarine fissure and where their respective arteries also usually meet, is located at the axial level of the splenial base. Further lateral occipital retraction can be aided by the sacrifice of small draining veins if necessary and mainly, by the opening of the parasplenial cisterns and release of CSF. The very white splenium and the vein of Rosenthal are identified and the ipsilateral isthmus of the cingulate

gyrus is easily seen wrapping around the splenium together with the precuneal base seen immediately posteriorly, which altogether constitute the site of the transcerebral approach to the atrium.

Since the atrial cavity lies laterally, such a window has to be made along a lateral and anterior orientation until the ventricular cavity is reached with the identification of the tumour or white pulvinar of the thalamus that constitute the anterior wall of the atrium, with the attached choroid plexus glomus.

The main limitation of this approach is the degree of occipital retraction and, as for any other ventricular approach, it is facilitated if there is ventriculomegaly. Since this approach requires significant brain retraction and is done through an indirect route, neuronavigation and intraoperative ultrasound are not as helpful as with other approaches, and its successful accomplishment depends on recognition of anatomical landmarks and their orientation.

Other approaches More basal temporal approaches, through a window made by the removal of the posterior part of inferior temporal gyrus and of its medially adjacent fusiform gyrus, which corresponds to the floor of the posterior aspect of the temporal horn and of the atrium, can spare both the optic radiation and the language areas within the dominant hemisphere, but are much more suitable for inferior lesions already occupying the temporal horn (Fig. 35.4). For these approaches it is important to have in mind that the inferior temporal gyrus although broad is short in height, and its exposure requires a very low temporal craniotomy. Since the fusiform gyrus lies predominantly over the superior surface of the petrous bone, the craniotomy base should include the area between the preauricular depression over the distal and superior aspect of the zygomatic arch root, and the meeting point of the horizontal parietomastoid and the posterior and ascending portion of the squamous suture located at the upper aspect of the mastoid process (Ribas and Rodrigues, 2007).

The ingenious supracerebellar approach is performed with incision of the tentorium to expose the collateral sulcus and then via a trans-sulcal approach entering the inferior aspect of the lateral ventricle 10 mm inferior to the trigone. This approach would be perfect for a lesion of an appropriate size and location. It is conceivable that a large solid mass especially with superior extension may not be adequately exposed through this approach. The medial structures including the hippocampus need to be protected with this approach.

Approaches to the temporal horn

See Chapter 81 and Figure 35.4.

Approaches to the third ventricle

Main ventricle

The initial approach is the same as the transcallosal approach to the lateral ventricle described earlier. It has to be noted that the callosotomy is to be performed at the usual place as the trajectory will still allow access to the whole third ventricle. The temptation to place the callosotomy more posteriorly not only risks damage of the underlying fornix but even if performed through the splenium of the CC can end up in the quadrigeminal cistern rather than the third ventricle. Furthermore, the visual component of posterior disconnection syndrome can have devastating effects on a patient.

Once the lateral ventricle has been entered the choice between the transforaminal and transchoroidal approach will depend on the configuration of the lesion and its relationship to, and size of, the foramen of Monro (Rhoton et al., 1981). An interforniceal approach starting with separation of the leaves of the septum pellucidum and opening the interforniceal space to gain access through the roof of the third ventricle carries a high risk of bilateral forniceal damage.

Transforaminal approach This is ideal for lesions presenting at a dilated foramen of Monro. This applies to the vast majority of colloid cysts and some other anterior third ventricular or 'dumb-bell' lesions. Surgery is facilitated in those mobile lesions that are deliverable into the lateral ventricle (Fig. 35.3). The configuration of the deep veins is variable and these have to be protected during the resection (Türe et al., 1997). Gentle traction is required to avoid avulsion of the vascular attachment at the roof of the third ventricle, which is a blind spot. Care is needed in resection of the anteroinferior aspect of the lesion to avoid hypothalamic damage.

Anatomical observations indicate that most colloid cysts arise in fact within the velum interpositum and hence are supplied by branches of the posterior medial choroidal artery and this also explains those situated cephalad within the leaves of part of the septum pellucidum through an extension of the velum interpositum (Morris and Santoreneos, 2012). In some colloid cysts especially incidental ones the anterior aspect of the taenia fornices is still intact and stretched over the capsule of the cyst. Grabbing this membrane to manipulate the cyst may result in distortion of the fornix to which it is attached and subsequent dysfunction. Therefore, under magnification incising this overlying layer renders the cyst mobile, allowing it to be delivered through the foramen of Monro and resected intact after coagulation and division of its vascular pedicle.

Transchoroidal approach Bearing in mind that the foramen of Monro is actually the anterior dilated, open portion of the choroidal fissure then a transchoroidal approach opens the space between the fornix and the thalamus posterior to the thalamostriate vein to gain access to the third ventricle (Figs. 35.3 and 35.4). This portion is covered by the choroid plexus and once this is gently delivered from the fissure it becomes apparent that it is attached superomedially to the fornix by a membrane, the 'taenia fornices', and inferolaterally to the thalamus by the 'taenia thalami'. As the later membrane may incorporate several draining veins from the thalamus to the thalamostriate vein then it is best to incise the taenia fornices, a 'transchoroidal infraforniceal' approach, rather than the taenia thalami to avoid compromise of the venous drainage of the thalamus (Rhoton, 2002). In practice, however, most lesions for which surgery is indicated are of such size that this part of the choroid fissure is 'splayed', and these membranes are stretched and easily opened. This will gain access and visualize the whole third ventricle from its anterior extent to the suprapineal recess (Ulm et al., 2009).

Blind spot

- The roof of the third ventricle and contralateral internal cerebral vein.

Anterior third ventricle

Such lesions extend from the suprasellar cisterns into the third ventricle. If these are predominantly intraventricular, then they can be approached through the transcallosal transforaminal or transchoroidal route. The others can be approached through the lamina terminalis from an anterior frontal interhemispheric or pterional craniotomy

or through an extended endonasal transplanum endoscopic route. See Chapter 27.

Posterior third ventricle

These are pineal tumours or other lesions arising in the quadrigeminal cistern and extending into the ventricle. These are best approached via the infratentorial supracerebellar approach which provides very good visualization of the third ventricular roof and allows careful dissection of the lesion from the deep veins. However caudal extension into the tectal region could represent a blind spot. Alternatively, the occipital transtentorial approach which better visualizes the caudal extent of the lesion may be used. A 'bulky' splenium may obscure the extension of the lesion along the roof of the third ventricle. See Chapter 37.

Endoscopic approaches

In addition to endoscopic procedures to obtain a biopsy and relieve CSF obstruction, there is an emerging role of endoscopic procedures to resect intraventricular lesions. Intraventricular cysts such as large symptomatic pineal or lateral ventricular arachnoid cysts or those associated with neoplasms can be endoscopically fenestrated into the ventricle and if needed a biopsy is obtained from the wall. Via a 'bipolar' fenestration of third ventricular arachnoid cysts (i.e. endoscopic fenestration of the upper dome presenting into the foramen of Monro into the lateral ventricle and through the cyst), the inferior pole is communicated to the prepontine cistern, establishes CSF circulation, and possibly decreases the risk of recurrence (Kirollos et al., 2001).

Endoscopic resection of colloid cysts is achievable in many but not all cases. Mobile cysts with contents that are easily aspirated in the presence of ventriculomegaly are favourable for the endoscopic technique (See Chapter 33).

In expert hands some solid intraventricular lesions are amenable for resection via an endoscopic route (Barber et al., 2013; Selvanathan et al., 2013).

Specific complications

Apart from technical complications described earlier with the operative technique resulting in neurovascular injuries, there are specific risks associated with surgery in this region (Hassaneen et al., 2010; Milligan and Meyer, 2010; Symss et al., 2014).

Memory dysfunction

This may occur from forniceal manipulations (Villani et al., 1997; Friedman et al., 2008).

Hypothalamic dysfunction

This may occur especially with lesions involving the floor of the third ventricle. Most commonly these are transient such as hyponatraemia or diabetes insipidus.

Visual and gaze dysfunction

This may be seen with pineal region lesions extending to the posterior third ventricle and involving the tectum. The restriction of vertical gaze can be compensated for functionally, but other dysfunctions such as skew deviation, disrupted far/near accommodation and diplopia of a dynamic nature from involvement of several pathways including the rostral medial longitudinal fasciculus have significant affection of functional outcome and quality of life (Hart et al., 2013).

Disconnection syndrome

Although classically this can result in alexia without agraphia, alien hand syndrome, tactile anomia, and left/right apraxia. However, is rarely seen in humans especially in the longer term after anterior callosotomies (Villani et al., 1997; Symss et al. 2014). The exception is in cases in which the disruption involves the splenium. In these cases, the visual consequences such as matching and comprehending objects in the different visual fields has significant implications for daily activities such as driving.

Controversies

The choice between the superior temporal and transparietal approaches to the atrium is controversial.

The posterior portion of the superior temporal sulcus is often deep and easy to identify, but on the dominant hemisphere the superior lip is the superior temporal gyrus harbouring the speech area. Hence mobilization or retraction if needed should veer on the inferior rather than the superior lip during splitting of the sulcus. Similarly, posterosuperior mobilization of the superior lip of the somewhat vertically oriented intraparietal sulcus is better undertaken to avoid excessive manipulations of the inferior parietal lobule which serves speech function located in the supramarginal and angular gyri.

With deep dissection the white matter tract encountered most superficially is the superior longitudinal or arcuate fasciculus which is oriented from the frontal lobe and its important connection regarding speech function is deep to the superior temporal sulcus (although there are possible extensions deep to the middle temporal sulcus) and to the inferior parietal lobule deep to the supramarginal and angular gyri. Therefore, the orientation of the trajectory to the trigone from either the superior temporal or intraparietal sulci should avoid severance of these important connections provided awareness of the proximity of this tract to the approach. The approach through either of these two sulci is quite away from the deeper posterior limb of the internal capsule or corona radiata. However, it is inevitable to transverse the two deeper layers which are the functionally important optic radiation and the tapetum which is without an identifiable neural deficit in case of transection. Disruption of the inferior fronto-occipital fasciculus (IFOF) may result in semantic paraphasia. At the sagittal stratum which is related to the lateral wall of the atrium the IFOF is medial to the arcuate fasciculus and lateral to the fibres of the optic radiation. More posteriorly, where the trajectory of these two approaches lies, the IFOF fibres are more splayed to reach the convexity surface of the occipital lobe, superior parietal lobe and the temporo-basal area (Martino et al., 2011).

In approaching through the superior temporal sulcus, the orientation of the optic radiation is parallel to that of the sulcus and hence a splitting dissection perhaps may separate the fibres and avoid division of a large number of tract fibres. The possible resulting superior quadrantanopia visual field defects usually have little practical impact on the patients' daily activities and these patients tend to adapt rapidly to this defect.

Conversely, through the intraparietal sulcus approach the orientation of the white matter dissection has to change orientation to keep 'in line' rather than across the optic radiation fibres. Anatomically a 'high' intraparietal approach passing superomedially to the optic radiation is advantageous as it causes minimal disruption to the white matter fibres, which are least dense on the roof of the atrium. Nevertheless, the resulting scotoma involving the inferior visual field is usually noticeable by the patient. If a large inferior quadrantanopic scotoma occurs, this may have impact on the patients' mobility and day to day activities (e.g. on descending a flight of stairs).

Although the superior temporal sulcus approach provides an early access to the choroid plexus which provides blood supply intraventricular meningiomata, nevertheless most of these lesions do not seem to be excessively vascular to impose a particular problem with bleeding by either approach.

Pineal tumours

Mueez Waqar, Samantha Mills, Conor L. Mallucci, and Michael D. Jenkinson

Introduction

The pineal region is located in the midline between the tectum of the midbrain and the roof of the third ventricle. Pineal tumours are rare and are more commonly seen in children than adults (Louis et al., 2016). A large variety of histological tumour types are found in the pineal region, including germ cell tumours (GCTs, 60%), pineal parenchymal tumours (PPTs, 30%) and gliomas (5%) (see **Fig. 36.1**). Other histological subtypes are rare but include papillary tumour of the pineal region (PTPR), ependymoma, meningioma, lymphoma, and metastases (Al-Hussaini et al., 2009). Historically, open surgery carried unacceptable levels of morbidity and many pineal tumours were treated with irradiation alone, without histological diagnosis. Modern neurosurgical and neuro-oncology management is determined by tumour type and includes biopsy, open surgery, fractionated radiotherapy, and chemotherapy. Most recent advances in the treatment of pineal tumours have mainly been driven by clinical trials in paediatric patients.

Presentation and preoperative workup

Patients with pineal tumours commonly present with raised intracranial pressure (87%), Parinaud's syndrome (76%) due to midbrain compression (restricted upgaze, loss of accommodation reflex, near-light dissociation, and convergence nystagmus) and cerebellar signs (52%) (Konovalov and Pitskhelauri, 2003). Contrast-enhanced magnetic resonance imaging (MRI) of the brain and whole spine is required to determine the presence of hydrocephalus, anatomy for surgical approaches, and presence of metastatic spread (Awa et al., 2014). Serum and cerebrospinal fluid (CSF) sampling for tumour markers is also necessary. Elevated β human chorionic gonadotrophin (β-HCG) and α-fetoprotein (AFP) may be diagnostic for GCT subtype without the need for biopsy. In the absence of elevated tumour markers, a tissue biopsy is required by endoscopic, stereotactic, or open approach. In the presence of hydrocephalus, CSF diversion by endoscopic third ventriculostomy (ETV) is the preferred treatment for hydrocephalus, allowing biopsy of the tumour in the same operation.

Germ cell tumours

Epidemiology

The pineal region is the most common site of intracranial germ cell tumours (Arora et al., 2012). Over 90% of cases occur before the age of 20 years with incident peaks occurring just after birth and in early adolescence. Males are more likely to be affected (Louis et al., 2016).

Pathology and genetics

Most intracranial germ cell tumours arise sporadically. These tumours may have an additional X chromosome, and there is an association with Klinefelter's syndrome. Other common chromosomal gains include 1q, 8q, and 12p, as well as less frequent losses of 11q, 13, and 18q. GCTs have been associated with Down's syndrome and neurofibromatosis type 1 (Louis et al., 2016).

Intracranial GCTs are most commonly found in the pineal region; rarely they may be suprasellar or bifocal (pineal and suprasellar concurrently). GCTs are divided pathologically into germinomatous tumours (germinomas; accounting for 70–80%) and non-germinomatous tumours (Al-Hussaini et al., 2009).

Germinomas resemble primordial germ cells, whereas non-germinomatous tumours have characteristics associated with the embryonic stage of development (e.g. the pluripotent nature of teratomas). Occasionally GCTs contain elements of both subcategories, in which case they are classified as non-germinomatous in the WHO classification (Louis et al., 2016). By convention, all GCT subtypes, except mature teratomas, are regarded as malignant.

Germinomatous tumours

Germinomas

Germinomas may seed the neuroaxis and are composed of cells with large nuclei featuring prominent nucleoli and clear cytoplasm, with a high proliferative rate and numerous mitoses (**Fig. 36.1**D). Immunoreactivity can be demonstrated to c-kit in the cell membrane and OCT4 in the nucleus (Louis et al., 2016). Germinomas with syncytiotrophoblastic giant cells can secrete low levels of βHCG (**Box 36.1**).

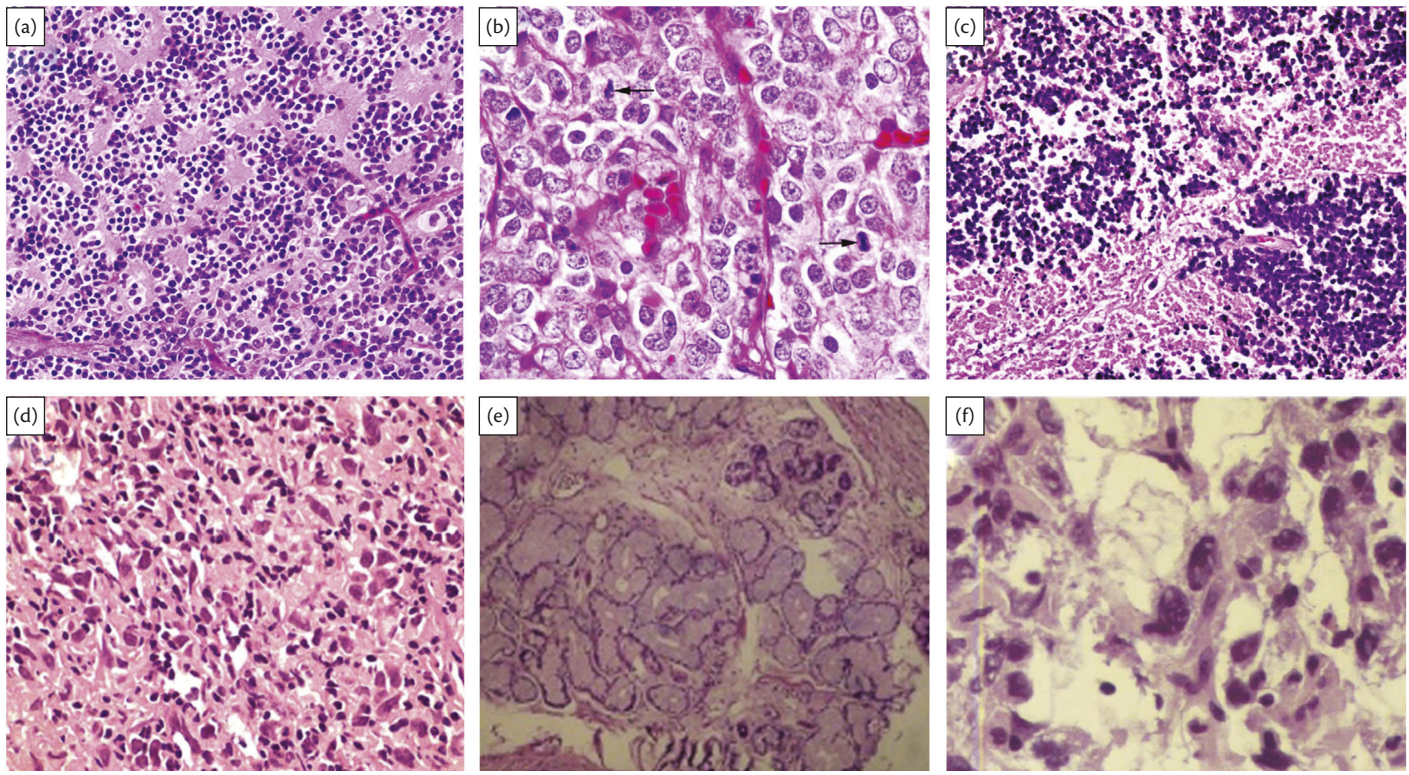

Fig. 36.1 Histopathology of pineal region neoplasms. (A) Pineocytoma: moderately cellular tumours, with well-differentiated cells that resemble pineocytes; usually cells feature a single nucleus. (B) Pineal parenchymal tumour of intermediate differentiation: although absolute diagnostic criteria are lacking, these tumours feature a moderate degree of cellularity, cellular maturity, nuclear atypia, and mitotic rate (arrows show foci of mitosis). (C) Pineoblastoma: highly cellular tumour containing primitive cells, with a high nuclear to cytoplasmic ratio and high mitotic rate. (D) Germinoma: characteristic cells with large nuclei and prominent nucleoli, and clear, glycogen-rich cytoplasm. (E) Mucous glands of a mature teratoma: these tumours can also feature several other cell morphologies. (F) Immature-looking stem cells that resemble embryonic stem cells; tumour cells are large with prominent nucleoli and abundant cytoplasm.

Non-germinomatous tumours

Non-germinomatous germ cell tumours (NGGCTs) include teratoma, embryonal carcinoma, yolk sac tumour, and choriocarcinoma. Approximately 13.5% of pineal germ cell tumours exhibit mixed histology (Al-Hussaini et al., 2009). Unlike germinomas, NGGCTs contain cytokeratin structural proteins, indicating epithelial cell lineage, a major histopathological differentiating factor between the two major GCT types.

Teratoma

Teratomas are the commonest pure NGGCT (7% of pineal GCTs) (Al-Hussaini et al., 2009). They contain elements from all three germ layers. If the elements are completely differentiated, the tumour is termed mature, while if there is any evidence of incomplete differentiation for any element, the tumour is termed immature (Figs. 36.1E and 36.1F). Rarely, somatic elements within teratomas can undergo neoplastic change, in which case the tumour is classified as teratoma with malignant transformation. Immunoreactivity depends on the tissue present in these tumours and they may stain positively for c-kit. Incompletely differentiated enteric glands in immature teratomas can also secrete AFP (Louis et al., 2016).

Embryonal carcinoma

These consist of immature-looking stem cells that resemble embryonic stem cells. Tumour cells are large with prominent nucleoli and abundant cytoplasm, which may be violaceous (eosinophilic) or clear. Cells tend to grow in sheets, gland-like patterns, or as papillary structures. Positive markers in addition to cytokeratins include PLAP, OCT4, and CD30 (Louis et al., 2016).

Yolk sac tumour

Yolk sac tumours contain cells that resemble the endodermal cells lining the yolk sac. Tumour cells are small, with non-prominent nucleoli and scant cytoplasm, which characteristically stains positive for AFP (Louis et al., 2016).

Choriocarcinoma

Choriocarcinoma contains transformed placental elements, primarily as two cells—cytotrophoblasts and synctiotrophoblastic giant cells (STGCs). Immunostaining for cytokeratins is demonstrable with both cell types, but STGCs are additionally positive for β-HCG and human placental lactogen (Louis et al., 2016).

Management pathway for germ cell tumours
